
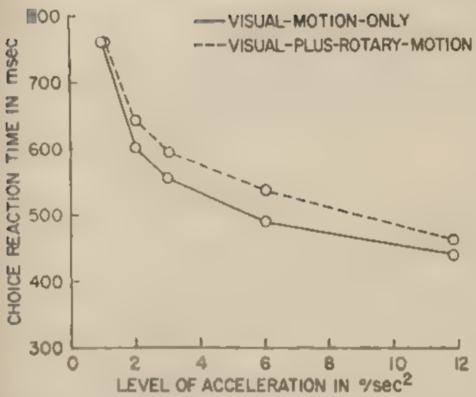

FIGURE 1. Mean choice reaction time at different levels of acceleration for 12 pilots.

Effect of rotary acceleration. The main effect of stimulation condition was significant, F (1, 11) = 11.37, $p < .01$, indicating a significant difference between the choice RT for unisensory stimulation and that for bisensory (see Figure 1). A comparison of the 2 stimulation conditions for each level of acceleration was performed, and the difference between the means of the 2 conditions proved significant in 4 out of 5 levels ($p < .05$). At the lowest level of acceleration (1°/sec²), the difference between the visual-only and visual-plus-rotary motion conditions was not significant ($p > .05$).

Effect of level of acceleration. The significant main effect of level of acceleration, F (4, 44) = 109.35, $p < .001$, demonstrated that the level of acceleration resulted in a decrease in choice RT (Figure 1). It should be noted that in the bisensory condition, the rotary acceleration and visual acceleration levels were both changed together, thus confounding these 2 variables. In spite of this ambiguity, the hypothesis that higher levels of visual acceleration produced lower choice RT is supported by the matching profiles of the bisensory and unisensory data (Figure 1).

Effect of peripheral angle. The main effect of viewing angle was significant, F (6, 66) = 43.13, p < .001, and indicated that there was a significant increase in choice RT as the eccentricity increased (see Figure 2). A subsequent trend analysis confirmed that a significant linear component characterized the trend across the various angles ($p < .01$), and no evidence of a quadratic or higher order component was found ($p > .05$). The significance of the difference between a reference mean (0°) and each treatment mean (10°, 20°, etc.) was tested. All differences were significant ($p < .01$) except for the comparison with the 10° position.

Interaction effects. A significant Levels of Acceleration × Peripheral Angles interaction was found, F (24, 264) = 12.43, $p < .001$, which is visible in Figure 2 as the change in the overall slope of the plots with increased acceleration magnitude. The flattening of the curves with increased level of acceleration indicates that the effect of peripheral viewing is diminished at higher levels of acceleration.

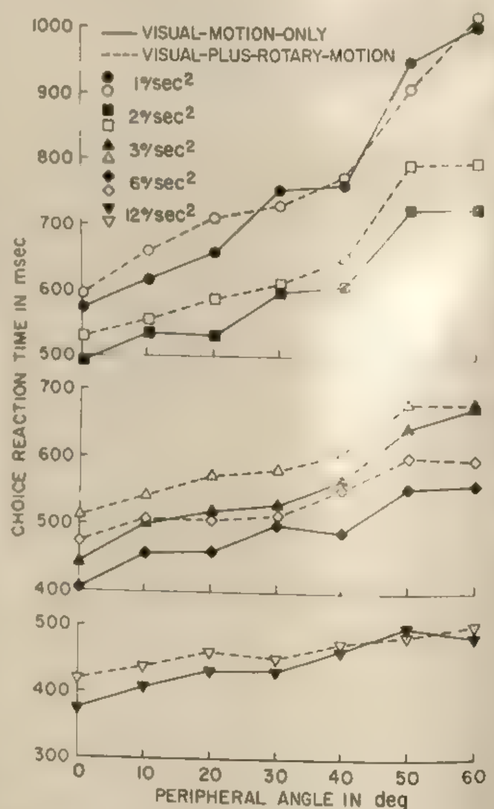

FIGURE 2. Mean choice reaction time at various peripheral angles for 12 pilots.

All other interactions were nonsignificant ($p > .10$).

Discussion

The larger choice RT for bisensory stimulation demonstrates an inhibitory effect of the accessory stimulus upon choice RT. This inhibition of response agrees with the findings of Clark and Stewart[3] for central vision. The absence of a significant inhibitory effect at the 1°/sec² level of acceleration was unexpected, since the low levels of acceleration produced the greatest inhibition in the Clark and Stewart study.

Theories of intersensory facilitation are not applicable to the results of the present experiment; however, the inhibition of response does suggest that some theory of perceptual interference would apply. Response conflict theory (Herman & Kantowitz, 1969) approaches the issue of double stimulation through the relationships of the responses to each stimulus, so an inhibition of response is predicted when there is an opposing response relationship. Because there is a response required to only one of the stimuli in this experiment, the response conflict theory is not properly applicable. Another approach has been concerned with the expectancy of the *S* and the time specification of the stimulus event. This analysis does not appear useful either, since the stimuli were presented simultaneously in this experiment. A popular concept in dealing with the inhibition of response in the double stimulation experiment has been the single-channel mechanism (Welford, 1967). The delay in response to double stimulation is explained by a limitation of the capacity of the CNS to transmit and process information. It may be that the vestibular stimuli are processed to some degree before the visual stimuli are allowed to proceed along the informational pathways. There is also the possibility, however, that a communication channel accepts both stimuli, and handles them simultaneously at a reduced rate of processing.

The choice RT in this experiment was greatly influenced by the viewing angle of the visual stimulus. Sensitivity of the peripheral retina to an accelerating visual target is clearly inferior to the foveal sensitivity, but the difference between peripheral and central sensitivity is diminished by increasing the magnitude of the acceleration. The overall linearity in the pattern of choice RT to an accelerating visual target is consistent with the linearity of sensitivity to a constant velocity stimulus (Leibowitz, Johnson, & Isabelle, 1972).

PROCESSING OF RECENCY ITEMS FOR FREE RECALL[1]

MICHAEL J. WATKINS[2] AND OLGA C. WATKINS

Yale University

The phenomenon of negative recency in secondary memory is usually attributed to the reduced *amount* of rehearsal associated with recency items. On the other hand, negative recency can be explained by the adoption of a different *type* of processing for recency items. An experiment is reported in which the recall of recency items was reduced in an immediate test, but increased in a subsequent test, under conditions in which the recency items could not be identified as such during their presentation. It was concluded that the mode of processing items for an immediate free-recall test is normally modified for recency items.

It is widely held that the serial position curve obtained in single-trial free recall reflects the operation of 2 memory systems. The recency effect is attributed to a fixed-capacity, highly accessible primary memory, while prerecency items are considered to be recalled from a more commodious and permanent secondary memory, with a probability that depends on a wide variety of experimental variables. Upon perception, an item is assumed to enter primary memory, where it remains until displaced. During its stay in primary memory, information concerning the item is transferred to secondary memory. In brief, these are the principal features of the modal model of short-term memory (Atkinson & Shiffrin, 1968; Waugh & Norman, 1965).

This 2-process view of short-term memory was given considerable support by Craik's (1970) finding of a negative recency effect in secondary memory. Craik presented a series of word lists for immediate free recall, and then asked *S*s to recall as many words as possible from all lists. It was found that in this final free-recall test, words presented in recency serial positions were the least well recalled, despite having been recalled well initially. This pattern of results has been replicated in several studies, and has usually been attributed to recency items gaining less rehearsal and therefore less registration in secondary memory than prerecency items. In other words, to the extent that an item is likely to be represented in primary memory at the end of list presentation, the transfer of information about that item to secondary memory will not have run its full course. It follows that items recalled from primary memory in an immediate recall test should be recalled least well on a subsequent recall test, in which only secondary memory is operative.

This quantity-of-rehearsal interpretation of negative recency has been well supported by studies using the overt-rehearsal technique, in which *S* is required to vocalize his rehearsal activity (Rundus & Atkinson, 1970). When the frequency of item rehearsal is plotted against serial position, the last few list items are found to be given progressively less rehearsal, so that the serial position function for rehearsal is very similar to that for the final recall phase of Craik's (1970) procedure (Rundus, 1971). These findings indicate that the number of times an item is repeated correlates strongly with its registration in secondary memory.

However, the notion that secondary memory registration is a simple function of quantity of rehearsal has not gone unquestioned. Even if we accept that the pattern of rehearsal yielded by the overt-repetition technique gives a reasonable indication of rehearsal in more conventional list-presentation procedures, a high correlation between number of rehearsals

[1] This study was partially supported by National Science Foundation Grant GB-24171X to Endel Tulving.

and probability of recall from secondary memory does not prove that repetition is the agent of secondary memory registration. The quantity-of-rehearsal approach has been challenged in a number of recent studies which describe procedures yielding very low or even zero correlations between the amount of rehearsal and secondary memory registration (e.g., Craik & Watkins, 1973; Meunier, Ritz, & Meunier, 1972). Of particular relevance here is an experiment by Craik and Watkins (1973, Experiment 2), in which an initial free-recall test was given immediately after list presentation or after an interval of 20 sec., during which the last 4 items were repeated continuously. A final free-recall test revealed that the last 4 items in the rehearsal condition were no better recalled than those in the control condition. These results were discussed within a depth-of-processing framework (Craik & Lockhart, 1972) with a simple "maintaining" type of rehearsal being assumed during the post-presentation rehearsal interval. A maintaining mode of rehearsal serves to keep items in primary memory, but is ineffective for secondary memory registration.

This approach suggests a quality-of-rehearsal interpretation of the negative recency effect. The negative recency paradigm involves the presentation of a series of lists, with list length typically 12–20 items. It seems reasonable to suppose that *S*s could quickly learn to anticipate the end of the list more or less accurately and so could adopt a maintaining rather than an "elaborative" mode of rehearsal for the last few list items. Thus, the negative recency effect would be explained by recency items being given a qualitatively different type of rehearsal, rather than a reduced amount of rehearsal.

Such a view derives good support from the general lack of negative recency in those studies in which primary memory is eliminated by a distractor task given immediately following list presentation (e.g., Glanzer & Cunitz, 1966). When *S* knows that a distractor task is to follow list presentation, it is to be expected that he will encode the recency items in the same comparatively durable form in which he encodes prerecency items. Jacoby and Bartz (1972) have reported an experiment which clearly favors this interpretation. In brief, they found that the interpolation of a 15-sec. arithmetic task between presentation and initial free recall reduced recency in the initial recall test but, at the same time, eliminated the negative recency effect in final recall. For those subscribing to the quantity-of-rehearsal interpretation of the negative recency effect, however, the fact that the effect is found with Craik's (1970) procedure but not with the distractor paradigm has been something of a paradox. When primary memory is eliminated with a distractor task, there can be no beneficial effects of initial retrieval, so that negative recency should be at least as pronounced as with Craik's procedure.

The aim of the present experiment was to seek further evidence relevant to deciding whether negative recency is better interpreted in terms of type or quantity of rehearsal. The experiment was designed to test a prediction of the quality-of-rehearsal view, a prediction not made by the quantity-of-rehearsal view. The procedure involved presenting word lists of variable length under conditions in which half of the *S*s were given information allowing them to anticipate the end of each list, while list length was unpredictable for the other half of the *S*s. There followed an unexpected final recall test. The quality-of-rehearsal view predicts that, while the final recall of prerecency items will remain unaffected by knowledge of list length, the final recall of recency items will be lower when list length is known. If it is not possible to identify during presentation which are to be recency items, then these items will be afforded the same relatively elaborate processing as prerecency items. On the other hand, when the end of the list can be anticipated, a simple maintenance rehearsal will be adopted for recency items; hence, these items will be recalled with a relatively low probability in the final recall test. A quantity-of-rehearsal view, by contrast, does not predict any difference between the 2 conditions.

Apart from the final recall test, the im-

mediate recall data could also prove of interest. One shortcoming of the quality-of-rehearsal interpretation is that it is post hoc. Recency items are assumed to be given a maintenance type of rehearsal because they are poorly recalled from secondary memory. Why *S*s should change their rehearsal strategy for processing recency items remains an unanswered question. One possibility is that maintenance rehearsal may be better suited to meet the task demands. That is, more recency items may be recalled in the immediate test when a maintenance rather than an elaborative mode of rehearsal is adopted. It should be noted that the evidence currently available lends little support to this possibility. Crowder (1969), using a serial recall procedure, found that knowledge of list length enhanced recall of primacy but not recency items. In addition, a number of studies have shown that the manner in which list items are encoded has little or no effect on the immediate free recall of recency items (e.g., Smith, Barresi, & Gross, 1971). However, the effect of being able to anticipate the end of the list on immediate free recall has so far not been investigated directly.

In sum, the main purpose of the present experiment is to test the hypothesis that recency items will be better registered in secondary memory when they cannot be identified as recency items during their presentation. The experiment also serves to test the possibility that being able to anticipate the end of the list will serve to enhance the recency effect in immediate free recall—a finding which would explain why the mode of rehearsal should be shifted for recency items.

Method

Materials. All *S*s were presented with 7 lists drawn from the same word pool of 98 2-syllable concrete nouns. These lists were of 8, 10, 12, 14, 16, 18, and 20 words. For each group of *S*s, a separate allocation of words to lists and positions was made. This allocation was essentially random, but with restrictions that (*a*) obvious within-lists acoustic and semantic associations were avoided, and (*b*) when measured from the *end* of the list, no word occupied the same list position for any 2 *S* groups.

The *S*s were given booklets for immediate free recall (IFR). Each page was headed with the appropriate list number, and contained a column of ¼-in. squares, drawn down the right-hand edge. For half of the *S*s, the number of cells always equaled the number of words in the list; hence, in this (informed) condition, *S*s knew during presentation which words were to be recency ones. For the other (uninformed) half of the *S*s, the number of cells was always 30.

Subjects and design. A total of 122 undergraduate students took part in the experiment. They were tested in 7 groups, with group size ranging from 12–30 *S*s. An even number of *S*s within each group allowed equal, but otherwise random, *S* assignment to the informed and uninformed conditions. The order of presentation of the 7 list lengths was balanced between groups according to a Latin square arrangement.

Procedure. The *S*s were told that they would be presented with a series of word lists for IFR, and that the number of words per list would vary considerably. The nature of the booklets was explained. As the words of a given list were presented, check marks were to be made in successive cells of the column. The *S*s were informed that if the column lengths varied from page to page, then they were arranged such that list length would always equal the number of column cells. The checking procedure was adopted in order to ensure that *S*s in the informed condition remained fully aware of the stage of list presentation.

The free-recall instructions were slightly modified, in that it was suggested that performance could be maximized by recalling the last few presented items first. This procedure was adopted to ensure that any effect of presentation condition on the IFR of recency items was due to a difference in the availability of primary memory items, and was not merely the result of a difference in retrieval strategy. Presentation was auditory and at a 2-sec. rate. The end of a list was marked by a pencil tap given 2 sec. after the last word. The *S*s in the informed condition were told not to begin recalling between presentation of the last word and the recall signal, but to remain quite still during this interval, in order to avoid giving unintentional cues to the uninformed *S*s. The time allowed for IFR varied between 60 and 90 sec., according to list length. After presentation of the last list a 1-min. arithmetic task was given. The *S*s were then allowed 6 min. for an unexpected final free-recall (FFR) test, in which as many of the presented words as possible were to be recalled.

Results

The main focus of interest will be the effects of knowing list length during presentation on the IFR and FFR of recency items. First, however, the results will be examined at a more general level. To this end, the data were subjected to an analysis

TABLE 1

PERCENT RECALL OF RECENCY ITEMS AS A FUNCTION OF RECALL TEST, PRESENTATION CONDITION, AND LIST LENGTH

Recall test and presentation condition	List length							M
	8	10	12	14	16	18	20	
Immediate								
Informed	65	64	63	66	63	66	67	64.9
Uninformed	60	61	60	61	55	55	57	58.6
difference	5	3	3	5	8	11	10	6.3
Final								
Informed	12	10	12	12	14	13	17	13.4
Uninformed	16	20	16	20	13	15	18	16.8
difference	−4	10	−4	−8	1	2	−1	−3.4

of variance, with recall test (IFR or FFR), presentation condition (whether *S*s were informed or uninformed of list length), position within the list (recency or prerecency) and list length as main effects. The data were collapsed across serial positions within the recency and prerecency components and across individual *S*s within *S* groups, leaving the *S* groups to serve as the random variable. The dependent variable was probability of recall. Recency items were defined as those presented at the last 6 serial positions. The decision to include 6 items in the recency span reflects the fact that this span encompasses the full extent of almost all reports of negative recency, and is also sufficient to capture the greater part of the recency effect in IFR. The statistical inferences to be drawn from the results remain essentially unchanged when 5, 7, or 8 items are used to define the recency span.

The main effects of recall test, position, and list length were all statistically significant, reflecting the higher probability of recall for IFR, recency items, and shorter list lengths. For recall test, $F\ (1, 6) = 1{,}802.26$, $p < .01$; for position, $F\ (1, 6) = 95.62$, $p < .01$; and for list length, $F\ (6, 36) = 7.75$, $p < .01$. Recall was higher in the informed than uninformed condition, but the difference was small and not significant, $F\ (1, 6) = 1.07$, $p > .05$.

Recall test interacted with presentation condition, $F\ (1, 6) = 14.73$, $p < .01$, position, $F\ (1, 6) = 924.72$, $p < .01$, and list length, $F\ (6, 36) = 3.42$, $p < .01$. These effects may be interpreted in terms of the IFR over FFR advantage being greater for the informed than the uninformed condition, for the recency than the prerecency items, and for the shorter list lengths. There was a significant Position × List Length interaction, $F\ (6, 36) = 5.89$, $p < .01$, which was very largely due to the recency over prerecency advantage increasing with list length. Presentation condition did not interact with either position, $F\ (1, 6) < 1$, or list length, $F\ (6, 36) = 1.43$, $p > .05$.

Two second-order interactions proved significant. A Recall Test × Position × List Length effect, $F\ (6, 36) = 2.45$, $p < .05$, was essentially attributable to the decreasing effect of recall test with increasing list length being more pronounced for prerecency than recency items. A Recall Test × Presentation Condition × Position effect, $F\ (1, 6) = 9.83$, $p < .025$, results from opposite effects of presentation condition on the recency items in the 2 tests. Specifically, while knowledge of list length had virtually no effect on prerecency items, it enhanced IFR and depressed FFR of recency items. This interaction is, of course, central to the present study. There is no evidence to suggest that this interaction should be qualified with respect to list length, insofar as the third-order interaction (Recall Test × Presentation Condition × Position × List Length) was not significant, $F\ (6, 36) = 1.56$, $p > .05$.

It will be recalled that the aim of the experiment was to test the hypotheses

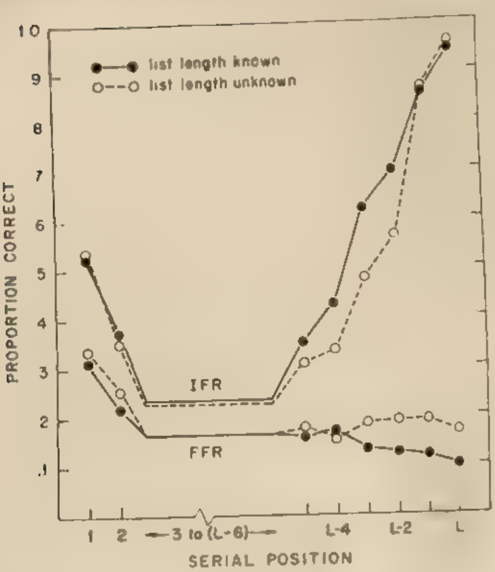

FIGURE 1. Immediate and final free-recall (IFR and FFR) serial position curves for informed and uninformed conditions.

that IFR would be depressed and FFR enhanced for recency items when the end of the list could not be predicted during presentation. While these hypotheses are certainly in good accord with the results of the overall analysis of variance, 2 further analyses were performed in order that they could be tested more directly. The data were collapsed across *S* groups in the first of these tests and across list length in the second.

Table 1 shows recall performance for the informed and uninformed presentation conditions as a function of list length and recall test. In IFR, performance in the uninformed condition was on average only 90.3% of that in the informed condition, whereas in FFR, the difference was in the opposite direction, with recall in the informed condition averaging 80.2% of that in the uninformed condition. Both of these differences were significant: for IFR, t (6) $= 4.94$, $p < .01$, and for FFR, t (6) $= 2.58$, $p < .05$.

Since Table 1 gives no suggestion of a systematic effect of list length on presentation condition, and since the analysis of variance showed that these 2 variables did not significantly interact with each other, either directly or by entering into a significant higher order interaction, it is meaningful to consider the effects of presentation condition with data collapsed across the list length variable. These effects are shown in Figure 1. Each point in the primacy and recency positions is based on 427 observations, while the "asymptotes" of intermediate serial positions are each derived from 2,562 observations. Since the number of observations contributing to the asymptotes varied with list length (from 10 for List Length 8 to 732 for List Length 20), the level of performance for prerecency items should not be taken too seriously. However, Figure 1 does allow a meaningful comparison of the effects of presentation condition on the IFR and FFR within both the recency and prerecency components of the serial position function. It is clear that for prerecency items there is virtually no difference between the presentation conditions. In IFR, the mean probabilities of recalling an item from prerecency positions were .289 and .282 in the informed and uninformed conditions, respectively; in FFR, these probabilities were .190 and .197. In contrast to the prerecency items, the recency items were appreciably affected by presentation condition. With scores collapsed over serial position, the superior IFR for *S*s in the informed condition was significant, t (120) $= 4.27$, $p < .01$, as was the superior FFR of the uninformed condition, t (120) $= 3.01$, $p < .01$.

DISCUSSION

The principal aim of the experiment was to test the prediction that in a delayed (FFR) test, recall of recency items would be enhanced when the end of the list could not be anticipated during presentation. This prediction was confirmed, and hence the notion that the negative recency effect results from switching to a different mode of processing for recency items was supported. It is not immediately apparent how the effect of presentation condition on FFR can be reconciled with the view that negative recency is due to the last few list items being given a progressively decreasing amount of a single rehearsal process (Rundus, 1971).

The quantity-of-rehearsal view has similar difficulties in accounting for the effect of presentation condition on the IFR of recency items. On the other hand, the superior IFR recency effect shown in the informed condition is clearly in line with the notion that mode of processing is normally switched for recency items. In addition, the IFR results have more general theoretical implications. There is an extensive literature documenting the effects of a wide range of variables to be confined to prerecency serial positions (for a summary, see Glanzer, 1972). To date, only presentation modality has been unequivocally shown to have the converse effect, with an auditory over visual advantage restricted to recency items (Murdock & Walker, 1969). Moreover, it is by no means agreed that this modality effect qualifies the primary memory property of invariant capacity, in that the auditory advantage is often attributed to a separate memory system (an interpretation that is perhaps less readily applied to the present findings). In this connection it should be noted that the effects of modality and of being able to anticipate the end of the list are not identical. Unlike the modality effect, the effect of knowing when to expect the end of the list is not apparent at the last 1 or 2 serial positions, but is observed only over the earlier portion of the recency effect. Although it is not entirely clear why the effect of presentation condition should be so specific with respect to serial position, it may be speculated that when *S* believes that the end of the list is imminent, he switches to a mode processing somewhat similar to that used in a memory span task.

We have noted that the quantity-of-rehearsal account of secondary memory registration does not predict the effects of presentation condition in either recall test. A far greater difficulty for this account lies in the fact that the effects were in opposite directions in the 2 recall tests. On the other hand, the interaction between recall test and presentation condition is not difficult to understand when qualitatively different types of rehearsal are allowed. Specifically, when a list of verbal items is presented for immediate free recall, a certain amount of processing capacity will be reserved for the elaborative and organizing operations which are collectively referred to as secondary memory registration. When the end of the list is thought imminent, secondary memory registration is reduced in order to increase primary memory capacity. The result is that recall of recency items is maximized in an immediate test, but at the expense of being reduced in a subsequent test in which only secondary memory is operative.

REACTIONS TO FRUSTRATIVE NONREWARD AS A FUNCTION OF PERCEIVED LOCUS OF CONTROL OF REINFORCEMENT

J. WESLEY LIBB[1] AND CAMELLA SERUM

University of Alabama

Based on Rotter's definition of the personality variable locus of control of reinforcement—it was predicted that internal *Ss* in an ambiguous experimental situation would be responsive to frustrative nonreward whereas external *Ss* might not be similarly frustrated. As predicted, internal *Ss* responded with reduced latencies following nonreward and, early in learning, made significantly more errors on a subsequent complex task. Consistent with Spence's theory of emotionally based drive, these same *Ss* showed improved performance following frustration at a later stage in learning when the task was largely mastered. No similar experimental effects emerged for the external *Ss* suggesting that only the internal *Ss* were significantly frustrated by the experimental procedures.

The hypothesis that people with differing personality characteristics react differently to frustrating situations is not a unique or novel hypothesis. Neither is the postulation that differing experiences may be differentially frustrating to various individuals. The possibility, however, of being able to predict in what situations a certain individual might be frustrated and the effects of his being frustrated upon his behavior in various situations would seem a meaningful contribution to attempts to relate learning theory to human behavior.

According to Amsel's (1958) theory of frustrative nonreward, failure of reward following the establishment of an expectancy for reward elicits a primary frustration reaction, R_f. Feedback from this reaction leads to enhanced motivational effects evident in subsequent instrumental behavior. The alleged motivational effects are typically evident in the invigoration of responses following nonreward. The term *frustration effect* (FE) refers to this invigoration of performance. Numerous studies attest to the empirical validity of frustration theory in regard to FE with both animals and children (Ryan & Watson, 1968; Wagner, 1959). The data for adult human *Ss* are lacking, with one recent exception (Libb, 1972), perhaps due to difficulties encountered in providing material incentives outweighing *Ss*' self-induced symbolic motivations.

The FE has generally been demonstrated in a task where there are few obvious competing responses and with a response well established by previous training. In general, frustration has resulted in increased running speeds and decreased latencies, which may be said to "enhance" performance. On more complex tasks, in which there are more obvious competing responses, effects differ. Both Schmeck and Bruning (1968) and Libb (1972) lend support to the hypothesis that frustration produces impaired performance on a complex task. The relationship between frustration and performance is not a simple, positive linear function. Based on Spence's (1960) theory of emotionally based drive, Libb predicted that during the early stages of learning a complex task, more errors would occur following a frustrating condition than following a neutral or rewarding situation. In later stages of learning, it was predicted that frustration would be less detrimental and might be associated with fewer errors, i.e., an interaction over trial blocks was predicted. These hypotheses were largely supported.

While FE is a reliable experimental phenomenon, it has been noted by several authors that individual differences may occur in reaction to frustrative nonreward in human research. Ryan and Moffitt

(1966) found that only approximately half of their *S*s demonstrated FE. They argued that this differential reaction may not be an isolated chance occurrence but rather an individual difference variable generally obscured by the use of averages. Little experimental attention has been devoted to systematic analysis of individual differences in regard to frustration theory.

Ryan and Watson (1968) suggested that the individual difference variable, locus of control of reinforcement (Rotter, 1966), may account for differential responding to nonreward. Internal-external locus of control of reinforcement refers to the extent to which a person perceives reinforcement as under his own control (internal), or under the control of powerful others, fate, or chance (external).

In the research that follows, a design similar to that of Libb (1972) was employed. Human *S*s were given ambiguous instructions with regard to locus of control of reinforcement. Based on previous research findings (Rotter, Liverant, & Crowne, 1961), it was assumed that internal *S*s would develop a higher expectancy for reward than external *S*s and would be more responsive to nonreward than externally oriented *S*s. Specifically, it was predicted that internal *S*s would show a significant reduction in response latency following nonrewarded trials. Should external *S*s manifest this effect at all, it was hypothesized to be of lesser degree than for internal *S*s. With regard to errors for the internal group, it was predicted that in the early stages of learning frustration would be evident in a decrement in performance or as increased errors following nonreward. Later in learning this effect was anticipated to disappear or a decrease in errors following nonrewarded trials actually would be evident. Since the external group was predicted to be less frustrated than the internal group, these effects were predicted to be of lesser magnitude, if present at all, for the external group.

Method

Subjects. Thirty-two *S*s from introductory psychology classes at the University of Alabama participated as part of a course requirement. All 32 *S*s volunteered to participate with no prior understanding of the precise nature of the experiment. Rotter's (1966) Internal-External Control Scale was administered to all *S*s who were divided into 2 groups based on a median score of 10.5. The internal group consisted of 16 internal *S*s (8 male and 8 female) and the external group, 16 external *S*s (11 male and 5 female). Little effort was made to match sexes within groups inasmuch as previous literature reveals no sex differences. Also, a *t* test for sex differences within this experiment was not significant.

Apparatus. The experimental chamber was a sound-dampened 10 × 10 ft. (3 × 3 m.) cubicle. Electromechanical programming equipment was located in a separate room. Manipulanda and the reward dispenser were mounted in the experimental chamber. Directly above a small table a Gerbrands Universal Feeder was mounted from which marbles were dispensed for appropriate responses in a 2-task sequence. The first manipulandum in position on the table was a single button (1 in. [2.54 cm.] in diameter) mounted on an 8 × 10 in. (2 × 2.5 dm. in diameter) panel. Immediately above the button on the panel a small 28-w. stimulus light was mounted. The second panel, 8 × 14 in. (2 × 3.5 dm.) in size, separately mounted to the right of the first, consisted of 4 buttons centrally positioned below a multiple-stimulus projector (Grason-Stadler, No. 4580-159), also mounted on the panel. Complexity on the second task, as part of a 2-task sequence paralleling Amsel's (1958) apparatus, was introduced by varying the stimuli presented on the multiple-stimulus projector which cued *S* as to the correct button on that trial.

Procedure. The *S*s participated to earn a predetermined number of marbles to qualify for extra credit in course work. They were escorted to the experimental chamber and seated before the apparatus. The *E* read the following directions:

> You have fifteen minutes to earn 46 marbles to qualify for course credit in this experiment. Marbles will be earned by pressing the button when the light comes on. Press the button on the first panel when the light comes on and the first button on the second panel when the colored light comes on. After you earn 10 marbles, there will be a slight delay and change in the program.

Instructions were repeated if procedure clarification was requested by *S*. All *S*s performed 5 training trials and 24 experimental trials. A trial consisted of a sequence of responses on both panels. The sequence started with illumination of the stimulus on the first panel. Five seconds after *S* responded on this panel, the multiple-stimulus projector on the second panel was illuminated permitting *S* to choose 1 of 4 buttons. The sequence recycled 30 sec. after the appropriate response on the second panel. Reinforcement consisted of the delivery of one marble on rewarded trials. On training trials for the second task only one stimulus was presented and the first button was always the correct response.

TABLE 1

Mean Errors and Latencies per Trial Block

Group and condition	Errors			Latency		
	Block 1	Block 2	Total	Block 1	Block 2	Total
Internal						
Nonrewarded	9.44	3.69	6.57	1.41	1.26	1.34
Rewarded	6.56	5.13	5.85	1.82	1.48	1.65
External						
Nonrewarded	7.50	3.69	5.60	1.74	1.72	1.73
Rewarded	8.00	2.75	5.38	1.81	1.68	1.75

Following training trials, stimuli on the projector were scrambled and *S* was required to learn the appropriate button to be paired with red, blue, yellow, or green lights. On this panel, *S* could press as many buttons as he wished as many times as he wished, but reward was forthcoming only when the correct button was pressed. Marble reinforcement for correct responses was continuous on the second panel for all *S*s. Both groups received randomized 50% reinforcement on Task 1 during experimental trials, with the one limitation that no more than 2 trials of either reward or nonreward occurred in succession. In addition to the color presented on the multiple-stimulus projector, irrelevant cues (an X, a square, a circle, or a dash) were also presented simultaneously so as to enhance the complexity of the task.

For each rewarded and nonrewarded response on Task 1, number of incorrect responses and latency to initial response on Task 2 were recorded. Latency was defined as the time from illumination of the multiple-stimulus projector to *S*'s first button press on Panel 2, whether correct or incorrect.

Results

The latency scores were calculated for each *S* following both rewarded and nonrewarded trials in Blocks 1 and 2 (see Table 1). Since the homogeneity of variance assumptions could not be established for these 2 groups, $F_{max} = 1.977$, $p < .01$, latency scores for each of the 2 groups were analyzed separately with a Treatment × Treatment × *S* analysis of variance. The internal group demonstrated a significant main effect, $F\ (1,\ 15) = 4.282$, $p < .05$, while the external group did not exhibit this effect. The internal group thus demonstrated significantly reduced latencies following nonrewarded trials when compared with rewarded trials.

Four separate error scores were calculated for each *S*: total error scores following nonreward and following reward in each of 2 blocks of experimental trials (see Table 1). A 3-factor analysis of variance on these data yielded a significant triple interaction, $F\ (1,\ 30) = 6.38$, $p < .02$, and a significant trial blocks effect, $F\ (1,\ 30) = 50.962$, $p < .001$. The latter indicates that *S*s performed with significantly fewer errors in the second block of trials than the first block. A Treatment × Treatment × *S* analysis of variance was performed separately on each of the 2 groups. A significant A × B interaction with the internal group indicated the appropriateness of individual *t* tests, $F\ (1,\ 15) = 5.684$, $p < .025$. Internal group *S*s made significantly more errors following nonreward than following reward in Block 1, $t\ (15) = 4.496$, $p < .01$. Although the *F* test was statistically significant for the interaction, the *t* test for the second block of trials on error scores was not statistically significant, $t\ (15) = 1.118$, $p < .3$. Again the trial blocks effect was statistically significant, $F\ (1,\ 15) = 15.788$, $p < .005$. The Treatment × Treatment × *S* analysis of variance for external group *S*s yielded only a trial blocks effect, $F\ (1,\ 15) = 43.01$, $p < .001$.

Discussion

These data, both error and latency scores, suggest that the internal group was frustrated by the experimental manipulation whereas the external group was not similarly frustrated. Hypotheses were thus supported in that the internal group showed a significant latency effect consistent with the animal literature and a significant interaction with regard to error scores, consistent with Libb (1972). The interaction was clearer than in Libb's study, perhaps due to the fact that *S*s who had little tendency to be frustrated by experimental manipulations were classified as externals. This experiment suggests that much of the difficulty in demonstrating FEs with human *S*s may be due to the fact that individual differences obscure results when such factors are undetected and uncontrolled. If, in fact, an *S* is not frustrated, it hardly seems reasonable to predict that he would manifest FE.

It is also noteworthy that the latency effect was observed in this experiment and not observed in the Libb (1972) experiment in which

both internal and external *S*s were likely participants. These data are thus unique in that the FE was evident in 2 dependent variables: latency and error scores. Such findings lend further support to Spence's (1960) theory of emotionally based drive and its effect on performance of tasks of varying complexity.

Difficulties in interpretation may be encountered in the lack of a significant reduction in errors from Block 1 to Block 2 following reward in the internal group. Since trials introducing both nonreward and reward were randomly but evenly distributed within each block, one would expect errors to decrease following both reward and nonreward as learning progressed. The internal *S* may have become bored with the task such that his performance deteriorated unless frustration was added to the motivational complex.

Alternative explanations of these data are possible. For example, internal *S*s more than external *S*s may initially be searching for a combination Task 1–Task 2 strategy which will permit them to be correct 100% of the time. Such an approach to the experimental situation could account for not only the higher number of errors following nonreward but also the equivalent reward performance on Blocks 1 and 2; i.e., occasionally trying out more complex strategies intrudes on performance following rewarded trials. Alternatively internal *S*s may have experienced some anxiety with regard to Task 1 since the nature of the task may have precluded their preferred perception of skill control. Increased anxiety may lead to enhanced drive and increased errors in parallel to the predicted FEs.

METACONTRAST AND SIMPLE REACTION TIME: A REEXAMINATION [1]

ROBERT W. PROCTOR AND IRA H. BERNSTEIN [2]

University of Texas at Arlington

D. L. SCHURMAN

Emory University

Fehrer and Raab and subsequent investigators have reported that simple reaction time (RT) to a metacontrast-inducing combination of test and mask stimuli is more rapid than to either component (test or mask) alone. Thus, they concluded that simple RT is not affected by metacontrast. We note that their conclusion is not warranted. A test–mask combination normally should evoke faster RT than either test or mask alone because of the greater area and, hence, total energy of the combination. A more appropriate comparison is between the metacontrast-inducing combination and a combination of equal area and energy that does not induce metacontrast. The results of this comparison were that 4 *S*s gave equivocal results; RT to the 2 combinations and to its components were all equal, but 4 *S*s showed faster RT to the non-metacontrast-inducing combination. The overall results indicated that metacontrast does, in fact, affect simple RT.

Metacontrast refers to a decrement in the clarity or visibility of a stimulus produced by adjacent, nonoverlapping stimuli that occur in close temporal proximity. One typical configuration used in studies of metacontrast is a centrally located square (test stimulus) and a pair of flanking squares (mask stimuli) which share adjacent contours with the test stimulus. The test, mask, and combination of test and mask occur in random order, over trials. The temporal spacing between test and mask—stimulus onset asynchronies (SOAs)—are generally varied over blocks of trials. When the test and mask energies are equal, the phenomenal brightness of the test square is a U-shaped function of SOA. With test energy less than mask energy, phenomenal brightness is an increasing function of SOA. In either case, the phenomenal brightness of a test stimulus is reduced by the presence of nonoverlapping mask stimulus. (See Kahneman, 1968, for a general substantiative and procedural review.)

Despite the phenomenal dimming of the test stimulus, however, simple reaction time (RT) to a test–mask combination is typically no slower than simple RT to the test alone. This finding has led several investigators to conclude that metacontrast does not affect simple RT (Fehrer & Raab, 1962: Harrison & Fox, 1966; Schiller & Smith, 1966). Fehrer and Raab further concluded that "It was therefore the physical dimensions of the [test] stimulus rather than its phenomenal characteristics that determined RT [p. 147]."

However, the support for the hypothesis that simple RT and verbal report obey different functional relationships may simply be based upon an improper comparison. The RT to the combination should not be compared to the test alone. A more proper comparison is with a second combination of equal energy and area which does not produce metacontrast. Such a combination could consist of squares of the same individual dimensions, durations, and luminances as the metacontrast combination but which are spatially arrayed so as not to induce metacontrast (i.e., are nonadjacent).

Comparing simple RT to a metacontrast-inducing (*experimental*) combination with a non-metacontrast-inducing (*control*) combination rather than the mask alone is necessary to equate for stimulus energy. The RT to both combinations can reflect spatial integration and, when SOA is not zero, temporal integration as well (Bernstein, Amundson, & Schurman, 1973; Kietzman & Gillam, 1972). Spatial integration was reported by Fehrer and Raab (1962) among many others; the 2 mask squares, being of greater combined area, produced faster RT than the single test square. The crucial question is whether metacontrast does or does not affect integrative processes.

The preceding implies that 2 additional findings must converge upon the observation that RT to an experimental combination is faster than RT to the mask alone (and, consequently, the test alone as the greater mask area normally yields the shorter RT of the 2 conditions) before one can conclude that metacontrast does not affect simple RT. One should demonstrate that the experimental configuration did, in fact, produce metacontrast as inferred from verbal report. In addition, RT to the experimental and control combinations should be equal if the extent of integration is the same. Conversely, if RT to the control combination is faster than RT to the experimental combination, one should conclude that metacontrast does affect RT even if RT to both combinations is faster than RT to the mask alone.

A third possible result is that RT to the mask and the 2 combinations are all equal to one another. This finding would be uninformative, since it would indicate that the mask alone was the effective stimulus, i.e., the additional energy provided by the test was not sufficiently great to affect RT.

The present data were gathered from the third study of a series. The first 2 studies employed a less optimal design and will be discussed briefly. As with other metacontrast studies in which the mask energy exceeded the test energy, pilot data revealed that the verbally inferred masking function for the experimental combination was monotonic. Since the metacontrast effect was greatest with concurrent test–mask onset, 0-msec. SOA was best suited to explore possible effects of metacontrast upon simple RT. Hence, SOA was not varied in the experiment reported here although some relevant data were gathered in the earlier experiments.

Method

Subjects. The *S*s were 8 paid volunteers, 4 males (RF, JSA, GB, and KS) and 4 females (VA, JS, SF, JC). All were graduate students in psychology at the University of Texas at Arlington. All had normal or corrected-to-normal visual acuity.

Apparatus and stimuli. Stimuli were presented by transillumination in a 3-channel tachistoscope (Scientific Prototype, Model GB) using standard Sylvania bulbs (F8T5/D). Because imperfections in mirror alignment might have produced binocular parallax, viewing was monocular through a 2-mm. artificial pupil. Luminances were measured with a McBeth Illuminometer. The tachistoscope's timing accuracy was verified with an oscilloscope (Tektronix, Model 564). The RT responses were right-hand telegraph key depressions timed with a Hunter Klockounter (Model 120G). A foot-pedal was used for *S* to self-initiate trials with the left foot. The *E* and the *S* were seated in adjacent rooms.

The stimulus display consisted of a dim fixation circle that remained on continuously. The circle was located in the blank field of the tachistoscope and was illuminated by an external source so that the blank field could be used as a separate exposure field. The fixation point had very low luminance and became clearly visible only after fixation. Exposure Field 1 contained a centrally located square, the base of which was .33° of arc above fixation (experimental test.) Exposure Field 2 also contained a centrally located square, the top of which was .33° of arc below fixation (control test). Exposure Field 3 (nominally the blank field) contained a pair of squares (the mask), whose inner sides were contiguous to the experimental test. The individual squares were all transilluminated. The dimensions (.67° of arc/side) and luminances (63 cd/m²) were identical to those used by Fehrer and Raab (1962).

The test and mask durations were 2 and 100 msec., respectively. This typically produced chance accuracy in discriminating experimental test + mask (TM–E) from mask (M) alone at an SOA of 0, the SOA used throughout the experiment. This duration was adequate to allow perfect discrimination of control test + mask (TM–C) from M alone in pilot work. The entire display fell within a 2° arc of fixation.

Procedure. All but 2 *S*s had extensive practice at reacting to the various stimulus conditions in either or both of 2 pilot studies and were run without additional practice. The 2 experimentally naive *S*s were run for a 1-hr practice period. All *S*s were then run in a single session of approximately 1 hr.

The session began with 5 min. of dark adaptation. Half of the RT trials were then run. A 3-min. break was provided following which a series of verbal report trials, described below, were run. A second 3-min. break was provided, and the remaining RT trials were run.

Both verbal report and RT trials began with a signal from *E* that the necessary adjustments had been made. The *S* then fixated, blinked if necessary, and when the circle appeared as sharp and clear as possible, initiated the trial with the foot switch. This activated a timer to initiate 1 of 3 randomly chosen foreperiods (1.9, 2.2, or 2.5 sec.).

For RT trials, 1 of 5 stimulus conditions was possible: (*a*) TM–E, (*b*) TM–C, (*c*) M alone, (*d*) experimental test (T–E) alone, and (*e*) control test (T–C) alone. These occurred randomly, subject to the condition that TM–E, TM–C, and M occur 20 times each and T–E and T–C occur 10 times each per half session. A complete factorial design combining the 2 test positions with masks above and below fixation was not possible since there was no fourth tachistoscopic field available for a mask below fixation. Thus, one purpose of the T–E vs. T–C comparison was to insure that the retinal regions stimulated were equally sensitive.

All responses were timed from the end of the foreperiod. All RTs longer than 350 msec. or shorter than 100 msec. were rerun (less than 1% of all trials).

The verbal report trials consisted of the random presentation of M and TM–E 50 times each. The *S*s responded on each of these trials along a 6-point confidence rating scale (Green & Swets, 1966), with 1 = very sure that TM–E had been presented, 2 = moderately sure that TM–E had been presented, . . . and 6 = very sure that M had been presented. As noted above, pilot data indicated that the TM–C and M could always be discriminated from one another. Likewise, T–C and T–E were never confused with each other or with the other alternatives.

Results and Discussion

The major finding was that metacontrast did affect simple RT. The RT to TM–C (201 msec. over *S*s) was faster than RT to TM–E and RT to M which, in turn, did not differ (205 msec.). The RT to T–E and T–C, likewise, did not differ, and due to their smaller area were the slowest (216 msec.). Analysis of variance (Stimulus Conditions × *S*s) indicated that the 5 means differed, F (4, 28) = 24.13, $p < .01$. Also, RT to TM–C was significantly faster than RT to TM–E, F (1, 7) = 5.67, $p < .05$, but RT to M and TM–E did not differ ($F < 1.0$) likewise, RT to T–E and RT to T–C did not differ ($F < 1.0$).

Receiver operating characteristic (ROC) curves were obtained from each *S*'s confidence ratings, treating TM–E presentations as "signal plus noise" and M presentations as "noise." The mean area under these ROC curves was .524. This is well within chance limits, indicating that concurrent presentation of the experimental test (T–E) and the mask (M) produced complete masking. Only 1 *S* (KS) exceeded chance.

Thus, the data show that more integration of test and mask energy occurred without rather than with metacontrast. In fact, with the present high level of metacontrast, no integration at all occurred; RT to the experimental combination and mask alone were equal. Fehrer and Raab's (1962) conclusion that metacontrast does not affect RT seems to be an artifact of

improperly comparing RT to the experimental combination with RT to the mask instead of RT to the control combination. Our results are not due to differential sensitivity of the retinal loci stimulated by the 2 test squares, since RT to each of them was identical.

The individual *S* data are presented in Table 1. The results of *t* tests comparing TM–C, TM–E, and M among themselves are included. Only 4 *S*s (KS, JSA, JC, and VA) had faster RTs to the control combination than to the experimental combination and mask alone. The remaining *S*s' RTs to these 3 stimulus combinations are all equal; hence, their data are inconclusive. The test energy was apparently too low for the latter *S*s to demonstrate any integration. No *S* fulfilled the criteria discussed earlier to support Fehrer and Raab's (1962) conclusion by manifesting equal amounts of integration to the 2 combinations. Since enough *S*s were run in the present study to demonstrate the metacontrast impairment in RT statistically over all *S*s, there seemed to be no reason to run additional trials or *S*s. We did look for factors separating the 2 groups of *S*s who, respectively, did and did not demonstrate integration with T–C. These analyses failed to show that verbal report performance, familiarity with the metacontrast phenomenon, RT experience, or *S*'s own expectancies were pertinent.

The results of our 2 prior studies (Bernstein, Amundson, & Schurman, 1973; Bernstein, Futch, & Schurman, 1973) were that RT to TM–E fell between the RT to TM–C and RT to M, unlike the present results. This was because the test energy was sufficiently high to allow partial verbal report detection and, hence, integration. The stimulus parameters in the Fehrer and Raab (1962) and related studies suggest partial detection. This would explain why RT to TM–E would be faster than RT to M. Despite the energy differences among the studies, the difference at 0-msec. SOA between RT to TM–C and RT to TM–E was about the same 4 msec. as shown here. These earlier studies also found that not all *S*s demonstrated integration effects.

The failure to obtain integration effects with the present high levels of metacontrast is contrary to findings reported by Fehrer and Biederman (1962) when (unlike the Fehrer & Raab 1962 study) verbal report performance was near chance due to a slightly different method of presenting the test. Fehrer and Biederman reported integration did occur with chance verbal report accuracy, a form of "discrimination without awareness." Recently, Bernstein, Admunson, and Schurman (1973) reported an artifact underlying Fehrer and Biederman's conclusion. The artifact was a difference of statistical power between the verbal report comparison and the RT comparison. Bernstein, Amundson, and Schurman 1973 used signal detection methods to compare verbal report and RT directly, using inferential tests of similar power. They found verbal report to be the superior performance index.

The results presented in this report and those of Bernstein, Amundson, and Schurman (1973) jointly suggest that verbal report and RT do not differ as much in the *type* of perceptual mechanism but, rather, in the *duration* of processing that occurs prior to a response. That is, a verbal discrimination, or more generally, any response requiring a choice, involves a longer period of temporal integration within the system. Additional evidence for this difference in processing duration is the shorter critical duration for simple RT when compared to verbal report (Bernstein, Futch, & Schurman, 1973; Bruder & Kietzman, 1973; Fehrer & Raab, 1962; Kietzman & Gillam, 1972). It is with this observation, first made in the Fehrer–Raab series of experiments and their most important conclusion, that we strongly agree. The shorter period of temporal integration would explain why Fehrer and Raab and others, including us in our pilot studies, found no difference between RT to the combination and RT to the mask alone at longer SOA even though verbal report was impaired.

Special note needs to be made about Fehrer and Raab's (1962) 25–75 msec. range of SOA, where there was partial to total phenomenal test suppression. The RT to the combination was essentially equal to the RT to the test (but slower than RT to the mask). As the authors noted,

*S*s easily learned to discriminate the combination from the mask by use of apparent movement cues. They also noted that these cues could have constituted part of the effective stimulus for RT to the combination. Thus, the near equality of RT to the combination and test alone seems to reflect opposing processes; apparent movement decreased RT to the combination whereas phenomenal dimming increased it. The surprising point of their experiment thus does not seem to be that these RTs were essentially equal. Rather, it is why the second event (mask) could influence simple RT at SOAs beyond the critical duration for the first event (test). There are abundant data to suggest that lengthening the duration of a target of moderate to high luninance beyond 10–20 msec. does not reduce and may even increase simple RT (Bernstein, Futch, & Schurman, 1973). Bernstein, Futch, & Schurman argued for the importance of "on" and "off" responses as RT determinants. These effects also seem appropriate to consider in the light of the present paradox.

Thus, one need not assume that the physical stimulus intensity is processed at one level, and that metacontrast affects a higher, more conscious level. Mechanisms, such as lateral inhibition and luminance summation, which collectively seem to account for much of the metacontrast phenomenon, can occur at the earliest stages of information processing and thus affect both verbal report and RT.

RELATIVE EFFECTIVENESS OF RHYMES AND SYNONYMS AS RETRIEVAL CUES[1]

DOUGLAS L. NELSON[2] AND DAVID H. BROOKS

University of South Florida

An experiment was performed to compare the relative effectiveness of rhymes and synonyms as extralist retrieval cues. The a priori relation between synonym cues and their targets and rhyme cues and their targets was equated, at both weak and strong levels, by the use of normative data. An attempt also was made to hold "set size" constant. The results indicated that recall was highest with strong cues, intermediate with weak cues, and lowest when no cues were provided. This relative ordering was obtained for both rhyme and synonym cues, suggesting that when a priori strength of relationship has been equated, at either weak or strong levels, both types of cues are equivalent as aids for retrieval. Implications for the encoding specificity principle and for generation-recognition models of free recall were discussed.

Words are represented in memory as complexes of distinctive features. This conjecture represents the principal assumption of several recent conceptualizations of word coding processes (e.g., Anderson & Bower, 1972; Nelson, 1972; Tulving & Thompson, 1973). These features are empirically identifiable as graphic, phonetic, associative, semantic, and imaginal, but they could plausibly consist of any discriminable attributes. According to one version of the multifeature hypothesis, the process of coding a word that is presumably already within *S*'s vocabulary consists of priming one or more of its distinctive features during the study portion of the current learning task (Nelson, 1972). Thus, when a word is presented along with an instruction to remember it, one or more of its attributes are either selectively or automatically primed, i.e., they become functionally effective in the task. Another assumption of this conception is that the priming of specific attributes can be influenced by task characteristics, contextual cues, and instructional sets, as well as by item attributes themselves, and that these features, once effective, function as redintegrative cues for subsequent stimulus retrieval.

One implication of this conceptualization is that items that cannot be recalled under noncued conditions might be made accessible in the presence of extralist cues that prime features shared by specific list items (cf. Tulving & Pearlstone, 1966). Strong extralist associates of list items (e.g., Bahrick, 1969), names of conceptual categories (e.g., Tulving & Psotka, 1971), hononyms and synonyms (Light, 1972) as well as rhymes and graphic cues (Bregman, 1968; Nelson & Brooks, 1974), have all been used as effective recall aids. However, with some exceptions (e.g., Bregman, 1968; Light, 1972), very little effort in this area has been directed toward assessing the relative efficiency of various types of cues. Although the apparent differential emphasis given semantic factors by psychological theorists leaves the impression that meaning is the sine qua non of memory, there is ample evidence suggesting that sensory features, both graphic and phonetic, play a prominant role in word processing (e.g., Gibson, 1971; Nelson, 1972). These considerations suggest that comparisons of the effectiveness of meaning and sensory features as extralist retrieval aids might shed some light on the relative importance of these attributes within the memory representation of a given word. Therefore, this

experiment directly compared rhymes and synonyms as retrieval cues for rendering access to words stored during a rapidly paced single presentation. In order to ensure that this comparison was on a sound basis, two potential problems had to be resolved. First, the a priori similarity between the synonym cues and their targets had to be equated to the a priori similarity between the rhyme cues and their targets. If not so equated, one type of cue may prove to be superior to or not different from the other because of an initial confounding of the cue-to-target relationship. Second, "set size" had to be equalized for both types of cues. If cued recall is analogous to a search task, then the cue that provides the greatest reduction of the number of relevant items will be the most efficient. Providing that the procedures used to eliminate these potential confoundings are effective, equivalent facilitation would suggest that the two types of cues were equally effective, while differential facilitation would imply that one type of cue provided superior retrieval access relative to the other. This experiment, therefore, was explicitly designed to manipulate type of cue—synonym or rhyme—at two levels of cue-to-target relationship, while, at the same time, the a priori relations between cue and target and set size were carefully equated for both types of cues.

Method

Design. The experimental design was a 2^5 between-within factorial. Type of cue, type of recall, lists, and *E*s were all between-*S*s factors and strength relation of cue to target was a within-*S*s factor. Cues were rhymes or synonyms, recall was cued or free, and strength was either strong or weak. Separate free-recall groups were used for rhyme and synonym conditions, since the targets for each of these lists had to be composed of different sets of words.

Materials. All words used in this experiment were chosen from norms obtained from a separate intact group of 74 *S*s in an ongoing psychology course. Each *S* was given a booklet containing 6 pages. The initial page contained rhyme instructions for half of the *S*s and synonym instructions for the remaining half of the *S*s, and the next 5 pages each contained 1 column of 20 words with a blank to the right of each item. The rhyme instructions indicated that on the blank beside each word they should write the *first* word that they could think of that *rhymes* with the word on the left and, similarly, the synonym instructions indicated that they should write down the *first* word that they could think of that means the same thing as the word on the left. The same 100 words were used with both instructional sets, and these words had been chosen by *E* in advance so that each item had several rhymes and synonyms. The order of the pages containing the sample was independently randomized for each *S*.

The normative data provided by these *S*s was then used to construct 4 lists, 2 for the rhyme condition and 2 for the synonym condition. Each list contained 24 pairs, the cue words having served as stimuli in the controlled association task and the targets having been provided by various proportions of *S*s in that task. For half of the pairs, the cue words were strongly associated to their respective targets. An average of 52% of the *S*s provided the target in response to the cue word and, for all of these pairs, the target was the primary response to the cue. For the remaining half of the pairs within a given list, the cue-to-target relation was weak, with an average of 7% of the *S*s responding with that particular target. The average numbers of responses given more frequently than response words selected as targets were 2.83 and 2.63, respectively, for synonyms and rhymes. Furthermore, of all the responses given during the recall phase of the experiment, 22.1% were given more frequently in the controlled association task than the targets used in the weak-synonym-cue condition, and 22.7% were given more frequently than the targets used in the weak-rhyme-cue condition. Thus, strength of relationship was carefully equated at each level for rhyme-related and synonym-related pairs. In addition, to preclude the possibility that the effects of type or strength of cue might be attributed to confoundings associated with differences in [illegible], an attempt was made to equate this variable in all conditions. Potential set size was estimated from the number of different responses given to each cue in the controlled association task. Thus, for the rhyme-related and synonym-related pairs there were an average of 6.83 ($SD = 1.74$) and 6.42 ($SD = 2.36$), respectively, different targets provided for each cue. To control for potential set size effects within the strength variable, the cues having a strong relation to their respective targets in one list had a weak relation to their targets in the other list. For example, in the rhyme condition, KEG was used as a strong cue for the target LEG in one of the lists and as a weak cue for the target PEG in the second list. In the synonym condition, FABLE was used as a strong cue for the target STORY in one of the lists and as a weak cue for the target LEGEND in its complementary list. This procedure resulted in using the same cues for each of the 2 lists in the rhyme condition and for each of the 2 lists in the synonym condition. The targets were, however, different for all 4 lists and, although it was possible to equate word frequency within types of cues, it was impossible to equate relative frequency within

the strength variable. Thus, for each of the 2 lists in the rhyme and synonym conditions, the targets having a strong relation to their cues had an average frequency of occurrence of approximately 80 times per million (Kučera & Francis, 1967). The targets having a weak relation to their cues had an average frequency of occurrence of approximately 17 times per million. This confounding of strength and frequency of occurrence was unavoidable since, in the controlled association task, words provided by the smallest percentage of the *Ss* were also less frequent than words provided by the largest percentage of the *Ss*. Because of this confounding, separate free-recall control groups were used for each list of targets. In addition to providing a direct assessment of the frequency variable, this procedure permitted evaluations of the effectiveness of strong and weak rhyme and synonym cues relative to a free-recall baseline appropriate for each frequency level.

Procedure. All *Ss* participated in individual sessions. On study trials, each list word was shown by a Kodak Carousel slide protector driven by an auxiliary timer at a 2-sec. rate. All words were typed in uppercase. The *Ss* were instructed to pronounce the items aloud as each one appeared and, since the list would be shown only once, to concentrate in order to remember as many items as possible. Immediately following the presentation of the last word, instructions for recall were read. In the cued-recall groups, these instructions specified the nature of the relationship of the cue words to the targets and indicated that using the cues would aid their recall. Thus, the information concerning the nature of the retrieval cues was provided *after* list presentation. In the free-recall control groups, these instructions indicated that a row of asterisks would be repeatedly flashed on the screen, and that each time the asterisks appeared, a word—any word from the list—should be recalled. Both sets of instructions were carefully equated for length. In all conditions, recall was oral and was response paced, i.e., as soon as the target was recalled or *S* indicated that he could not remember the appropriate word, the next cue or row of asterisks was shown. The order of presentation of the targets on the study trial and the order of presentation of the cues on the test trial, if any were independently randomized for every *S*.

TABLE 1

Mean Number of List Words Correctly Recalled

Strength of cue	Rhyme: Cued recall	Rhyme: Free recall	Synonym: Cued recall	Synonym: Free recall
Weak	9.20	4.70	9.00	4.50
Strong	6.65	4.75	5.80	4.35

Subjects. Ten *Ss* were assigned to each list within each condition, and each *E* collected data from 5 of these *Ss*. This procedure resulted in 20 *Ss* within each of the major conditions, and a total of 80 in the entire experiment. For each *E*, *Ss* were assigned to conditions in blocks of 8, with 1 *S* from each condition and list per block. Assignment within blocks was determined by a table of random numbers. All *Ss* were selected from introductory psychology courses and received points toward their grades for participation.

Results

Table 1 presents the mean number of correct recalls as a function of type of cue, type of recall, and strength of relation of cue to target. An analysis of variance of these data indicated that type of recall, $F(1, 76) = 94.61, p < .01$; strength of cue, $F(1, 76) = 22.93, p < .01$; and the Type of Recall × Strength of Cue interaction, $F(1, 76) = 21.40, p < .01$, were the only significant sources of variance. Type of cue and all other interactions were not reliable. When recall was free, an average of 4.60 items were recalled in the strong-cue (high frequency) condition, and an average of 4.55 items were recalled in the weak-cue (low frequency) condition. When recall was cued, an average of 9.10 items were recalled when cues were strong, and an average of 6.22 items were recalled when cues were weak. Fisher's least significant difference for this interaction was .87. Thus, when recall was free, there were no differences between the strong- and weak-cue conditions, i.e., word frequency had no reliable effects. When recall was cued, significantly more items were recalled when strong as compared to when weak cues were provided. Furthermore, comparison of recall performance in the weak-cue condition to the free-recall conditions indicated that weak cues significantly facilitated recall compared with no cues at all. Thus, recall was highest when strong cues were provided, intermediate when weak cues were provided, and poorest when no retrieval aids were presented. The facilitating effects obtained with weak cues contrast with the inhibiting effects obtained with comparable cues used by Thompson and Tulving (1970).

Discussion

When set size and a priori strength of relation of cue to target have been equated, synonyms and rhymes are apparently equally effective as extralist retrieval aids. This equivalency is obtained at both strong and weak levels of associative strength. Therefore, cuing with either semantic or sensory attributes can provide equally effective access to the coded representations of target words primed in the context of a rapidly presented list of unrelated items. Presumably, the two types of cues are effective either because they provide independent access routes to two different representations of the target word, one based on sensory attributes and one based on semantic attributes, or because they provide access to a multifeatured representation that contains both types of information. Irrespective of the correctness of either of these alternatives, the primary implication of the results of this experiment is that the sensory attributes of a word may be as functionally important in its representation as are its semantic attributes.

These results also carry implications for two theories concerning extralist cuing effects, the encoding specificity principle (Tulving & Thompson, 1973) and the generation–recognition models (Anderson & Bower, 1972; Bahrick, 1970). According to the encoding specificity principle, the effectiveness of an extralist cue is completely determined by what is encoded while the target items are being studied. A retrieval cue cannot be effective unless the target is specifically encoded with respect to that cue at the time of its storage. The generation–recognition models assume that the extralist cue serves to generate relevant response alternatives and that recognition tests are applied to each item. Items meeting the criteria of acceptability are produced as overt responses. These models make no explicit assumptions concerning the relation between the effectiveness of the extralist cue and the manner of storage of the target item. However, most of them assume that words are represented in memory as lists or collections of features that specify their sound, meaning, and other attributes and, presumably, most might easily incorporate the notion that the representation of a word might be modified when presented with a context word that primes a specific attribute. Thus, at least in general orientation, the theories are similar in many respects.

To account for the facilitating effects of cuing in this study, the encoding specificity principle would have to assume that both semantic and sensory features of the target words were primed during the encoding phase of the task. False recognitions obtained by using synonym distractors in a recognition memory paradigm attest to the reasonableness of the assumption that meaning attributes are primed during the presentation of a list of unrelated words (e.g., Anisfeld & Knapp, 1968). Furthermore, false recognition and transfer data using homophones are consistent with the assumption that sensory attributes also are primed in this situation (Nelson & Davis, 1972), and therefore, extralist cuing effects obtained with these stimuli (Light, 1972) can be interpreted as being compatible with this principle. Thus, synonyms and rhymes were presumably effective cues because they provided sufficient redintegrative information about their respective targets. However, although this interpretation accounts for the cuing effects per se, it fails to explain why differences were obtained between strong and weak rhyme cues. Words at either level provide the same degree of overlap of sensory features and, therefore, in contrast to synonym cues, there should have been no strength effect associated with these cues. This strength effect might be explained by the assumption that, given the cue, *S*s simply guessed the first rhyme that came to mind. This possibility would account for some portion of the cuing effect associated with strong [illegible]. (Bahrick, 1969). However, simple guessing would appear inadequate as an explanation for the cuing effect associated with weak cues since, if *S*s were saying the first word that occurred to them, nearly all of their responses would have been intrusions. Alternatively, the strength effect might be explained by assuming that, in cued recall, the retrieval aid acts to initiate a search through items sharing features with the cue word and, as items are generated, recognition checks are performed (Anderson & Bower, 1972; Bahrick, 1970). If it can be assumed that words associated with each type of cue are generated hierarchically, then the chances of producing a list word are greater when extralist cues serve as cues for responses that are high in the hierarchy (strong cues) than for those low in the hierarchy (weak cues). This explanation for the facilitating effects of cuing incorporates the major assumptions of both the encoding specificity hypothesis and the generation–recognition models.

RHYTHM IS PROCESSED BY THE SPEECH HEMISPHERE[1]

GEORGE M. ROBINSON[2] AND DEBORAH JO SOLOMON

Duke University

Following Lashley and Neisser, models of speech cognition frequently stress a rhythmic organizing principle and would predict that speech processing is intimately related to the processing of rhythmic patterns. However, in agreement with clinical data, dichotic listening studies establish that, while speech stimuli are processed by the left hemisphere, other nonspeech auditory stimuli are processed by the right. Challenging this distinction, the present study shows that nonspeech rhythmic patterns carrying no phonetic information are processed by the same hemisphere as speech. Twenty-four *Ss* listened to 30 dichotic pairs of rhythmic pure-tone patterns. In a counterbalanced, forced-choice recognition task, they were able to correctly identify the pattern heard in the right ear significantly more often than the left. The results suggest that since rhythmic patterns are the only nonspeech auditory stimuli to share the processing of the left hemisphere with speech, models involving rhythmic organization in speech cognition are to be encouraged. Since both speech and rhythm require hierarchical organization, it is likely that the left hemisphere is better able to process hierarchically.

Lashley's (1951) classic paper focused attention on the problems of organization in speech cognition. He proposed that the temporal order of the elements of speech results from an underlying hierarchical structure. The regular appearance of a series of elements with respect to time has recently been described as a rhythmic phenomenon.

> One way to think of the effect of rhythm is that it may provide a set of reference points to which digits and words can be attached. . . . A rhythmic pattern is a structure which serves as a support, an integrator and a series of cues for the words to be remembered [Neisser, 1967, pp. 223, 235].

In a recent review, Martin (1972) presented "a good deal of evidence that rhythmic patterning carries a heavy information load in ordinary connected speech [p. 500]."

In the past decade, several converging lines of research have supported and refined the classical notion that language functions are primarily mediated by the left cerebral hemisphere. Such hemispheric specialization is supported by studies on patients with unilateral lesions and excisions (e.g., Milner, 1971) and cerebral commisurotomy (e.g., Milner, Taylor, & Sperry, 1968). For normal *Ss*, the asymmetries found using the dichotic listening technique, in which different stimuli are presented simultaneously, one to each ear, have closely paralleled the clinical studies. Speech material entering the right ear is processed more effectively, while the opposite is true for nonspeech material (Kimura, 1973; Studdert-Kennedy & Shankweiler, 1970). The resulting conclusion that contralateral auditory pathways are stronger than ipsilateral ones is independently supported by electrophysiological evidence (e.g., Rosenzweig, 1951). Thus, the dichotic listening technique has become a tool for investigating hemispheric specialization.

Given the well-established laterality of speech functions, theoretical models that involve rhythmic organization in speech processing would predict that the hemisphere that is more effective in processing speech will also be the more effective hemisphere for rhythm. Since a wide variety of nonspeech auditory stimuli, including music, were demonstrated to be processed better by the right hemisphere (Dee, 1971; Gordon, 1970; Kimura, 1964;

[1] Thank you Charles W. White and John S. [illegible] Health Service Grant 1-R03-MH21981-01 supported the research.

Milner, 1962; Spellacy, 1970), such a prediction is far from obvious. In fact, both Milner and Spellacy, expecting the right hemisphere to be superior, tested for laterality of rhythm but found no significant effect.

Halperin, Nachshon, and Carmon (1973) pointed out, however, that the speech vs. nonspeech distinction is no longer adequate to describe hemispheric specialization for auditory stimuli. Their *Ss* were able to report the order of 3 broad-band noises heard in the right ear more accurately than in the left when the frequency and bandwidth or pulse durations included 1 or 2 changes. For noises without these changes, the left ear was superior. A related finding is the one by Carmon and Nachshon (1971) that left-hemisphere lesions impair the ability to correctly report the order of a series of sounds and colored lights. Halperin et al. concluded that these findings suggest

> that the left hemisphere specializes in the processing of temporal patterns of stimuli and that perception of verbal stimuli might be associated with sequential analysis of acoustic stimuli [p. 49].

Some cautions should be observed in interpreting the results of Halperin et al. (1973). The frequency shifts and bandwidth changes in the noises used in their first study may have directly involved the phonetic analyzing ability of the speech hemisphere. Thus, instead of attributing the increasing dominance of the right ear to increasing complexity of the temporal pattern, the shift may have occurred because changes in the spectrum were actually encoded in a way similar to speech encoding. Their second experiment, using changes in the durations of 3 noise bursts, comes much closer to isolating temporal complexity as the factor responsible for shifting dominance from the right to the left hemisphere. It may be, however, that the abrupt onset and offset of the broad-band noises were not so unlike speech sounds. In fact, their data do not show that the right hemisphere was dominant when there were zero duration changes.

The following experiment attempted to directly investigate the hypothesis that complex nonspeech temporal patterns containing no phonetic information (rhythms) are processed by the speech hemisphere.

Method

Subjects. Twenty-four Duke University students with normal hearing were unobtrusively screened to eliminate left-handers by noting which hand they used to sign their names. After the listening task, *Ss* were further examined for handedness. None were ambiguous cases. The *Ss* were volunteers without any knowledge of the purpose of the study. None were familiar with Morse code.

Stimuli and procedure. Each rhythm consisted of a "refrain" repeated 3 times with a 50-msec. interval. Each refrain consisted of a random series of 4 7 short (50-msec.) and long (150-msec.) 900-Hz. sinusoidal pulses separated by 50 msec. The durations were chosen so that both the short and long pulses with their interpulse intervals would fall well within the range of spoken syllable durations. Each of the 30 trials consisted of a dichotic pair of rhythms followed by a random series of 4 individual recognition test rhythms, binaurally presented: the 2 components of the dichotic pair and 2 new ones. These 4 recognition test rhythms were separated from the dichotic rhythm and from each other by 4 sec., with a 10-sec. intertrial interval. Within each trial, all 6 rhythms had identical durations. The components of the dichotic pair began and ended simultaneously.

The test materials were generated by a PDP-8I. computer, recorded on a Revox A77 stereo tape recorder and played through Koss PRO-4A earphones at 60-db. SPL.

Each *S* first balanced the 2 channels for a binaural series of regular pulses so that the sound appeared to be centered in his head. The *Ss* then listened to the test materials in 1 of 4 conditions: counterbalanced by interchanging left and right channels of the tape and interchanging the 2 half blocks of 15 trials. The *Ss* were required in a forced-choice paradigm to mark 2 of a row of 4 boxes to indicate which 2 of the 4 recognition choices they believed to be part of the dichotic pair. No letters or numerals appeared anywhere on the coding sheets.

Results

Table 1 shows the number and percentage of correct identifications out of 30 trials for the right and left ears of each *S*. The right-ear scores were significantly better: $t = 3.01$, $p < .01$, 2-tailed test. The scores for each ear were both better than chance: for the right ear, $t = 6.45$, $p < .001$, and for the left ear, $t = 2.87$, $p < .01$, 2-tailed tests.

Discussion

The results show that rhythmic patterns unlike other nonspeech auditory stimuli, are

processed better by the same hemisphere that is dominant for speech stimuli. This study supports the heuristic discussions of Lashley (1951) and Neisser (1967). The results confirm the suggestion by Halperin et al. (1973) that temporal patterns as well as speech stimuli are processed by the left hemisphere. Because rhythm is the only nonspeech auditory feature found to be processed by the speech hemisphere, models of speech cognition based on rhythmic organization are to be encouraged.

Because the rhythms used in the present experiment were moderately complex, rapid, and repeated 3 times, it is likely that they were processed hierarchically in the manner described by Lashley (1951) and Neisser (1967). The interested reader will find a discussion of how the details of the hierarchic structures underlying rhythmic patterns might be organized in Martin (1972). It is probable that the left hemisphere is dominant for both nonspeech rhythms and speech stimuli because it is better able to do the hierarchical processing they both require.

The dichotic listening technique demonstrates directly only a relationship between the performance of one ear and handedness. Two inferences permit conclusions about whether or not a particular stimulus is processed better by the speech hemisphere. The first was discussed in the introduction, that is, that contralateral auditory connections are stronger than ipsilateral ones. In this study, material entering the right ear was processed (mainly) by the left hemisphere. The second inference is that right-handed *Ss* do their speech processing with the left hemisphere. Branch, Milner, and Rasmussen (1964), by comparing the effect on speech of injecting sodium amytal into first one and then the other of their *Ss*' carotid arteries, determined that 90% of right-handers and 60% of left-handers have their speech functions mediated by the left hemisphere.

On the assumption that the hypothesis is correct, we should not be surprised that our data show (as do other dichotic studies) a few *Ss* to have higher scores for their left ears. Although it is possible that this is a major source of variance, there is no independent means to assess it within this study. While the distribution tends to be bimodal, the tendency is not significant.

Halperin et al. (1973) asked their *Ss* to name the noises in the order they appeared. In our study, the coding sheet was deliberately kept free of language-related material to avoid biasing the data by "priming" the left hemisphere. The spatial array used would, if anything, invite right-hemisphere processing. In addition, the recognition test rhythms for the left and right ears appeared in random order. These procedures avoid the bias claimed by theories which attribute the dichotic listening effect to differences in the order of recall, claiming a greater short-term memory loss for material played to the left ear (e.g., Inglis, 1965). Such caution may not be necessary. Bryden (1967) reviewed the several explanations for dichotic listening asymmetry and concluded that Kimura's (1961) theory attributing the asymmetry to perceptual differences is the only one that is consistent with all experimental results.

PERFORMANCE DURING CONTINUOUS AND INTERMITTENT NOISE AND WEARING EAR PROTECTION

L. R. HARTLEY[1]

Medical Research Council, Applied Psychology Unit, Cambridge, England

The *S*s were tested on the 5-Choice Test of Serial Reaction for 40 min. in intermittent and continuous broad band noise (Experiment I) and while wearing ear protection in continuous noise (Experiment II). Gaps in performance during intermittent noise were approximately half those in continuous noise. Errors were affected equally adversely by both intermittent and continuous noise. Ear protection interacted with noise and time-on-task, reducing gaps in noise in the first half but not the second half of the test. Results are consistent with the theory that there are 2 different effects of noise. The improvement of performance when noise was intermittent was attributed to a reduction in the monotony experienced during a long exposure to continuous noise. The value of ear protection was attributed to a reduction in perceived loudness and prevention of temporary arousal following the onset of noise.

One recent interpretation of the adverse effect of noise was that it functioned as a distractor (Broadbent, 1958) causing impairment in tasks that had characteristics rendering them sensitive to distractions. However, evidence against this view arose from the beneficial effect of noise on performance of the 5-Choice Test of Serial Reaction following sleep loss (Corcoran, 1962; Wilkinson, 1963) when both conditions, applied separately, caused impairment. In addition, incentive augmented the adverse effect of noise as compared to its normal beneficial action (Wilkinson, 1963). These results suggested that the adverse effect of noise was mediated by an increase in arousal which offset the effect of sleeplessness but which was further enhanced by incentive. One difficulty with this view was that the arousing effect of noise, and consequent change in performance, would probably be greatest when the noise was first introduced, but the observed adverse effect generally increased with duration of noise exposure, independent of time-on-task (Hartley, 1973). The results of Hartley's experiment, which also involved the 5-Choice Test of Serial Reaction, ruled out the possibility that the adverse effect of noise was dependent on prior performance of the test, since noise introduced after many minutes of performance had virtually no effect. Consequently, the appearance of the adverse effect of noise after exposure was attributed to an accumulating function of the noise.

This conclusion was substantiated by performance on a Stroop color interference test in noise (Hartley & Adams, 1974). Interference was increased by 20-min. prior exposure to noise as compared to quiet. An additional finding of interest in Hartley and Adams' experiment (also, Houston, 1969; Houston & Jones, 1967; O'Malley & Poplawsky, 1971) was that interference was reduced if noise was given only during performance and not also prior to it, suggesting different effects of short and long noise exposures. There is some evidence that reduced interference accompanies a raised level of arousal. Agnew and Agnew (1963) and Tecce and Happ (1964), using threat of electric shock, and Callaway (1959), using amphetamine, obtained results indicating reduced interference under these conditions; a short exposure to noise may thus be arousing. The explanation of the increase in interference following a long exposure could be in similar terms. The increase

Note. Abbreviations: Q = quiet, CN = continuous noise, and IN = intermittent noise.

may indicate some form of reduced arousal, which would be consistent with results indicating increased interference following amylobarbital (Callaway, 1959) and hyoscine (Ostfeld & Arugete, 1962). The initial arousing effect of noise could be attributed to the onset of the intense stimulation to which *S* later adapted. The later reduction in arousal could be attributed to the monotony and sensory isolation accompanying the longer exposure to noise.

To test these suggestions, 2 experiments were considered. If the later part of the adverse effect of continuous noise is due to the monotony and lack of variability, then presenting the noise intermittently should reduce this part of the adverse effect. Secondly, if the adverse reaction following the onset of noise is due to its loudness or intensity, then wearing ear protection should be beneficial at the start of the exposure. Wearing ear protection should not be of any further benefit when adaptation to loudness has occurred and the adverse effect of monotony predominates.

EXPERIMENT I: INTERMITTENT AND CONTINUOUS NOISE

Performance of *S*s on the 5-Choice Test of Serial Reaction was compared during quiet (Q), intermittent noise (IN), and continuous noise (CN) conditions.

Method

Subjects. There were 2 groups of *S*s. Each group consisted of 18 housewives and professional men, ranging 18–45 yr. of age and totaling 36 *S*s in all. All possessed normal hearing (i.e., an absence of hearing loss greater than 35 db. in one ear or 30 db. in both ears at any of 7 test frequencies covering the audible range).

Apparatus. Performance was measured with Leonard's (1959) 5-choice serial reaction apparatus, which requires that *S* be seated before a display consisting of 5 neon light sources arranged in a pentagon, one of which is always illuminated. Arranged on a horizontal response board are 5 brass disks corresponding to the light sources. The *S* is required to tap the disk appropriate to the lamp illuminated. The light promptly extinguishes and another is lit. The *S* works as quickly and accurately as possible, scoring as many corrects and as few errors as possible. The third score consists of pauses or gaps of 1½ sec. between tapping one disk and tapping the next. The *S*s in this study performed with and without knowledge of their results (KR and NKR). Immediate knowledge of gaps and errors was furnished by a brief illumination of a lamp on the left of the response board if an error was made, and by a brief illumination of a lamp on the right of the board if a gap was made. Knowledge of the number of correct responses made in each test was provided at the end of each test.

Procedure. Following 40-min. preliminary practice on the test, each *S* performed the test for 40 min. in Q at 70 db., CN at 95 db., and IN at 70 and 95 db., measured on the C scale of the sound level meter. Although *S*s were tested at different times of day, each *S* was given 1 treatment per day at the same time of day. The order of presentation of the 3 treatments was determined by counterbalanced Latin squares for each group of 18 *S*s. One group of 18 *S*s performed the test with KR and the other group performed with NKR. The former group received brief flashes from the indicator lights at the side of the response board whenever a gap or error was made, and they were also shown the total number of gaps, corrects, and errors made by each *S* in each test in a chart. Broad-band noise having equal energy per octave was used in all conditions. The IN condition consisted of alternate presentations of 95 and 70 db. The mean duration of the 70-db. interval was 1.5 sec., with a range .3–2.7 sec. The mean duration of the 95-db. interval was 3 sec., with a range .6–5.4 sec.

Results

Performance was scored in 10-min. blocks for each 40-min. test. Table 1

TABLE 2

MEAN NUMBER OF ERRORS IN EACH 10-MIN. BLOCK UNDER EACH [illegible]

Condition	Knowledge of results					No knowl[illegible]				
	Block 1	Block 2	Block 3	Block 4	Total	Block 1	Block 2	Block 3	Block 4	Total
Q	3.17	4.94	4.17	3.61	15.89	3.72	4.11	5.44	6.72	19.99
IN	5.11	5.83	4.22	4.89	20.05	5.39	7.72	10.00	8.50	31.61
CN	3.33	6.50	6.39	5.89	22.11	6.89	5.94	7.17	9.44	29.44

Note. Abbreviations: Q = quiet, CN = continuous noise, and IN = intermittent noise.

shows mean gaps and Table 2 shows mean errors for KR and NKR for each experimental condition. These scores were analyzed using analysis of variance as described by Winer (1962, p. 329) following arc sine square root transformation of the data. Considering gaps, there was no difference between the KR and NKR groups, F (1, 34) = .86, $p > .10$. Knowledge of results did not interact with any of the other treatments, and hence results from the 2 groups were pooled together for further analysis. There was a large adverse effect of the noise conditions upon the number of gaps made, F (2, 68) = 21.92, $p < .001$. Mean number of gaps in Q was 15.6, and in IN, 25.8. This increase ($p < .01$) was very similar to the increase in gaps in CN ($\bar{X}$ gaps = 35.5) as compared to IN ($p < .01$). The noise conditions did not interact with any other factor.

Considering errors, there was no overall reliable difference between KR and NKR, but more errors were made in the last 10 min. of the test with no knowledge than with knowledge, F (1, 272) = 3.91, $p < .05$. Pooling the NR and NKR conditions together, the noise conditions had a reliable effect upon errors, F (2, 68) = 4.49, $p < .025$. Compared to Q, the mean increase of 7.89 errors in IN ($p < 0.05$) was virtually identical to the mean increase of 7.84 errors in CN ($p < .05$). These results indicate that IN caused approximately half of the impairment apparent in the CN condition in terms of gaps, but that the effect of the 2 conditions upon errors was highly similar.

EXPERIMENT II: EAR PROTECTION

The *S*s were tested on the 5-Choice Test of Serial Reaction in Q and noise (N), both with and without wearing ear protection.

Method

Subjects. The *S*s were 16 housewives and professional men, ranging 18–45 yr. of age. All possessed normal hearing (i.e., an absence of hearing loss greater than 35-db. in one ear or 30 db. in both ears at any of 7 test frequencies covering the audible range).

Procedure. Following 40-min. preliminary practice on the 5-Choice Test of Serial Reaction, each *S* performed the test for 40 min. in continuous Q and continuous N, both with and without ear protection. The order of presentation of the 4 treatments was determined by counterbalanced Latin squares (Williams, 1949). Broad-band noise having equal energy per octave was used throughout. In the N conditions it was presented at 95 db., and in the Q conditions, at 70 db., measured on the C scale. Each *S* was given one treatment per day at the same time of day, although *S*s were not all tested at the same time of day.

The ear protection was provided by Amplivox Sonogard ear defenders, specified as providing a substantially linear attentuation with frequency over the audible range (20 db. at 200 Hz., 30 db. at 500 Hz., 38 db. at 1 and 2 kHz., and 45 db. at 4 kHz., measured at one-fifth octave bands and the American Standard Method for the Measurement of the Real Ear Attenuation of Ear Protection at Threshold, ASAZ-24.22-1957).

Results

Performance was scored in 10-min. blocks for each 40-min. test. Table 3 shows mean gaps and Table 4 mean errors for each experimental condition. These scores were analyzed using analysis of variance with repeated measures on each factor, following arc sine square root transformation of the data. Error terms in the F ratios utilized interactions with *S*s.

Considering gaps, as Table 3 shows, there was an overall, adverse effect of N

TABLE 3

Mean Gaps in Each 10-Min. Block under Each Condition

Condition	Block 1	Block 2	Block 3	Block 4	Total
Q	2.57	5.13	6.69	7.31	21.70
Q + ED	4.07	6.57	8.25	7.50	26.39
N	5.06	11.12	10.44	8.94	35.56
N + ED	3.57	6.50	9.81	9.88	29.76

Note. Abbreviations: Q = quiet, N = noise, and ED = ear defenders.

as compared to Q, $F\ (1,\ 15) = 10.88$, $p < .01$. Overall, ear defenders had no effect, $F\ (1,\ 15) = .05$, $p > .10$, but ear defenders interacted with Test Blocks × Noise, $F\ (7,\ 105) = 2.12$, $p < .05$. This interaction was mainly due to the fact that in the first 20 min. of the test, when ear defenders were worn, the N as compared to the Q condition had no adverse effect at all. Without ear defenders, N as compared to Q had a large adverse effect ($p < .02$), reliably larger than when wearing ear defenders ($p < .02$). In the last 20 min. of the test, this antagonistic Ear Defenders × Noise interaction disappeared ($p > .10$), and the benefit of wearing ear defenders in N as compared to Q was reliably less than in the first half of the test ($p < .05$).

As Table 4 shows, errors were not significantly adversely affected by either noise or ear defenders; since the variables did not interact, their analysis was not pursued. These results indicate that ear defenders greatly reduce the adverse effect of the first 20 min. of the N condition but have little or no effect after this point in terms of gaps. Clearly there would be no point in looking for changes in errors

TABLE 4

Mean Errors in Each 10-Min. Block Under each Condition

Condition	Block 1	Block 2	Block 3	Block 4	Total
Q	2.10	4.67	6.11	5.72	18.60
Q + ED	3.30	5.22	8.80	6.25	23.57
N	2.87	6.10	8.10	5.19	22.26
N + ED	3.45	9.90	9.73	7.97	31.05

Note. Abbreviations: Q = quiet, N = noise, and ED = ear defenders.

if noise and ear defenders had no reliable effects on this score.

Discussion

In general, the pattern of results from both experiments is consistent with the suggestion of 2 rather different effects on the organism of loud noise. In terms of the introductory hypothesis, IN greatly reduced the adverse effect upon gaps, and although interactions between noise conditions and time-on-task were not apparent, it is clear from the means in Table 1 that the beneficial effect of intermittency developed only after the first 10 min. of exposure. In the first block of a test, IN was approximately similar to CN in its adverse effect, but substantially less in the following part of the test. This pattern fits in well with the expectation that any initial adverse effect would, in the main, be due to arousal, but that any later decrement would be due to monotony which would be partially alleviated by intermittency or variability in the noise.

Still considering gaps, the benefit of wearing ear protection appears to be restricted to the first 20 min. of exposure, suggesting that intensity causes the initial adverse effect, which is consistent with the arousal interpretation. Similarly, the absence of any such benefit in the latter half of the test points to an increasing influence of monotony and isolation on performance, unaffected by ear protection.

Although the changes in gaps support the view that there are 2 different effects of noise, the rather similar effects of IN and CN on errors has to be accounted for. The prevailing view of the relationship between gaps and errors has been that they represent opposite points on the speed and error dimension. Performance under stress has often shown a reciprocal relationship between the 2 scores; noise usually increased errors (Broadbent, 1953) but sleep loss increased gaps (Wilkinson, 1963). Increasing arousal was conceived as moving the criterion in a risky direction and vice versa (Broadbent, 1971). Hartley[2] found just such a reciprocal relationship when noise presented over headphones caused more gaps and fewer errors than noise in the free-field condition. On this view, if the effect of the monotony was to reduce arousal, errors would be expected

[2] L. R. Hartley. Comparison of headphone and free-field noise on the Stroop test. In preparation.

to be more numerous in IN as compared to CN, particularly toward the end of the test when IN should have most benefit in opposing the reduction in arousal during the monotony of the CN condition. There is little evidence here that this is the case. Probably the most satisfactory explanation is that IN and CN are broadly similar in their arousing quality, since they have the same intensity, and that the main benefit of intermittency is in reducing the monotony and isolation of continuous noise rather than increasing the level of arousal. This conclusion would rather imply that monotony does not simply oppose arousal. Indeed there may be 2 mechanisms involved in arousal, one of which is affected by monotony and the other of which is affected by loudness or intensity, in this case. Such a view has support from a number of experiments involving the interaction of stresses, including the combined effect of noise and sleeplessness, alcohol and incentive, and personality variables and stresses (Broadbent, 1971).

SHORT REPORTS

RECOGNITION AND RECALL AS A FUNCTION OF INSTRUCTIONAL MANIPULATIONS OF ORGANIZATION[1]

ROBERT M. SCHWARTZ[2] AND MICHAEL S. HUMPHREYS[3]

University of British Columbia, Vancouver, British Columbia, Canada

Recognition and recall were examined as a function of organizational instructions. In Experiment I instructions to group items in input order by using visual imagery produced increased recall but did not increase recognition performance. In Experiment II instructions to rehearse overtly the item being presented produced decreased recall but did not decrease recognition performance. The results were discussed as supportive of a 2-process theory of recognition and recall.

A recent controversy concerns the effect of organization on recognition accuracy. Some studies have demonstrated a facilitative effect (e.g., Jacoby, 1972), and other studies have found no effect (e.g., Bruce & Fagan, 1970). One possible reason for the discrepancy is that the manipulations of organization which have been used are manipulations of the structure of the to-be-presented list; that is, *Ss* in experimental and control conditions have not been presented the same lists in the same presentation order, and thus the effects of organization may be confounded with the effects of the nature of the lists. In order to avoid this possible confounding, in the present experiments, the manipulations used involved instructions about processing the list items. With instructional manipulations, *Ss* in experimental and control conditions could be presented the same lists in the same orders. Also, in addition to recognition tests, recall tests were used. The use of recall tests allows differences in organization to be inferred from differences in order of output and/or differences in recall performances.

Experiment I. In Experiment I *Ss* in experimental conditions were instructed to group the words to be recalled in their input order by using visual imagery. The *Ss* in control conditions were given no special instructions. Insofar as organization includes grouping of items at input, the present instructions can be interpreted as manipulations of organization (see, e.g., Bower, Lesgold, & Tieman, 1969).

The stimuli were 120 concrete ($C > 5.50$) and frequent ($F > 20$) nouns chosen randomly from the Paivio, Yuille, and Madigan (1968) norms. Of these 120 nouns, 60 were randomly chosen to be on the list to be presented to all of the *Ss*; the other 60 nouns served as distractors for the *Ss* in the recognition conditions.

Each of the 60 nouns on the list to be presented was mounted as a slide. The slides were then randomly arranged to determine order of presentation for all of the *Ss*. Presentation was via a Kodak Carousel projector (model 850) with an external timer. Answer sheets were prepared for *Ss* in the recognition and recall conditions. For the recall conditions, the answer sheets contained 2 columns of 30 blank lines. At the top of the answer sheet was an instruction asking *S* to write down, in any order he desired, as many words as he could remember from the list he had been presented. For the recognition conditions, the 60 presentation and 60 distractor items were randomly arranged and typed in 4 columns of 30 items each. The instruction at the top of the answer sheet asked *S* to put a line through all of the words he thought were contained in the list he had been presented.

A 2 × 2 factorial design, with both factors varying between groups of *Ss*, was used. The first factor was whether the *S* was given standard learning instructions or instructions to group items. The second factor was whether *S* was given a recognition or recall test. The 4 resulting conditions were labeled standard-recall, standard-recognition, grouping-recall, and grouping-recognition.

The *Ss* were 57 volunteers from introductory psychology classes. They were tested in groups of 1-3 with all *Ss* in a group receiving the same instructional manipulation. There were 14 *Ss* in each condition except the standard-recognition condition, which had 15 *Ss*.

The *Ss* in all conditions were told that they would be presented with 60 nouns that would be familiar to them. Upon seeing each noun, they were to try to remember it as best they could. They were also told that after seeing all 60 nouns, they would be tested on how well they remembered them, although they were not informed of the nature of the test.

The *Ss* in the grouping conditions were given additional instructions about learning the list. These instructions told the *Ss* to group the words in input order by using visual imagery. They were to use 5 or fewer items in each group, and they were given an example of how to group a set of items.

If the *Ss* had no questions, the list was then presented. Rate of presentation was 4 sec. per item.

Immediately following presentation and according to their conditions assignment, the *S*s were handed a recognition or a recall answer sheet. The *S*s were told that the instructions were at the top of the sheet and that they would have 4 min. to complete the task.

Following Kintsch (1968), the score for *S*s in all conditions was the difference between the number of correct and the number of incorrect responses. Means for these scores were 45.29, 42.27, 20.71, and 16.29 for the grouping–recognition, standard–recognition, grouping–recall, and standard–recall conditions, respectively. Each *S*'s score was transformed using a square root transformation, and the transformed data were subjected to analysis of variance. The results of the analysis indicated that the recognition scores were higher than the recall scores, $F(1, 53) = 191.60, p < .001$. The grouping instruction resulted in significantly improved recall performance, $F(1, 53) = 4.30, p < .05$, but not significantly improved recognition performance, $F < 1$.

A second analysis was performed on the data of the recall conditions to assure that the superiority of the grouping–recall condition could be attributed to the instructional manipulation. As the *S*s in the grouping conditions were told to form groups of 5 words according to input order, it was predicted that the protocols of the *S*s in the grouping–recall condition would show more clustering according to input order than those of the *S*s in the standard–recall condition. To test this prediction, the presentation list was treated as if it contained 12 categories of 5 words each. Each category was a group of 5 words presented adjacently, starting with Words 1–5, 6–10, etc. Then each *S*'s recall protocol was analyzed according to Frankel and Cole's (1971) adaptation of the runs test, and a z score was determined for each *S*. The mean z scores for the grouping–recall and standard–recall conditions were 3.53 and 1.93, respectively. Both means indicated significantly more clustering according to input order than would be expected by chance, $z = 13.20$ for grouping–recall and $z = 7.21$ for standard–recall, both $ps < .001$. However, the grouping–recall condition showed significantly more clustering according to input order than the standard–recall condition, $z = 4.24, p < .001$. Thus, it can be concluded that the grouping–recall *S*s were organizing in accordance with the instructions.

Experiment II. Rundus (1970) had *S*s rehearse aloud during list presentation and found that items that had been rehearsed together were likely to be recalled together. Thus, if *S* could be prevented from rehearsing items together, it is possible that his level of organization would be depressed. In Experiment II *S*s in the experimental groups were required to rehearse aloud the item being presented, thus reducing the opportunity to rehearse 2 or more items together (see, e.g., Fischler, Rundus, & Atkinson, 1970). The *S*s in the control groups were not required to rehearse aloud and were not asked to use any particular rehearsal strategy.

The stimuli were 480 words, 3 from each of 160 conceptual categories in the Battig and Montague (1969) and Shapiro and Palermo (1969) norms. The words were high associates to the category names. One word from each category was chosen to be on the lists to be presented; the remaining 2 words from each category served as distractors for the recognition conditions.

The 160 words to be presented were typed on 3×5 in. cards. The cards were then randomly divided into 4 lists of 40 words each. Within each list, the cards were randomly arranged to form a presentation order for that list.

Recall answer sheets were prepared in the same manner as in Experiment I, except there were only 20 blank lines in each of 2 columns. Four separate recognition answer sheets were prepared, one for each of the 4 lists. A recognition answer sheet for a given list contained a random arrangement of the 40 words on that list and the 2 distractor words from the categories of those 40 words. The recognition answer sheets were arranged in 4 columns of 30 words each, and the instructions at the top of the recognition answer sheets were the same as those used in Experiment I.

Like Experiment I, Experiment II could be conceptualized as a 2×2 factorial design. The first factor was rehearsal conditions, silent or overt, and the second factor was type of test, recognition or recall. Thus, there were 4 conditions which were labeled silent–recognition, overt–recognition, silent–recall, and overt–recall.

However, unlike Experiment I, the 4 conditions were varied within *S*s so that each *S* served in each of the 4 conditions. Each *S* was presented each of the 4 lists and served in one of the 4 conditions on that list. To counterbalance order of conditions and presentations of lists, a Greco-Latin square design was used. The Greco-Latin square resulted in 4 arrangements of lists and conditions for presentation.

The *S*s were 20 volunteers from introductory psychology classes. Five *S*s served in each of the 4 Greco-Latin square arrangements. The *S*s were tested individually.

Each *S* was read 2 sets of instructions, one set before he served in each of the 2 rehearsal conditions. In neither set of instructions was *S* informed of the type of test which would follow the presentation of the list.

For both sets of instructions, *S* was told that he would be presented 40 words that were familiar to him. He was shown a deck of cards on which one of the lists of words was typed and was told that he would be presented the list, one word at a time, by *E* turning over the cards. The *S* was told that a card would be turned over every 5 sec. and that he should try to remember as many words as he could. In addition, for the silent rehearsal conditions, *S* was told he could study the words in any way that he wished. For the overt rehearsal conditions, *S* was told to repeat aloud the word he was currently being presented. He was to repeat the word throughout the 5 sec. that he saw it and repeat it at a 1-sec. rate.

After S was read the set of instructions appropriate for his first 2 lists, the first list was presented. The click of an electric timer paced E's presentation. Immediately following the completion of first-list presentation, S was handed an answer sheet appropriate to the condition and list under which he was being tested. He was given 2 min. to complete the answer sheet. Then he was told that he would be presented another list and he was to rehearse this list in the same way as he rehearsed the first list. Following the test of the second list, S was read instructions appropriate for rehearsal of the third and fourth lists. The third and fourth lists were then presented and tested.

The *Ss*' protocols were scored as in Experiment I. Means for these scores were 27.60, 28.60, 12.75, and 10.00 for the silent–recognition, overt–recognition, silent–recall, and overt–recall conditions, respectively. Again the data were transformed using a square root transformation, and analysis of variance was used to examine the transformed data. The results of this analysis indicated that recognition scores were higher than recall scores, $F\ (1, 48) = 905.04$, $p < .001$. The instruction to rehearse overtly resulted in a significant decrement in recall performance, $F\ (1, 48) = 18.57$, $p < .001$, but no significant decrement in recognition performance, $F < 1$. Thus, Experiment II has replicated Experiment I by showing an effect of organization in recall but not in recognition.

Discussion. The data from the 2 experiments clearly suggest that the instructional manipulations affected recall but not recognition performance. As the present experiments manipulated organization without changing list members or order of presentation, the results are an alternative form of evidence that organization does not affect recognition accuracy.

The present data are also supportive of a 2-process theory of recognition and recall, such as that offered by Kintsch (1970). A 2-process theory includes the argument that there are qualitative, rather than quantitative, differences between recognition and recall. One-process theories, such as the assertion that the superiority of recognition as compared to recall performance lies in the greater "strength" necessary for recall of those items, predict that experimental manipulations would have the same effect on recognition and recall. The present data, which showed that instructional manipulations of organization affected recall but not recognition performances, are an example of the type of data which Kintsch (1970) cites as support for his 2-process theory.

CONCRETENESS OF PEG WORDS IN TWO MNEMONIC SYSTEMS

DENNIS J. DELPRATO[1] AND ELIZABETH J. BAKER

Eastern Michigan University

Two experiments provide evidence that (*a*) concreteness of peg words facilitates recall in the one–bun mnemonic system as well as in a paired-associate (PA) system, and (*b*) the one–bun system, in which peg-word retrieval cues are not explicitly presented at study and recall, and the PA system, in which peg words are explicitly presented, yield comparable results with respect to the effect of peg-word concreteness on recall. These findings are consistent with current views of imagery.

The one–bun (Bugelski, Kidd, & Segmen, 1968) and paired-associate (PA) techniques (Wood, 1967) have been used to study the role of imagery in verbal learning and memory. In the former approach, *S* first memorizes a list of rhyming numbers and peg words (e.g., ONE–BUN, TWO–SHOE). Once the rhyme list has been learned, *S* is instructed to learn new words in ordinal position of presentation by associating them with images evoked by the corresponding rhyming peg words. The PA mnemonic system involves presenting *S* with the list of peg words during study and recall trials; as with the one–bun system, *S* is instructed to integrate to-be-learned words with images aroused by the pegs. Both techniques are basically typical PA tasks on which response terms (to-be-learned words) are learned by associating them with stimulus terms (pegs). The approaches differ because the peg words are explicitly supplied by *E* in the PA technique, whereas they must be memorized by *S* in the one–bun technique.

According to contemporary views of imagery and the conceptual-peg hypothesis (Paivio, 1969), the higher the concreteness of stimulus items, the [illegible] function as mediators of associative learning. Given this basic theory, the empirical evidence of the capacity of concrete nouns to readily evoke images, and the documented facilitative effect of concreteness with the PA system (Paivio, 1969), concreteness of pegs in the one–bun mnemonic [illegible]

This latter finding led Paivio (1968, 1969) to [illegible] that the effect of peg concreteness in the one–bun system is attenuated because the pegs are [illegible] it; with instructions to use imagery, abstract [illegible] imagery as concrete pegs. The situation with the one–bun system is presumed to differ from that with the PA system, which consistently shows concreteness effects, due to the implicit nature of the pegs (retrieval cues) in the former and their explicit nature in the latter system. In other words, Paivio assumes a fundamental difference in the functional effectiveness of identical pegs that is based upon their nominal presence or absence, even though *S* can demonstrate they are in memory by his recall of the pegs. This assumption is not supported by experiments showing that well-learned retrieval cues can be just as effective in mediating recall when physically absent as when physically present (e.g., Delprato & Garskof, 1969); these findings are not surprising if activation of the memory trace is critically dependent upon *S*'s functional encoding of the nominal stimulus, since mere external absence of the stimulus should not influence its encoding when it is in memory.

On the basis of considerations such as the above, we submit that it would be more consistent with current imagery and encoding theory if peg concreteness were a significant factor in the one–bun technique than if it were not. Therefore, Experiment I was designed as a partial replication of Paivio's (1968) study.

EXPERIMENT I

Method. The *Ss* were 84 male and female undergraduates.

The concrete and abstract rhymes were identical with those used by Paivio (1968), i.e., ONE–BUN, TWO–SHOE, etc., and ONE–FUN, TWO–TRUE, etc., respectively.

Two 10-item word lists (A and B) to be recalled were composed of nouns from the Paivio, Yuille, and Madigan (1968) norms. The mean imagery ratings, associative meaningfulness, and Thorndike-Lorge frequencies for Lists A (first value of each pair) and B (second value) were 6.31, 6.30; 5.98, 5.98; 27.8, 22.7, respectively.

The *Ss* were individually tested and were randomly assigned to 1 of 3 conditions (one–bun, one–fun, and control), with 28 *Ss* in each. All *Ss* were given a single study and recall trial on each [illegible]. Half of the *Ss* in each group received List A first, the other half received List B first. The instructions for the first list did not include mnemonic instructions and were identical for all *Ss*. The *Ss* were read the list of 10 words at a 4-sec. rate, with the words preceded by the numerals 1–10. After the list was read once, the numerals alone were read in a prepared random

[1] Requests for reprints should be sent to Dennis J. Delprato, Department of Psychology, Eastern Michigan University, Ypsilanti, Michigan 48197.

order and S was given 10 sec. per numeral to recall the corresponding item. One point was given for each word recalled to the appropriate number.

After S recalled the first list, those who were in the rhyme conditions were told that they were going to go through the same thing again with another list. This time, however, *Ss* were told that an easy technique for learning the 10 words required that they first learn a simple rhyme, then use mental images to picture the object represented by the word in the list in relation to the word that rhymed with the particular number given with the word. The *Ss* were then read the rhyme (abstract or concrete) and tested on it until they could recite it 5 successive times without error. Examples appropriate to the rhyme condition were given. The *Ss* in the control condition did not receive mnemonic instructions between lists. Instead, E engaged S in casual conversation for approximately the same length of time required to give the mnemonic instructions to *Ss* in the experimental conditions.

Results and discussion. The mean recall scores on the first list were 3.89, 3.96, and 4.00 for the control, one-fun, and one-bun conditions, respectively. The means on the second list were 4.96, 5.29, and 6.36 for control, one-fun, and one-bun, respectively. The data were analyzed by a 3×2 (Groups $\times$ Lists) factorial analysis of variance with lists as a within-*Ss* variable. The between-groups effect over both lists was not significant ($F = 1.32$) but the list effect, $F\ (1, 81) = 39.85$, $p < .001$, and the Groups $\times$ List interaction, $F\ (2, 81) = 3.25$, $p < .05$, did reach significance. The significant interaction indicates differential improvement over the 2 lists in the different groups; analysis of the simple main effect of the list variable showed that all 3 groups did improve significantly from the first to the second list, $Fs\ (1, 81) > 4.92$, $p < .05$.

Individual comparisons via Duncan's range test among the group means on each list yielded results consistent with the prediction that peg concreteness is a critical variable in the one-bun technique. The groups were statistically equivalent prior to differential treatment ($p > .05$). On the critical second list, the abstract-peg one-fun rhyme was not more facilitative than the control treatment ($p > .05$). The one-bun group was superior to the control group ($p < .05$) and, in contrast with the results of Paivio (1968), the concrete-peg one-bun rhyme led to significantly higher recall scores than the abstract-peg one-fun rhyme ($p < .05$).

Paivio's (1968) failure to obtain an effect of peg [illegible] questioned by Experiment I), coupled with repeated demonstrations of the effect of this variable with PA learning, suggested to him that the 2 systems produce different results with respect to peg-word concreteness, i.e., the Mnemonic System $\times$ Peg Concreteness interaction. Wood and Bolt (1970) tested this implication with the same materials in the 2 systems and did not find the predicted interaction, i.e., comparable results were found with the 2 systems. However, since they did not find an effect of peg concreteness with either the one-bun or the PA system with their materials, Wood and Bolt's finding of equivalent effects of peg concreteness in the 2 systems is inconclusive in that they did not show the expected effect of concreteness with the PA technique.

Comparable recall differences between lists learned with concrete and abstract pegs in one-bun and PA systems are predicted if functional encoding of retrieval cues is not differentially affected by the mere presence or absence of the nominal stimulus at the time of study and test. While the results of Experiment I indirectly support this prediction, Experiment II was designed to test it directly. Further, the role of peg concreteness in the one-bun system, theoretically important in itself, was again attacked.

Experiment II

Method. The *Ss* were 64 undergraduates of both sexes. Two mnemonic systems (one-bun vs. PA) were factorially combined with 2 levels of peg concreteness (concrete vs. abstract) to form 4 independent conditions ($n = 16$/group).

The materials were identical to those of Experiment I. In the present study, the abstract and concrete peg words became the abstract and concrete stimulus words for the PA conditions, therefore, both stimulus and peg words are referred to as pegs.

All *Ss* were given 2 study and test trials on a single list, with mnemonic instructions prior to the first trial. Half of the *Ss* in each condition received List A and half List B. The study-test procedure on both trials for *Ss* in the one-bun and one-fun conditions was the same as that used with the second list in Experiment I.

The procedure for PA *Ss* was as similar as possible to that of one-bun *Ss*. The PA *Ss* were not required to learn the rhyme, but they were given instructions corresponding to those given to one-bun *Ss* on the use of imagery for study and recall. The E read the peg words to PA *Ss* on study and recall trials in place of the numbers read to one-bun *Ss*. On recall trials, E read PA *Ss* the peg words in a prepared random order (a different order on each trial) that corresponded to the random order in which the number cues were read to one-bun *Ss*.

TABLE 1

Mean Recall Scores, Experiment II

Trial	One bun fun		Paired associate	
	Abstract peg	Concrete peg	Abstract peg	Concrete peg
1	4.50	5.69	4.75	6.31
2	8.06	8.50	6.94	8.75

Results and discussion. The mean number of words correctly recalled to the pegs on each trial by the 4 groups is presented in Table 1. Groups receiving concrete pegs in both mnemonic systems had higher recall scores than groups with abstract pegs. The only significant effects in a Mnemonic System × Peg Concreteness × Trials analysis of variance were those of trials, F (1, 60) = 143.13, $p < .001$, and concreteness, F (1, 60) = 6.11, $p < .025$. The nonsignificant Mnemonic System × Peg Concreteness interaction, F (1, 60) = 1.02, supports our suggestion that the functional encoding of stimulus pegs of varying concreteness would not be differentially affected by their mere nominal presence or absence at the time of study and test.

In conclusion, it appears that peg concreteness is a critical factor in both one–bun and PA mnemonic systems. These findings are consistent with contemporary imagery theory and the conceptual-peg hypothesis (Paivio, 1969).

PROBABILITY OF CONDITIONED RESPONSES AS A FUNCTION OF VARIABLE INTERTRIAL INTERVALS[1]

KARL HABERLANDT,[2] KEVIN C. HAILS, AND ROBERT LEGHORN

Trinity College, Hartford

Rabbits were trained and extinguished in classical eyelid conditioning with variable intertrial intervals. Responding in each rabbit was recorded as a result of the interval immediately preceding a trial. Conditioned responses were more likely in early acquisition and less likely in early extinction when trial $n + 1$ followed trial n by a shorter rather than a longer interval. These results confirm predictions of stimulus fluctuation and 2-store theories of memory which suggest that events experienced on a trial, whether in acquisition or extinction, are more available and generally influence performance more the sooner a subsequent trial is given.

The present experiment examined the probability of conditioned responses (CRs) on trial $n + 1$ as a result of the interval since trial n in light of predictions based on Atkinson and Shiffrin's (1968) memory theory and Estes' (1955a,b) stimulus fluctuation theory. Both theories expect that a CR should be more likely in early acquisition and less likely in early extinction when trial $n + 1$ is preceded by a relatively short rather than a long intertrial interval (ITI). Atkinson and Shiffrin suggested that a CR occurs on trial $n + 1$ when information about the preceding trial is in the short-term store (STS). If the information is not in STS, a search will be made for it in the long-term store (LTS). Early in training, such information is found only in STS, where it decays relatively quickly. Accordingly, whether in acquisition or extinction, S should recall events from trial n better at shorter than at longer ITIs. Similarly, Estes based his prediction on the assumption that stimulus elements of trial n are better available on trial $n + 1$ when the ITI is relatively short, thus allowing little opportunity for stimulus fluctuation.

Estes (1955, pp. 375–376) cautioned that stimulus fluctuation factors may be masked by more transient posttrial processes. Previous work on ITI effects confirmed Estes' caution and showed that brief posttrial processes may depress or enhance subsequent responding temporarily. Prokasy (1965) and Prokasy and Papsdorf (1965) investigated the probability of CRs as a function of the preceding ITI within the context of evaluating opposing predictions from Estes' (1955) theory and Hull's (1951) reactive inhibition concept. The experiments studied the acquisition of eyelid responses in

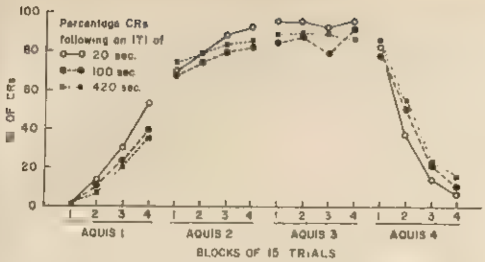

FIGURE 1. Mean percentage of conditioned responses (CRs) following each of 3 intertrial intervals (ITIs) in 3 acquisition sessions and 1 extinction session.

a classical conditioning situation using variable ITIs within *Ss*. Prokasy used ITIs of 2, 4, 6, 8, 10, 12 and 14 sec. in human eyelid conditioning, and Prokasy and Papsdorf used ITIs of 15, 20, 25, 30, 40, and 45 sec. in rabbit eyelid conditioning. Both studies reported that CRs tend to increase with longer ITIs, reflecting the dissipation of reactive inhibition, as Hull had proposed. Inspection of Prokasy's and Prokasy and Papsdorf's data suggests that the probability of CRs increases most between the 2 shortest ITIs, remaining essentially stationary thereafter. Apparently, the response decrement is temporary, and the influence of reactive inhibition decreases or is balanced by stimulus fluctuation after about 20 sec. following trial n. Temporary response enhancement (up to 5 sec.) was reported by Prokasy in those conditions where only 2 ITIs, a short and a long one, were randomly distributed. According to Prokasy, "*S* learns to pay attention immediately following a trial and then in the absence of another trial, relaxes and is subsequently not ready for one when it does occur [p. 471]." Temporary response enhancement, lasting up to 10 sec., was observed by Landauer (1969) in a free-responding situation and was taken as evidence for "posttrial hyperexcitability" which may be initiated by the unconditioned stimulus (UCS). In addition to the choice of relatively short ITIs, previous research may have made it difficult to detect ITI effects occasioned by stimulus fluctuation in another way. That is, ITIs are assumed to affect responding differentially in early acquisition. Later in training, events from trial n are expected to be in STS and LTS and equally available, regardless of the length of the ITI, and hence CR probability should be invariant (Prokasy, p. 471). The studies mentioned above, however, do not detail percentage of CRs during early acquisition.

The present study sought to evaluate the expectations of Estes' (1955) and Atkinson and Shiffrin's (1968) theories by minimizing transient posttrial processes through the choice of relatively long ITIs (20, 100, and 420 sec.) and by observing responding from early acquisition through extinction.

Method. Data were collected from 22 male New Zealand white rabbits in acquisition and from 21 of these rabbits in extinction.

A 3,160-Hz. tone of 88 db. as measured at the position of *S*'s head (General Radio sound pressure meter, Scale 20 kHz.) was used as the conditioned stimulus (CS) and an 8-ma. shock delivered through 2 stainless-steel sutures (ga. #32) across the eye was used as the UCS. Eyelid responses were measured by means of a microtorque potentiometer affixed to *S*'s head and an Offner dynograph. During experimentation, each *S* was restrained in a 50.8 × 17.8 × 14.0 cm. Plexiglas box which was located in a 66.0 × 63.5 × 53.5 cm. sound-attenuated air-ventilated chamber. After *Ss* had been habituated for 4 hr. to the restraining box and the experimental chamber, they received 3 acquisition sessions and then 1 extinction session each, separated by 18 hr. On each of 61 acquisition trials per session, the CS was presented for 600 msec., overlapping with the UCS for the last 100 msec. On extinction trials, the CS was presented alone. Trials were separated throughout by an average ITI of 180 sec. The individual ITIs of 20, 100, and 420 sec. each occurred 20 times in each session, their occurrence following a predetermined order with the restrictions that each ITI occur twice within 6 trials and that during each block of 18 trials, the ITIs follow each other with equal frequency. In acquisition, all *Ss* received the same ITI sequence. In extinction, *Ss* received the same sequence as in acquisition, except that the sequence was started at an ITI of 20 sec. for 7 *Ss*, at 100 sec. for 7 other *Ss*, and at 420 sec. for the remaining *Ss*.

Results. The CRs following the 3 different ITIs were analyzed separately within *Ss*. Figure 1 presents the mean percentages of CRs following each of 3 ITIs during 3 sessions of acquisition and the extinction period. In Session 1 of acquisition, *Ss* responded significantly more following an ITI of 20 sec. than following the longer ITIs, Friedman $\chi^2(2) = 9.30$, $p < .01$. Specifically, CRs following an ITI of 20 sec. were more likely than CRs following ITIs of 100 sec., $t\ (21) = 1.93$, $p < .10$, and 420 sec., $t\ (21) = 2.45$, $p < .05$. There was no significant difference in responding following the latter 2 ITIs.

Analyses of runs of consecutive CRs for each *S*, regardless of the ordinal number of trials on which CRs occurred, showed that of the *first* 10 CRs, 40.9% followed an ITI of 20 sec., 31.8% followed

TABLE 1

MEAN PERCENTAGE CONDITIONED RESPONSES ON TRIAL $n + 1$ AS A FUNCTION OF INTERTRIAL INTERVALS AND PRESENCE OR ABSENCE OF A CR ON TRIAL n

Conditioned responses on trial n	Intertrial interval (in sec.)		
	20	100	420
Session 1 of acquisition[a]			
Present	83.8	69.8	59.4
Absent	16.5	7.3	6.7
Extinction[b]			
Present	71.9	82.5	75.7
Absent	7.4	16.5	26.2

[a] $n = 15$.
[b] $n = 21$.

an ITI of 100 sec., and only 27.3% followed an ITI of 420 sec., $\chi^2(2) = 7.66$, $p < .05$, although there was an equal opportunity (33.3%) for CRs to follow each ITI equally often. Later in acquisition, the percentages converged, such that out of the first 40 CRs, 35.1% followed an ITI of 20 sec., 32.5% followed an ITI of 100 sec., and 32.4% followed an ITI of 420 sec. Table 1 summarizes percentage CRs on trial $n + 1$ following each of the 3 ITIs as a function of the presence or absence of a CR on trial n. (Prokasy & Papsdorf, 1965). Percentages are shown only for Session 1 of acquisition and extinction, because most *S*s had missing data in some cells. For the same reason, only 15 *S*s were included for Session 1 of acquisition. As in the Prokasy and Papsdorf experiment, CRs were more likely on trial $n + 1$ when a CR was present on trial n than when there was no CR, F (1, 14) = 84.45, $p < .01$. This finding was a reflection of the tendency of CRs to occur on adjacent trials rather than on separate trials. Similarly, the ITI effect was significant, F (2, 28) = 3.88, $p < .05$. However, unlike Prokasy and Papsdorf's study, CRs were more likely following the short than the longer ITIs. This result obtained regardless of whether or not a CR occurred on trial n as indicated by the absence of a CR Presence vs. Absence × ITI interaction, F (2, 28) = 1.22. In Sessions 2 and 3 of acquisition there appeared to be somewhat more responding following the short than the longer ITIs, but the difference was not significant.

In extinction, the pattern of responding was opposite to that found in early acquisition, i.e., CRs were more likely following the 2 longer ITIs than following the short ITI, as indicated by a significant main effect, F (2, 40) = 5.20, $p < .01$. Specifically, CRs were significantly less likely after an ITI of 20 sec. than after ITIs of 100 sec., t (20) = 2.58, $p < .02$, and 420 sec., t (20) = 2.88, $p < .01$. There was no significant difference in responding following the latter ITIs. Of the first 10 failures to respond, analyzed separately for each *S*, 40.5% followed an ITI of 20 sec., 31.9% followed an ITI of 100 sec., and only 27.6% followed an ITI of 420 sec., Friedman $\chi^2(2) = 3.90$, $p < .15$. Analysis of variance of percentage CRs on trial $n + 1$ as a function of ITI and presence vs. absence of a CR on trial n revealed a significant CR presence vs. absence effect, F (1, 20) = 181.98, $p < .01$, and a significant ITI effect, F (2, 40) = 8.86, $p < .01$. The significant CR Presence vs. Absence × ITI interaction, F (2, 40) = 4.12, $p < .05$, shows that ITIs affected the occurrence of CRs on trial $n + 1$ differentially, depending on whether or not a CR was present on trial n. That is, percentage CRs on trial $n + 1$ increased between ITIs of 20 and 100 sec., regardless of whether a CR was present on trial n, t (20) = 2.87, $p < .01$, or absent, t (20) = 2.47, $p < .05$. Beyond an ITI of 100 sec., CRs on trial $n + 1$ continued to increase when no CR was present on trial n, t (20) = 1.98, $p < .10$, but they appeared to decline, if not significantly, when a CR was present on trial n, t (20) = 1.54, $p < .20$.

Discussion. The present study found that the length of the ITI preceding a trial influenced the likelihood of a CR early in acquisition and extinction. Early in acquisition, a CR was more likely when the preceding ITI was relatively short than when the ITI was relatively long (100 sec. and longer). On the other hand, in extinction, a CR was more likely when the preceding ITI was relatively long than when the ITI was relatively short.

The results support a stimulus fluctuation theory such as Estes' (1955) and a 2-store theory of memory such as Atkinson and Shiffrin's (1968). These theories suggest that trial events are more available to *S* the sooner a subsequent trial is given. Even if it is assumed for a moment that transient posttrial processes, whether hyperexcitability or reactive inhibition, last for intervals as long as used here, neither process could account for the present data in their entirety. The occurrence of posttrial hyperexcitability could explain the present acquisition results, because it might be argued that the shock UCS had increased the likelihood of a blink response for a brief period. However, the fact that new learning was more prominent at the shorter ITI than at the longer ITIs in extinction cannot be accounted for simply by assuming that a shock UCS temporarily excited *S*. Similarly, while a reactive inhibition construct would predict the higher overall responding at long than short ITIs in extinction, it could not readily explain the higher occurrence of CRs following long than short ITIs when *no* CR was present on extinction trial n, or the higher occurrence of CRs following short than long ITIs in acquisition.

The advantage of Estes' (1955) stimulus fluctuation theory and Atkinson and Shiffrin's (1968) memory theory is their ability to handle the present data with comparable ease and to integrate them with results obtained in human verbal learning. For example, the results reported here invite comparison with results from some continuous paired-associate experiments, especially Bjork's (1966) study. In Bjork's research, *S*s were tested for the recall of paired-associate responses after varying interpresentation intervals (IPIs). Early in training, i.e., before the trial of the last error, the proportion of correct responses was higher the shorter the IPI. Bjork suggests that these short-term effects may be due to the better retention of items in STS with shorter than with longer IPIs.

TEMPORAL SEPARATION IN VERBAL DISCRIMINATION TRANSFER [1]

STANLEY J. PASKO AND EUGENE B. ZECHMEISTER [2]
Loyola University, Chicago

In verbal discrimination transfer: when situational frequency is initially superior for incorrect (I) than correct (C) items, Hintzman and Block have predicted that the degree to which transfer is inhibited will depend on the temporal separation of the original and transfer tasks. As a test of this hypothesis, *Ss* learned a reversal list task wherein designation of C and I items learned in List 1 was reversed in List 2 (*A*–B, A–*B*, where italics indicate C item). Temporal separation between lists (0 or 7 min.) and number of List 1 trials (4 or 8) were factors. Support for the hypothesis was found only for conditions of low List 1 learning. It is suggested that *Ss* obtain information concerning List 1 context and intrapair associations as number of List 1 trials increases. This information may aid transfer discrimination as frequency accrues to List 2 C items.

A serious shortcoming of the frequency theory of verbal discrimination (VD) learning (Ekstrand, Wallace, & Underwood, 1966) has been the failure to predict, completely, transfer performance in those situations wherein situational frequency is initially greater for incorrect (I) than correct (C) VD items. A study by Raskin, Boice, Rubel, and Clark (1968) is of this general type. These investigators examined VD transfer when pairs from List 1 were retained in List 2, with the designation of C and I items reversed in the second list (*A*–B, A–*B*, where italics indicate C item). Positive transfer was observed on the initial List 2 trial; however, performance first deteriorated slightly and then improved on the next few trials, becoming inferior to that of a control group on remaining trials. The frequency theory assumes that on the initial transfer trial situational frequency is greater for List 2 I than C items due to their prior designation as correct in List 1 and that *Ss* can discriminate correctly by choosing the lower level frequency items as correct. However, as learning demands the continued frequency buildup to C items (e.g., saying aloud the C items on the test trials), the initial advantage to I items is lost and a discrimination based on a relative frequency difference between pair members is made difficult and transfer is inhibited. A strict interpretation of the theory suggests that discrimination should fall to chance levels of responding when the point of frequency equality is reached. Although some investigators, such as Raskin et al., have reported a slight deterioration during early List 2 learning, a complete breakdown in discrimination has not been observed. This is evident even when individual pair frequencies have been adjusted for the effect of wrong responding or, to ensure the hypothetical equality point for all pairs simultaneously, when individual pair frequencies have been rigidly controlled through pronunciation instructions (Underwood & Freund, 1970). It has been concluded that, at some point during second list learning, *Ss* make use of attributes other than frequency to aid discrimination (cf. Underwood & Freund, 1970).

Hintzman and Block (1971) have recently suggested that frequency theory need not predict deterioration to chance levels of responding in the relevant transfer cases if *S*'s ability to discriminate recently from remotely accrued frequencies is taken into consideration. These authors reason that if early in acquisition of the transfer list *Ss* ignore recent frequencies (List 2), and as frequency accrues to C items, later ignore older frequencies (List 1), then deterioration to chance would not be expected. Since the ability to separate List 1 from List 2 frequencies is presumably based on the discriminability of "time tags" present on the list items, it can be expected that "the effectiveness of a manipulation, particularly one designed to inhibit verbal discrimination performance, should depend on the temporal separation of the initial and transfer task [p. 305]."

[1] This experiment is part of research submitted by the first author in partial fulfillment of the requirements for the MA degree at Loyola University, Chicago.

The present experiment is a test of the Hintzman and Block (1971) hypothesis as it applies to VD transfer. Specifically, transfer in a VD task was examined after designation of C and I items learned in List 1 was reversed in List 2 (*A*–B, A–*B*) and when List 2 learning followed List 1 learning either immediately (0 min.) or after a short interval (7 min.). A reversal task was chosen since both members of the transfer list were part of List 1 learning and, therefore, differed only in terms of situational frequency. Also, transfer was examined following 2 different degrees of List 1 learning (4 or 8 trials).

Method. Sixty-four 2-syllable nouns varying 20–50 in Thorndike and Lorge (1944) frequency were selected with an attempt at minimizing semantic and orthographic overlap. Under the restriction that pair members not begin with the same letter, 32 words were randomly selected to form 16 pairs for presentation to the experimental groups. The remaining 32 nouns were randomly paired under the above restriction to serve as List 1 for the control group.

In both experimental and control lists, one item of each pair was randomly designated the C term. For the reversal conditions, 2 forms of List 1 were prepared so that each item might be both a C and I item. In List 2 the C and I relationships were reversed in both forms. For the control groups, one form of List 1 was used for all *Ss*. Control *Ss* were then equally assigned to the 2 forms of the reversal list as List 2. Four orders of all the above forms were created and were presented to *Ss* equally often in counterbalanced form.

After all *Ss* received standard VD instructions, the experimental groups received 4 or 8 trials on List 1. The *Ss* were not informed as to the number of List 1 trials or as to the learning of a second list. The C and I items of a single pair were printed in juxtaposition and exposed on a memory drum. Each pair first appeared for a 2-sec. anticipation interval, after which the C term was shown alone for 2 sec. Across the 4 orders, the C term of each pair appeared equally often, but nonsystematically, in the left and right positions. The intertrial interval for each list was 4 sec. The first trial was always a study trial (*S* did not guess). On the second and succeeding trials, *Ss* responded to each pair, having been told to guess if not sure. The List 1 trial numbers given earlier include the study trial. The control group was arbitrarily given 4 trials on List 1 in order to provide warm-up and/or learning-to-learn experience.

After the requisite number of List 1 trials, experimental *Ss* in the 7-min. temporal separation conditions performed a mathematical filler task, while *Ss* in the 0-min. conditions were immediately informed as to the nature of the second list and that the first trial would again be a study trial. The same instructions were repeated to *Ss* in the delay conditions following the math activity. Control *Ss* were informed that the second list was unrelated to the first and, for these *Ss*, List 2 learning followed immediately after List 1. List 2 learning consisted of 11 trials for all *Ss*, with the first trial a study trial.

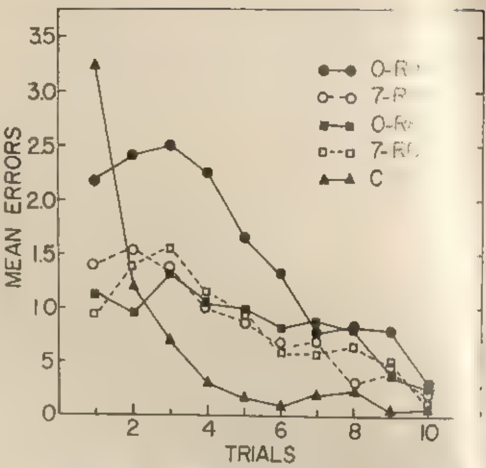

Figure 1. Mean error performance during transfer and acquisition for the experimental and control conditions. (Abbreviations: 0-R4 = 0 min/4-trial reversal list, 7-R4 = 7-min/4-trial reversal list, 0-R8 = 0-min/8-trial reversal list, 7-R8 = 7-min/8-trial reversal list, C = control.)

A total of 120 Loyola University undergraduates participated in the experiment in partial fulfillment of their introductory psychology course requirements. Each of the 5 transfer conditions contained 24 *Ss*. Conditions were randomized in blocks of 5 and assignment of *Ss* was made on the basis of appearance in the laboratory.

Results. Analysis of variance of the total number of errors made on the first 3 List 1 trials indicated that the 4 reversal list conditions did not differ on List 1 learning ($F < 1$). For each experimental condition and for the control condition the mean total errors were as follows: 0-min/4-trial reversal list (0/R4), 8.12; 0-min/8-trial reversal list (0/R8), 8.04; 7-min/4-trial reversal list (7/R4), 6.62; 7-min/8-trial reversal list (7/R8), 8.08; and control, 9.29. Within the experimental conditions, however, the 2 forms of the VD list could not be judged of equal difficulty, F (1, 88) = 4.95, $p < .01$. Nevertheless, the differences between forms of the list did not vary with experimental conditions, F (3, 88) = 2.49, $p > .05$.

Figure 1 shows mean errors made on each of the 10 transfer trials by those *Ss* learning a reversal list and for control *Ss*. Statistical analysis of the reversal list performance indicated reliability for the pattern of results seen in Figure 1. While neither temporal separation nor number of List 1 trials was significant as main effects, the Number of List 1 Trials × Reversal List Trials interaction was significant, F (9, 92) = 3.06, $p < .01$, as was the second-order Temporal Separation × Number of List 1 Trials × Reversal List Trials interaction, F (18, 828) = 2.38, $p <$ 01. These results reflect the initially inferior performance, and subsequent faster rate of improvement, of the 0/R4 condition

relative to the remaining reversal list conditions. The reversal list trials effect was significant, F (3, 92) = 29.33, $p < .01$, but no other effects were reliable. Separate analysis of transfer performance for the 0/R4 and 7/R4 conditions indicated a significant effect for temporal separation, F (1, 6) = 5.19, $p < .05$, as well as for the Tem-...aration × Reversal List Trials interaction, ...1) = 1.94, $p < .05$.

...man–Keuls range test of mean errors on ... transfer trial indicated that the experi-...roups were all significantly different from ...rol group ($p < .05$). Within the experi-...groups, the 0/R4 and 7/R4 groups did not ...nificantly, but the 0/R4 group was sig-... different from the 0/R8 and 7/R8 groups ...). In terms of overall errors, *Ss* in Condi-...R4 were significantly different from the ...aining 4 transfer groups ($p < .05$).

Discussion. The frequency theory of VD learning requires that several predictions be met regarding reversal list performance as a function of number of List 1 trials. For the present task, an increase in number of List 1 trials presumes a larger difference in situational frequency between C and I items at the point of the first transfer trial. If frequency alone serves as a discriminative ...e larger the initial frequency difference be-...nd I pair members, the easier should be discrimination and the greater should be positive transfer on the first reversal list trial. An examination of Figure 1 shows that this expectation is satisfied only when List 2 immediately followed the learning of List 1 (0/R4 vs. 0/R8). The same ...on between conditions differing on number ...l trials, but when transfer list acquisition was delayed (7/R4 vs. 7/R8), shows no overall difference as a function of increasing trials on the original list. A further prediction made on the basis of frequency theory concerns the point during second-list learning at which deterioration of transfer performance should be observed. The larger the initial frequency differential between C and I items, the more transfer trials will be required to approximate an equalization of apparent frequency. Looking again at Figure 1 and comparing groups differing only in number of List 1 trials, there is a slight tendency for delayed deterioration between Conditions 0/R4 and 0/R8, but little difference between Conditions 7/R4 and 7/R8. However, differences are slight and, therefore, the results are equivocal for this prediction. Finally, frequency theory cannot presently account for the difference in performance between conditions differing only in temporal separation of original and transfer lists (0/R4 vs. 7/R4). This latter finding, however, is amenable to predictions made from the multiple-trace hypothesis of Hintzman and Block (1971) and provides evidence that attributes other than frequency (e.g., temporal) are involved in transfer of a discrimination.

An explanation for the fact that temporal separation was effective in reducing transfer list inhibition only for a relatively low degree of List 1 learning may be related to one of several consequences of increasing number of List 1 trials. First, it can be noted that in the present experiment degree of List 1 learning is confounded with temporal separation between the initial trials of the original and transfer lists. It might be logically argued that an increase in the number of List 1 trials would lessen the effectiveness of the present temporal manipulation since the more trials on List 1, the greater is the time associated with List 1 practice and, conceivably, the more discriminable are the time tags. On the other hand, if increasing the number of List 1 trials is correlated with other than temporal changes which can mediate list discrimination, then *Ss* may ignore List 1 frequency, on the basis of these cues, as List 2 frequencies become sufficiently disparate to provide a consistent cue for discrimination performance. Additional cues that can mediate discrimination may be expected to obviate the use of a temporal cue if these added attributes are more dominant in discrimination performance.

Two correlates of increasing number of List 1 trials can be expected. First, as number of List 1 trials increases, so too does *S*'s information regarding List 1 context. If frequency can be assumed to be context related, then it is likely that List 1 frequency is more discriminable after a larger number of List 1 trials. For example, this interpretation would explain the failure of King and Levin (1971) to find inhibition in VD transfer after 8 List 1 trials when between-lists changes involved either designation of a new C item (*A*–B, *C*–B), or both the reversal of List 1 C items and the designation of a new C item (*A*–B, *C*–A). In both these paradigms, situational frequency is greater for I than C items on the initial transfer trial and the frequency theory predicts initial positive transfer and subsequent deterioration on remaining transfer trials. King and Levin's results are in contrast to results seen in Figure 1 where reversal list inhibition after 8 List 1 trials was found. If context aids list discrimination, less inhibition would be expected in those VD paradigms which change list composition between initial and transfer lists (e.g., *A*–B, *C*–B) than in a reversal paradigm wherein changes in original and transfer list learning are not correlated with changes in list composition (*A*–B, A–*B*).

A second correlate of increasing number of acquisition trials is an increase in *S*'s information regarding intrapair associations (e.g., Zechmeister & Underwood, 1969). In terms of reversal list performance, this fact suggests that as frequency accrues to the C items of the transfer list, discrimination may be aided by *S*'s information about intrapair relationships, particularly as equalization of frequency between pair members is approximated.

Finally, all reversal conditions of the present experiment showed a slight deterioration on early List 2 trials and subsequent inhibition on later transfer trials. This finding suggests that *Ss* are not entirely successful at ignoring prior frequency during List 2 acquisition, a fact which tends to

confirm the notion that frequency is the dominant attribute governing discrimination performance and that *S*s have difficulty using less preferred cues.

MOTIVATING EFFECT OF CONTINGENT SELF-REWARD[1]

GISELA E. SPEIDEL[2]

Kamehameha Early Education Project, Honolulu, Hawaii

The motivating effects of contingent self-reward on an intellectual though boring task were studied. The *S*s were instructed to work on simple addition problems for as long as they wished. The *S*s in the self-reward condition presented themselves with sections of a television film contingent upon a fixed-ratio schedule that they had selected from 3 alternatives. An *E*-rewarded group, yoked to the self-reward *S*s, received the movie sections automatically. A control group received rest periods instead of the film. The results partially supported the hypotheses that contingent self-reward can have motivating effects. The self-reward group completed significantly more problems than the control group while there were no significant differences in number of problems completed between the self-reward and the *E*-rewarded groups.

The variables that are relevant to the establishment and occurrence of contingent self-reward have been charted extensively under laboratory conditions (for reviews, see Bandura, 1971; Kanfer, 1970). By comparison, there are relatively few studies seeking to demonstrate that self-reward can have a reinforcing or motivating function. Examination of the most frequently cited studies (Kanfer & Duerfeldt, 1967; Marston & Kanfer, 1963) has revealed methodological problems that make equivocal the conclusion that self-administered reward functions to motivate behavior (Speidel, 1972).

The present experiment was designed to furnish further evidence on the effects of contingent self-reward. Specifically, the study tested whether sections of a movie, self-administered contingently upon the completion of a certain number of addition problems, would serve to increase the number of problems completed and to increase the rate of responding.

[1] This research was submitted in partial fulfillment of the requirements for the PhD degree at the University of Hawaii. The author wishes to thank Roland G. Tharp, W. J. M. Evans, Clifford R. O'Donnell, and John G. Carlson for their helpful critical comments.

Method. The *S*s were 45 undergraduate psychology students. Fifteen *S*s (7 males and 8 females) were assigned to each of the following groups: self-reward (SR), *E*-rewarded (ER), and no-reward control receiving rest periods. The *S*s in the ER and the control groups were yoked to *S*s in the SR group in terms of the schedule on which they received the reward or the rest period, respectively.

The *S*s were tested individually and were presented with a stack of 70 pages containing 25 simple addition problems each. The problems all had the same pattern of 2 rows and 3 columns of numbers as shown in the example $\begin{array}{r}234\\+867\end{array}$. A panel with 2 buttons and a counter were connected to a central relay system in *E*'s room. One of the buttons activated a cumulative recorder and a counter in *E*'s room and also the counter on *S*'s panel (during the ER and SR conditions). The other button activated a buzzer in *E*'s room; *E* then turned on a videotape recorder (for the SR condition only). A television monitor was placed in the *S* room. A videotaped television detective story served as the reward.

All groups received instructions to work on the

addition problems and to press the "problems completed" button every time they had finished a problem. They were given one page of trial problems for practice. (The rate with which *S*s worked on this page was used as a preexperimental rate measure.)

The SR *S*s were then shown how they could keep track of the number of problems they had completed by checking the counter on their panel. They were instructed to treat themselves to some "movie time" whenever they had finished a certain number of problems by pressing the television button on their panel. The film was briefly described to them and they were shown how to tune the monitor. The *S*s were presented with a card that contained 3 alternative schedules on which they could reward themselves. They were asked to choose one of the schedules (but not to tell *E*). If they found the schedule on which they worked too easy or too difficult they could change schedules, but not more than once.

The ER *S*s were given the same information relating to the counter on their panel, the film, and the television-tuning instructions as SR *S*s. However, they were told that the television would come on automatically each time they had completed a certain number of problems. For each *S*, the schedule on which he was to be rewarded (which was the same as that on which the SR *S* to whom he was yoked had rewarded himself) was stated.

In place of the television instructions the control group was informed that occasionally the loudspeaker would come on and announce break time. During this period they were not to work on the problems. Control *S*s were yoked to SR *S*s in terms of the schedule on which they received the rest period. However, rather than giving the period in a single unit at the completion of the schedule, it was given in 2 parts—one at some point in the middle of the set of problems and the other at the completion of the schedule. This was done so as not to convey to *S*s that the rest period was contingent upon performance.

The final instructions for all 3 groups informed *S*s that the experiment was open ended in length and that they could leave the experiment whenever they wished. When they decided to stop they were to come into *E*'s room and fill out the questionnaire. If *S* had not signaled that he wanted to leave after 900 problems, *E* stopped him. The *S*s were given a questionnaire and asked to rate the movie or the break on a 7-point bipolar scale from -3 (extremely boring) through 0 (the neutral point) to $+3$ (extremely interesting or restful).

Results. The effects of the experimental conditions were measured on 3 dependent variables: (*a*) the number of problems completed; (*b*) the average number of seconds needed to complete a problem, i.e., rate; and (*c*) the decrease in number of seconds per problem from the beginning to the end of the experiment, i.e., increase in rate.

The mean number of problems completed by the control, SR, and ER groups was 527.53, 723.33, and 826.67, respectively. The differences among the means were statistically significant, F (2, 42) $= 7.23$, $p < .005$. A comparison of the means by the Newman–Keuls method showed that both the SR and ER groups completed significantly more problems than the control group; the difference between the ER and control groups was significant at the .01 level; the difference between the SR and control groups was significant at the .05 level. Although the ER group completed more problems than the SR group, this difference was not significant.

Both rate and increase in rate of performance during the experiment showed no significant treatment effects. However, the pretreatment rate correlated positively with rate during the experiment, r (43) $= .78$, $p < .001$, and negatively with an increase in rate, r (43) $= -.61$, $p < .001$. Therefore point-biserial correlations were conducted between treatment conditions and each of these 2 dependent variables with pretreatment rate partialed out. These correlation coefficients were in the predicted direction: The ER group worked faster and increased more in rate during the experiment than the control group while the SR group took an intermediate position. However, the correlations were not significantly different from each other.

The mean rest-period rating given by the control group was .33 and did not differ significantly from the neutral point. The mean movie ratings given by the SR and the ER groups were 1.4 and 2.0, respectively. The movie was rated significantly more positively than the rest period, t (44) $= 4.28$, $p < .001$. The more attractive an *S* rated the movie, the more problems he tended to complete, r (29) $= .28$, $p < .06$.

Discussion. The results on the number of problems completed indicated that self-reward can function to motivate behavior in a manner similar to *E*-presented contingencies. Further support for the conclusion that the difference in performance between the experimental groups and the control group was due to the motivating function of the film, was provided by the findings that the movie was rated significantly more positively than the neutral rest period and that the more attractive the movie was rated, the more problems were completed.

The fact that the other 2 dependent measures showed only tendencies in the predicted direction does not provide any evidence against the present hypothesis. Since not even the ER group exhibited any significant treatment effects, it is concluded that these measures did not constitute a sufficiently sensitive test for the effects of contingent reward whether externally or self-administered. These measures seem to reflect mainly stable individual differences in arithmetic skill, as pretreatment performance accounts for most of their variation.

It is therefore concluded that the present results confirm the findings of Bandura and Perloff (1967) who demonstrated that self-administered tokens could maintain a motor task in children. A broader

data base is thus provided for past and future applied studies using self-reward to effect behavior change.

A warning, however, against overenthusiastic application of self-reward in a clinical setting, at this stage, is appropriate. Experiences gained from conducting pilot work and the present experiment suggest that the motivating effect of contingent self-reward is a delicate one that requires special conditions for its demonstration. Some of the factors to which special attention must be given are the (*a*) other self-control behaviors an individual already has in his repertoire; (*b*) appropriate level of aversiveness of the task on which the motivating effects are to be demonstrated; and (*c*) appropriate level of attractiveness of the reward, so as to ensure motivating effects but not to evoke rule violation. Furthermore, most experiments in self-reinforcement have some demand characteristics for compliance with the rules for contingent self-reward (Bass, 1972). A still unanswered question is whether contingent self-reward can occur without such demand characteristics. Even in the present experiment demand characteristics existed (e.g., the presence of *E* in an adjoining room, wanting to be a good *S*, etc.) that may have been responsible for the maintenance of contingent self-reward, and therefore prevented rewarding oneself before the completion of the criterion behavior. The design of the present study greatly reduced the potential operations of such demand characteristics in that (*a*) *S*s were given a choice of alternative work schedules and the opportunity to change schedules; (*b*) they monitored the number of problems they had completed on their counter; and (*c*) they received no signal to indicate that they had reached their criterion for self-reward and they consumed the reward immediately and did not have to exchange tokens for a reward at the completion of the experiment. The last 2 features had been present in the Bandura and Perloff (1967) study.

In light of the above discussion the conclusion permissible from the present study and Bandura and Perloff's (1967) study is that under circumstances that insure compliance with the rule of contingent self-reward, self-administered rewards can be shown to motivate and maintain behavior in a manner similar to rewards controlled by another person.

USE OF RULE 1 AND RULE 2 IN VERBAL DISCRIMINATION TRAINING[1]

SLATER E. NEWMAN,[2] RALPH E. SUGGS, AND CAROL H. AVERITT

North Carolina State University

During verbal discrimination training, each *S* in Experiment I was told on study trials which item of each pair was *right* or *wrong*. Appropriateness of Rule 1 (select the more frequent item of the pair) and Rule 2 (select the less frequent item of the pair) was manipulated by having *S* designate on test trials the same item of the pair designated by *E* on study trials (Rule 1 thus being the more appropriate) or the other item of the pair (Rule 2 being the more appropriate). In Experiment II, appropriateness of Rules 1 and 2 was manipulated by having *S* designate on the test the same item of the pair *E* had instructed him to learn during study trials or the other item. In both experiments, performance during training was better for *S*s for whom the use of Rule 1 was the more appropriate.

According to the frequency theory of verbal discrimination (VD) learning (Ekstrand, Wallace, & Underwood, 1966), a frequency unit is added to an item each time *S* responds with it. The theory asserts that correct responding during VD training is directly related to the difference in frequency units between items of a pair. According to Ekstrand et al., *S* responds with the more frequent (Rule 1) or less frequent (Rule 2) item of a pair depending on the requirements of the situation.

A transfer experiment by Underwood, Jesse, and Ekstrand (1964) has provided some data on the use of these rules. After each *S* learned a VD list to 3 consecutive perfect trials, he learned a second list. For half of the *S*s, the *right* items from List 1 were still right on List 2 but the *wrong* items were new; for the other *S*s, the *wrong* items from List 1 were still *wrong* on List 2 but the *right* items were new. Performance on the first test of List 2 was almost perfect for the *right S*s (for whom the use of Rule 1 was the more appropriate). The *wrong S*s (for whom the use of Rule 2 was initially the more appropriate) also made few errors on the first test of List 2, though substantially more than *right S*s. (This difference in performance between the *right* and *wrong S*s can be explained by assuming that the frequency difference between old and new items for the *right* group was greater than for the *wrong* group.) These data thus accord with the statement that "either Rule 1 or Rule 2 can be applied depending on the appropriateness of the situation [Ekstrand et al., 1966, p. 570]."

Experiment I

This experiment studied the use of Rule 1 and Rule 2 in a single-list situation. For half of the *S*s, Rule 1 was the more appropriate from the beginning of training; for the remaining *S*s, Rule 2 was the more appropriate. A 2×2 design was used which permitted study of the effects of (*a*) designating an item as *right* or *wrong* on study trials and (*b*) requiring *S* to designate the *right* or *wrong* items on test trials. Thus, on study trials, half of the *S*s were told which item of a pair was *right* and half were told which item was *wrong*. On test trials, half of the *S*s in each treatment were instructed to indicate the *right* item of each pair, and half were instructed to indicate the *wrong* item of each pair. As in the experiment by Ekstrand et al. (1966), *S* was asked to indicate whether the to-be-designated item was first or second rather than to pronounce it, thus presumably eliminating the buildup of frequency units on test trials. The 4 groups were designated RR, RW, WR, and WW (the first letter refers to the item designated on study trials, i.e., R = right, W = wrong; the second letter to the item to be designated by *S* on test trials). All *S*s were given 4 study trials, each followed by a test.

Method. The 20 pairs were those used in the control condition by Ekstrand et al. (1966). For each treatment, 2 lists were constructed so that on study trials each item of a pair was repeated either on List A or on List B (e.g., in Group RW, half of the *S*s heard "queen–fast, queen is right"; the rest heard "queen–fast, fast is right"). During training, 8 different orders of the pairs were used, 4 for study trials and 4 for test trials. Each item appeared first in its pair on half of the study trials and on half of the test trials.

The *S*s were run individually. A tape recorder was used to present the instructions and to present the items on study trials and on test trials. The instructions told *S* which item of a pair would be designated on study trials and which item he was to designate on test trials. On study trials, each item of a pair was presented and *S* was then told which item was *right* (Groups RR and RW) or *wrong* (Groups WR and WW). On test trials, each item of the pair was presented and *S* called out that item of the pair (first or second) that he believed was *right* (Groups RR and WR) or *wrong* (Groups WW and RW). A 4-sec. rate was used

[1] The authors appreciate the help of Harry K. Dorsett in making students at Meredith College available for participation in this experiment, and of Donald H. Mershon who commented on an earlier version of this manuscript.

TABLE 1

Mean Correct on Each Trial for Each Treatment: Experiments I and II

Treatment[a]	Trials 1	2	3	4	Total
Experiment I					
RR	14.25	16.55	18.50	19.35	68.65
RW	11.75	14.40	15.50	17.10	58.75
WR	11.85	13.00	15.30	16.45	56.60
WW	13.35	16.35	17.55	18.95	66.20
Experiment II					
RR	12.70	14.95	17.15	17.40	62.20
RW	10.80	13.25	13.90	14.25	52.20
WR	10.75	12.85	14.10	14.45	52.15
WW	12.80	14.50	17.25	16.60	61.15

[a] Abbreviations: R = right, W = wrong; for further explanation, see description in text for each experiment.

on both study and test trials. There were 4 study trials each followed by a test. A 50-sec. interval separated the first study trial from the first test trial. During this interval, *E* reiterated instructions for the test. Subsequent intervals between each study trial and its following test trial were 15 sec. and between each test trial and its subsequent study trial, 4 sec.

There were 80 *S*s, 56 from the introductory psychology course at North Carolina State University and 24 from a class in educational psychology at Meredith College. A balanced Latin square was used in assigning *S*s from each population to the treatment conditions.

Results and discussion. A 2 × 2 × 4 (Study Trial Repetition × Test Response × Trials) analysis of variance was applied to the data for number correct on Tests 1–4. Only the effects of trials, F (3, 228) = 102.34, $p < .001$, and the Study Trial Repetition × Test Response interaction, F (1, 76) = 30.25, $p < .001$, were significant. Application of Duncan's multiple-range test showed that the means for Groups RR and WW each differed ($p < .01$) from the means for Groups RW and WR; but the RR mean did not differ from that for WW ($p > .05$) and the RW mean did not differ from that for WR ($p > .05$). The mean correct for each treatment on each trial is shown in Table 1.

In accord with predictions derivable from the frequency theory, performance during training was affected neither by the item (*right* or *wrong*) designated on study trials nor by the item to be designated on test trials. Performance was affected only by whether the item designated during study trials was the same as (or different from) the item to be designated on the test trials. If it was the same (as in Groups RR and WW, for which use of Rule 1 was the more appropriate), then performance was better than if it was different (as in Groups RW and WR, for which use of Rule 2 was the more appropriate). Examination of the treatment means on each test shows that the between-treatments differences occurred on the first test and remained relatively stable throughout training.

The improvement in performance during training may be taken as evidence that during VD train . . "either Rule 1 or Rule 2 can be applied depending on the appropriateness of the situation [Ekstrand et al., 1966, p. 570]." The present results appear to indicate, however, that where use of Rule 1 is the more appropriate, performance during training (as early as the first trial) may be be[illegible] where the use of Rule 2 is the more appro[illegible]

Experiment II

In explaining the results from Experiment I [illegible] was assumed that the difference in frequency unit[illegible] between items of a pair derived from the f[illegible]quency of their overt occurrence. In Experim[illegible] *right* and *wrong* items of each pair were p[illegible] only once on each study trial, *S* was instru[illegible] prior to each study trial which item (*right* or *wrong*) he was to learn (but not which item he was to designate on test trials), and was then tested for those items or for the other items. If frequency units accrue to an item only as a result of its overt occurrence, all groups should perform at chance level since the number of frequency units for the 2 items of a pair would be equal. Four trials were run to determine whether performance of any of the 4 groups would change with practice.

Method. The method was similar to that used in Experiment I with the following exceptions: (*a*) *S*s were instructed prior to each study [illegible] to learn the *right* (Groups RR and RW[illegible] (Groups WR and WW) item of each pair [illegible] were not told until after the first study trial which item they would have to designate on test t[illegible] (*b*) on study trials, half of the *S*s heard "q[illegible] right, fast is wrong" (List A) and the rest heard "queen is wrong, fast is right" (List B); (*c*) a 3- rather than a 4-sec. rate was used on study and test trials; (*d*) immediately prior to the first test and to each test thereafter, half of the *S*s in each treatment were asked to indicate (by saying "first" or "second") the items they had been instructed to learn (Groups RR and WW) and the remaining *S*s were asked to indicate the other item of each pair (Groups RW and WR); and (*e*) 50 sec. intervened between each subsequent study trial and the test that followed, and 24 sec. between each test and the study trial that followed.

The design was 2 × 2 with 20 *S*s, 12 male and 8 female, in each treatment. All were undergraduates at North Carolina State University. Males and females were separately assigned in counterbalanced order to each of the treatments.

Results and discussion. To determine whether *S*s performed better than chance on Test 1, a t test was done comparing the mean correct (11.76) for all 80 *S*s and the mean expected by chance. The t (78) = 2.79, $p < .01$, may be interpreted as indicating that at the end of the first study trial a discriminable difference in frequency units existed between the items of each pair.

An analysis of variance for number correct on Test 1 showed a significant effect only for the

Study Instructions × Test Response interaction, F (1, 76) = 6.94, $p < .05$. For both main effects, F was smaller than 1.00. Duncan's test showed no significant differences between the 4 treatment means. When, however, the mean for *S*s in Groups RR and WW was compared with the mean for *S*s in Groups RW and WR, the difference was significant at the .01 level.

A separate analysis of variance for number correct on each trial during training showed that only the effects of trials, F (3, 228) = 53.72, $p < .001$, and the Study Instructions × Test Response interaction, F (1, 76) = 23.01, $p < .001$, were significant. The means appear in Table 1. Duncan's test showed that the means for Groups RR and WW differed from the other 2 means but not from one another, and that the RW mean did not differ from the WR mean.

The results from this experiment replicate those from Experiment I in demonstrating that having *S* designate the *wrong* items on the test has the same effect as having him designate the *right* items. These results demonstrate also that instructing *S* to learn the *wrong* items has the same effect as instructing him to learn the *right* items.

The better-than-chance performance on Test 1 may be explained by assuming that *S*s rehearsed covertly those items they were instructed to learn. If they did, then the better performance of *S*s in Groups RR and WW than of *S*s in Groups RW and WR suggests that performance is better where use of Rule 1 is the more appropriate than where use of Rule 2 is the more appropriate. This could occur if, as in these experiments, *S* had little time to respond and if use of Rule 1 involved fewer operations (e.g., "A is more frequent than B, select A") and thus took less time than use of Rule 2 (e.g., "A is more frequent than B, reject A, select B").[3]

An alternative explanation for these results is based on the assumption that *S*s rehearse covertly those items they expect to designate on the test. Since these are the same items that *S*s in Groups RR and WW were instructed to designate on tests, the difference between items of each pair would increase during training, Rule 1 would become easier to use, and this would be reflected in improved performance over trials. For *S*s in the other 2 groups, RW and WR, the results for Tests 2, 3, and 4 are harder to interpret since *S*s were instructed to learn one item of a pair, but were tested for the other. One possibility is that as training proceeded *S*s came to expect that they would have to designate those items they had to designate on previous tests. Thus during Study Trials 2, 3, and 4, *S*s would rehearse those items (rather than those they were instructed to learn) so that Rule 1 would come to be the more appropriate for *S*s in those groups also. The better performance by *S*s in Groups RR and WW would then be due to a greater difference in frequency units between items of each pair in those groups than in the other 2 groups.

The assumption that *S*s rehearse covertly those items they expect to designate on the tests, can also be used to explain the results from Experiment I. Thus Rule 1 could have been the more appropriate for *S*s of all 4 treatments of that experiment, since all *S*s were told at the beginning of training the items they were to designate on the test and there would be more covert rehearsal for those items. The better performance by *S*s in the RR and WW groups would then be due to a greater difference in frequency units between items of each pair in those groups than in the other 2 groups.

[3] Such behavior for Rule 1 *S*s would also result in a difference in the accrual of frequency units for the 2 items of a pair on test trials.

ACQUIRED PLEASANTNESS AS A STIMULUS AND A RESPONSE VARIABLE IN PAIRED-ASSOCIATE LEARNING[1]

ALBERT SILVERSTEIN[2]

University of Rhode Island

Two experiments are reported in which nonsense syllables paired with pleasant pictures (P-paired syllables) were subsequently learned more rapidly than [illegible] not when they served as stimuli—in paired-associate lists. The bulk of the superiority of P-paired syllables was in response availability, and only a smaller effect was found in association learning. Both effects depended upon Ss learning to anticipate responses differing in acquired pleasantness. Superior ratings of pleasantness were given to the P-paired syllables regardless of whether they were learned as stimuli or responses on the list or whether by anticipation training or associative-match training.

Recent demonstrations that nonsense syllables that have been paired with pleasant pictures (P-paired syllables) are subsequently learned faster in paired-associate (PA) lists than are syllables that have been paired with indifferent [illegible] syllables) have been limited to the case in which the syllables are in the response positions of the list (Silverstein, 1966, 1972a, 1972b). The present study [illegible] nonsense syllables placed in stimulus and response positions of PA lists.

The aforementioned studies support the hypothesis that the acquired-pleasantness effect is based largely upon Ss' disposition to implicitly rehearse P-paired syllables more vigorously than I-paired syllables during the response-learning stage. The bulk of the difference between performance with P- and I-paired syllables has been found in the number of trials before the first response (whether it is correct or not), a measure used to index speed of response learning (Underwood & Schulz, 1960). Moreover, instructions to continuously pronounce the P- and I-paired syllables during the learning task removed the superiority of the former (Silverstein, 1972b). Since [illegible] of the stimulus terms are largely [illegible]

syllables in *either* the stimulus *or* response positions of a PA list. The second task of Experiment I consisted of standard anticipation learning, while that of Experiment II consisted of alternating study and test trials of various types.

Experiment I. Thirty-two female and 48 male Ss were first given 6 trials of rating the difficulty of learning 8 pairs of pictures and nonsense syllables. They were told that we wanted to find out how well people can judge the difficulty of learning a pair of items as a "unitary pair" and were instructed to mark 9-point scales ranging from "very easy" to "very difficult" that were printed on each page of a booklet. The members of each pair were shown simultaneously for 10 sec., and there was [illegible] intertrial interval. On each trial, half of [illegible] had the syllable on the left side and half [illegible] syllable on the right side. The syllable for each pair was shown on each side on an equal number [illegible] but S's task was the same regardless of the [illegible] the syllable and picture. In the second task [illegible] and female Ss were each randomly divided [illegible] groups receiving the syllables from Task 1 as either responses to or stimuli for 2-digit numbers for 1[illegible] anticipation trials. Stimulus and response terms were each shown for 5 sec., and there was a 10-sec. intertrial interval. Following this task, all Ss rated the syllables for pleasantness on a 7-point scale.

Materials shown in both tasks were displayed by a Kodak Carousel slide projector at a distance of 6 ft. from S. Different sets of pictures were used for male and female Ss, having previously been rated [illegible] Ss of the appropriate sex. Four pictures in [illegible] list were in the "very pleasant" range of a 9-point scale, and 4 were rated as "indifferent." All [illegible] tures had very small [illegible]

[illegible] in Task 1 [illegible] pairings in Task 2, such that each syllable was paired with both

ber was paired with both a P- and an I-paired [illegible] used for both lists, with the restriction that pleasant and indifferent items appear in first [illegible] quentially assigned to each order for their first trial.

Table 1 shows that for both male and female Ss [illegible] correct to the I-paired syllables when they were in [illegible] the stimulus position. Pooling the data for male and female Ss produced a significant Pleasantness × Position of Syllables interaction, $F(1, 76) = 5.63$, $p < .05$. The superior performance of male Ss to female Ss was also significant, $F(1, 76) = 4.41$, [illegible]. Correlated means comparisons of the P- and I-paired syllables for the various groups [illegible] when in the response position, $t(24) = 1.89$, $p < .10$, for males, but not for females. The indifferent-pleasant difference did not approach significance for either of the stimulus position groups.

No significant influence of acquired pleasantness was found in the analyses of the response learning [illegible] effect or in interaction with other variables (probably [illegible] of P-paired syllables). The P-paired syllables yielded higher pleasan[illegible] I-paired syllables for all 4 groups, $F(1, 76) = 6.96$, $p < .01$, [illegible] superiority being equally great in the stimulus and the response groups.

Experiment II. The superiority of P- to I-paired syllables found in Experiment I for the response position was a weak effect. However, the pairing of [illegible] bles with the pictures in the first task was simultaneous rather than successive as in previous experiments.[2] Since the acquired pleasantness effect is presumed to be the consequence of classically conditioned affective responses to the syllables [illegible] beneficiary of acquired pleasantness can be advanced with certainty only with data from a task that [illegible] completely than an anticipation task can [illegible] either by response recall (in any order) or by associa-

tive matching, both written (the former test being [illegible] sensitive to response learning, while the [illegible] only by associative matching and were included to control for any possible effect on similarity between test and study trials.

A total of 72 male Ss were assigned in randomized blocks to the 6 groups. The apparatus, lists, and first task were identical to those of Experiment I M, except that the number of trials was increased to 9 in order to strengthen the conditioning of positive affect to the syllables.

In the groups given anticipation training in the second task, S was shown the stimulus term alone for 3 sec., followed by the correct pair for 3 sec., with no overt response required. In the groups given associative-match training, S was shown the stimulus term along with all 8 response terms for 3 sec., followed by the correct pair for 3 sec., with [illegible] required. In both types of study [illegible] erent random order of the pai[illegible] between study and test trials. Following the second task, all Ss rated the nonsense syllables for pleasantness on a 7-point scale.

Table 2 shows the mean number of correct responses for both the first test trial and all 4 test trials, as well as the mean pleasantness ratings. The only significant differences between P- and I-paired syllables were found when the syllables were in the response positions and when Ss had been given anticipation training. A surprising result was that the P-paired syllables were superior as response

TABLE 2

MEANS OF MAJOR STATISTICS IN EXPERIMENT II

Measure	Training-testing sequence: Anticipation–recall		Anticipation–matching		Matching matching	
	P	I	P	I	P	I
Syllable in response position

** $p < .01$.

terms to the I-paired syllables even by the associative matching test, provided that anticipation training had been used. This superiority, however, was clearly smaller and appeared later in training than that obtained by the response recall test (the latter was largest on Trial 1). This pattern is consistent with the typical finding that the primary locus of indifferent–pleasant differences is prior to the first response, whether it is correct or not. As in Experiment I, the P-paired syllables were rated as more pleasant than the I-paired syllables regardless of whether or not PA performance was superior with them.

Discussion. Both of the experiments reviewed here confirmed the prediction that acquired pleasantness affects PA learning when it is manipulated on the response side, but not when it is manipulated on the stimulus side. The expectation that the acquired-pleasantness effect is essentially a response effect was based on the hypothesis that the primary mechanism for the effect is a disposition to select P-paired items for earlier and more vigorous response rehearsal (Silverstein, 1972a). This hypothesis received additional support in Experiment II, in which response recall was found to benefit from acquired pleasantness to a greater extent and earlier in training than did associative matching. The small superiority found in the associative-matching test for P-paired responses suggests a secondary mechanism for the acquired-pleasantness effect that operates exclusively within the association-learning stage. Silverstein (1972a) hypothesized such a secondary mechanism after finding a small superiority for P-paired responses in *homogeneous* (with regard to pleasantness) test lists, located exclusively within the association-learning stage, and suggested that it was based upon P-paired items having acquired a more reliable capacity to evoke distinctive and effective mediators. But even this association-learning effect requires active response rehearsal, since it appeared only after anticipation training and only on the response side of PA learning.

The fact that the P-paired syllables were rated significantly higher in pleasantness than the I-paired syllables in all conditions of both experiments demonstrates that the absence of superior performance for P-paired syllables in some experimental conditions was *not* the result of their having failed to acquire affective characteristics. Silverstein (1973) has shown that there is often no correlation between judgments of affective quality and performance in learning tasks.

SUBJECTIVE CORRELATION AND THE SIZE NUMEROSITY ILLUSION [1]

MICHAEL H. BIRNBAUM [2]
University of California, San Diego

MARC KOBERNICK AND CLAIRICE T. VEIT
University of California, Los Angeles

Judgments of the numerousness of patterns of dots vary with the size of the background on which the dots are presented. The direction of this judgmental illusion depends upon the experimental correlation between background size and actual number of dots. When the correlation is positive, judged numerousness varies inversely with background size; however, when the correlation is negative, the illusion is reversed. The subjective correlations estimated from an expectancy-contrast model were found to be a monotonic function of the 7 actual correlations used in 2 experiments. These results replicate and extend previous findings for the size–numerosity illusion.

An expectancy-contrast model for the size–numerosity illusion was proposed and tested by Birnbaum and Veit (1973). According to the model, the judgment of numerousness reflects an additive contrast between the numerousness of the dots and an expectancy produced by the context. The expectancy is assumed to depend upon the subjective correlation between numerousness and background size. In simplified form, the model can be written:

$$J = N - R_{NB}B,$$

where J is the impression of numerousness, N is the numerousness of the dots apart from the background effect, R_{NB} is the subjective correlation between numerousness and background size, and B is the subjective size of the background. The product, $R_{NB}B$, is interpreted as the expectancy for numerousness, based on background size. Overt ratings of numerousness are assumed to be a linear function of the impressions.

Several implications of the expectancy-contrast model have received tentative experimental support. First, it should be possible to reverse the direction of the illusion by changing the sign of the subjective correlation. Second, this interaction between background size and correlation is multiplicative and thus should be located in the bilinear component. Third, the effects of background size and numerosity should combine additively, independent of the correlation. Although the data appeared to be in general agreement with the first 2 predictions, a small but statistically significant discrepancy was obtained in 1 condition for the third prediction.

This report replicates the previous work, with an improved experimental design, to provide larger and cleaner effects. The second experiment employs more levels of correlation to examine the relationship between actual and subjective correlation and also explores the effect of changing the correlation.

METHOD

The general experimental procedure was similar to that of Birnbaum and Veit (1973), with several improvements. The main differences were as follows: (*a*) greater variation in background size relative to the variation in number of dots, (*b*) greater manipulation of the correlation, and (*c*) a longer series of warm-up trials.

The stimuli were patterns of black dots, 2.5 mm. in diameter, on square white cardboard back-

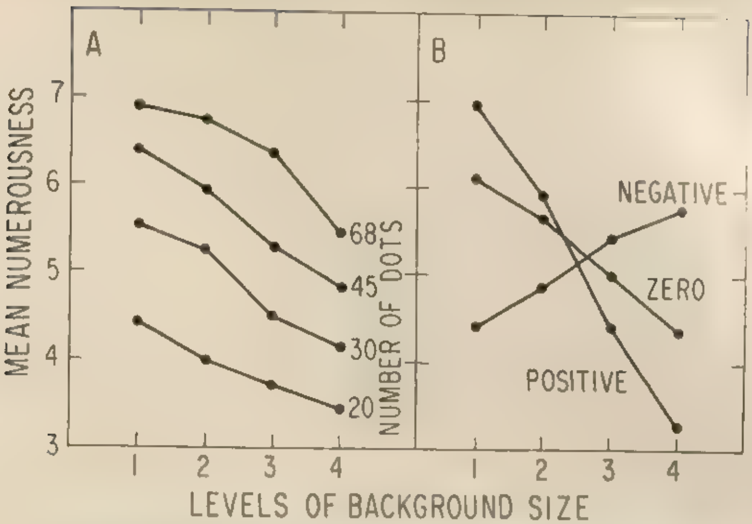

FIGURE 2. Panel A presents mean judgments of test stimuli, averaged across correlation conditions. Panel B, mean judgments of test stimuli, averaged across levels of number and plotted as a function of size for each correlation condition (Experiment I).

grounds of varying size. In presenting the stimuli, the blank side of the card was shown first, then the card was turned over so that *S* could see the dots for 5 sec. The *Ss* made their ratings on a 9-point scale, with 1 = very very few dots and 9 = very very many dots.

The experimental design is shown in Figure 1. The test stimuli (solid squares) represent a 4 × 4 (Number × Size) factorial design, in which either 20, 30, 45, or 68 dots were presented on square backgrounds with side lengths of either 10, 15, 22.5, or 33.8 cm.

The contextual stimuli were presented to manipulate the overall correlation between background size and number of dots. The contextual stimuli for the *positive correlation* (plus signs in Figure 1) paired 8–13 dots with background sizes of 5.0–6.5 cm., and 102–135 dots with background sizes of 54–60 cm.; thus, small numbers of dots appeared on small backgrounds and large numbers of dots appeared on large backgrounds. Contextual stimuli for the *negative correlation* (minus signs in Figure 1) paired 8–13 dots with background sizes of 54–60 cm., and 102–135 dots with background sizes of 5.0–6.5 cm., so that small numbers of dots appeared on large backgrounds and large numbers of dots on small backgrounds. The *zero correlation* condition included half of either type of contextual stimuli.

In Experiment I, the 21 University of California, Los Angeles, undergraduates were divided into 3 groups of 7 *Ss* each, with either positive, zero, or negative contextual stimuli for each group. Each group received an inducing series of 24 randomly ordered presentations of contextual stimuli. Following this series, there were 2 replicates of the 16 test stimuli randomly interspersed among 48 trials of contextual stimuli, giving a total of 104 trials.

In Experiment II, the ratio of contextual trials to test trials (and hence the correlation between size and number) was manipulated. The *Ss* were 30 University of California, Los Angeles, undergraduates divided into 6 groups of 5 *Ss* each. Each group received 16 presentations of contextual stimuli followed by either 36, 24, or 16 positive or negative contextual stimuli interspersed among the basic 16 test stimuli.

After the first series came the counterinducing series, in which 16 contextual stimuli of the opposite sign were presented, followed by the 16 test stimuli interspersed among 24 contextual stimuli of the opposite sign from the first series.

RESULTS

Experiment I. Figure 2A plots mean ratings of numerousness as a function of background size, with a separate curve for each level of numerosity, averaged over correlation conditions. According to the expectancy-contrast model (Equation 1), the curves in Figure 2A should be parallel, because the effects of background size and number of dots combine additively. Although the graphical appearance is somewhat rough, there do not appear to be any systematic deviations from parallelism. The parallelism prediction is supported by a nonsignificant overall Background × Numerosity interaction, $F\ (9,\ 162) = 1.42$. Analyzed separately for each correlation condition, this interaction was also nonsignificant, $Fs\ (9,\ 54) = 1.39$, 1.75, and 2.01 for the positive, zero, and negative conditions, respectively.

Figure 2B shows mean judgments of numerousness as a function of background size, with a separate curve for each correlation condition. Con-

sistent with theoretical predictions, judgments vary *inversely* with background size when the correlation is *positive* and *directly* when the correlation is *negative*. The illusion for the zero correlation group is intermediate, but similar in direction to the positive correlation, consistent with previous results (Birnbaum & Veit, 1973). The interaction between background size and correlation is statistically significant, F (6, 54) = 20.23, with about 98% of its variance in the bilinear component. The residual interaction is nonsignificant ($F < 1$) as were the Context × Number, F (6, 54) = 2.11, and the Context × Background × Number interactions, F (18, 162) = 1.67. These results replicate previous findings for the size-numerosity illusion (Birnbaum & Veit, 1973).

The expectancy-contrast model implies that the curves in Figure 2B should be linear functions of B with slopes proportional to R_{NB}. The curves are very nearly linear functions of the a priori levels of background size, which were chosen in equal log steps. The slopes (reversed in sign) are 3.7, 1.7, and −1.4 for the positive, zero, and negative correlations, respectively. The present illusory effects are much greater than those reported by Birnbaum and Veit (1973). The larger illusions are probably due in part to the improved experimental design and the greater manipulation of the experimental correlation. Part of this increase may be due to a range effect on the category rating scale, attributable to the smaller variation in actual number of dots relative to the variation in background size.

Experiment II. The values of R_{NB} for the first series, estimated from Equation 1, were 5.6, 3.9, 2.8, −1.1, −1.5, and −1.8 for the 6 conditions, in order of decreasing actual correlation. The trend is clearly monotonic. This finding lends further support to the notion of subjective correlation by showing that R_{NB} is sensitive to the actual correlation employed.

The estimated values of R_{NB} for the second series of Experiment II showed a small and nonsignificant effect of the correlation used in the first series; they were positive when the second correlation was positive and negative when the second correlation was negative. The intervening series of 16 reversed contextual trials may have been sufficient to largely erase the preceding experience.

Discussion. The fact that the illusion can be manipulated and reversed through manipulation of the correlation supports the expectancy interpretation of the illusion. The slope for the zero correlation condition would be interpreted to imply that everyday experience produces a positive correlation between size and number (Birnbaum & Veit, 1973). By analogy, these results support an expectancy account of the size-weight illusion (Anderson, 1970).

These results replicate and extend the previous findings for the size numerosity illusion. The improved experimental design appears to produce larger and cleaner effects (Experiment I). The fact that subjective correlation estimated from the model is a monotonic function of actual correlation (Experiment II) provides further support for the expectancy-contrast model of Birnbaum and Veit (1973).

SPATIAL STIMULUS GENERALIZATION AS A FUNCTION OF WHITE NOISE AND ACTIVATION LEVEL

ROBERT E. THAYER[1] AND DAVID CAREY

California State University, Long Beach

Three experiments (91, [illegible], and 68 Ss) were conducted to study spatial stimulus generalization with voluntary S response as a function of white noise and activation level. Activation was assessed by several verbal report measures. Stimulus generalization consistently [illegible]creased with noise, but changes were apparently unrelated to measured activation level. The results do not entirely rule out activation as a mediator, and if a relationship exists, it could involve more than 1 activation dimension. Arguments are made concerning use of the present experimental task and procedure to assess hypotheses concerning attentional selectivity.

Several studies have been conducted on spatial stimulus generalization with voluntary responses. Typically, Ss are trained to respond rapidly to a

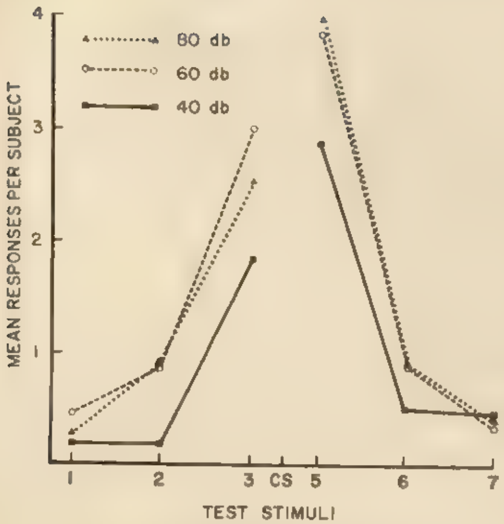

FIGURE 1. Spatial generalization gradients as a function of white noise.

center stimulus and are tested on successive trials when peripheral stimuli are occasionally presented. Generalization gradients as a function of stimulus proximity are then observed.

Previous research has focused on generalization as a function of such variables as "speed-up" instructions, drive, anxiety, and shock (Harleston, 1961; Mednick & Freedman, 1960). Activation is probably common to all these variables. (See Thayer & Moore, 1972, for a further discussion of this point.) However, if it is to be argued that activation is a mediating variable, it is important to provide some kind of direct arousal assessment. Otherwise, diverse underlying physiological states might be confused with a single activation dimension.

While physiological activation measurement is quite complicated, the development of the Activation Deactivation Adjective Check List (AD ACL; Thayer, 1967) offers an easy way of determining multidimensional activation changes from experimental manipulations. The AD ACL is composed of a group of activation-descriptive adjectives which *S*s use to rate their momentary activation feelings. The adjectives have been factor analyzed into 4 independent dimensions: General Activation (e.g., lively, active, full of pep), High Activation (e.g., clutched up, jittery, stirred up), General Deactivation (e.g., at rest, still, leisurely), Deactivation-Sleep (e.g., sleepy, tired, drowsy). These activation dimensions were shown to substantially correlate with physiological measurements and to be sensitive to a variety of activation-inducing conditions. (See Thayer & Moore, 1972, for a current review of validation research.)

The purpose of the present research was twofold. The first purpose was to study spatial stimulus generalization with voluntary *S* response as a function of activation and to assess activation directly with the AD ACL. A second research purpose was to study the effects of white noise as an influe... on generalization. Noise is associated with acti... effects, but previously has not been show... crease generalization.

TABLE 1

MEANS AND STANDARD DEVIATIONS (IN PARENTHESES) OF PERIPHERAL ERRORS (PEs) AND CENTER RESPONSES (CRs) AS A FUNCTION OF WHITE NOISE

Experiment	Noise level and response measures					
	40–45 db.		60 db.		80 db.	
	PE	CR	PE	CR	PE	CR
I	6.1 (3.9)	22.7 (5.3)	9.5 (5.0)	26.8 (5.4)	9.0 (4.1)	25.3 (5.7)
II	5.7 (3.4)	28.1 (5.3)			6.6 (4.0)	28.8 (4.5)
III	4.8 (3.4)	29.0 (4.5)			7.9 (6.6)	30.1 (3.8)

Note. Half of the center responses in Experiment II were multiplied by 1.66 to equate frequency of conditioning trials across counterbalanced conditions.

[2] In this and the 2 subsequent experiments, noise was presented continuously throughout conditioning, testing, and AD ACL administration.

Results. The response measures were defined as follows: *Peripheral errors* occurred during the test period when S responded to a peripheral light as though it were a center light; *center responses* were correct responses to the center light during the conditioning *and* test periods.

Figure 1 indicates the shape of the generalization gradients for the 3 noise conditions. It can be seen that gradients for 40 db. are flatter than those for 60 and 80 db., particularly from Test Stimuli 1, 2, 6, and 7.

Table 1 presents the means and standard deviations of peripheral errors and center responses in each of the noise conditions. Analysis of variance in peripheral errors showed the expected significant effect of intensity, $F\ (2, 88) = 5.34$, $p < .05$. Post comparison tests showed significant differences in the 40:80 and 40:60 db. comparisons, ts $(58, 60) =$ 2.79 and 2.94.

While the above results indicate increased generalization as a function of noise, changes might be due to greater responsiveness to all stimuli, including center stimuli, or primarily to peripheral-stimuli responsiveness. Analyses of center responses showed no significant differences, though the responses did increase as a function of noise. A comparison of the strength of effects (omega squared) for the 40:80 db. conditions showed that noise accounted for 10% of the peripheral-error variation, and 4% of the center-response variation.

The anticipated reported-activation differences as a function of noise were not obtained, nor was there a correlation between errors and activation. The differences across noise conditions were small and inconsistent. There was some tendency for the AD ACL General Activation subtest to be related to peripheral errors within each condition, but the relationships were weak.

Experiment II

Since Experiment I showed noise effects on generalization, but highly variable activation reports, an attempt was made to further investigate the activation relationship with somewhat less error variance. Thus, the manipulations of Experiment I were repeated in a within-*S*s design.

Method. Forty-two male and female *S*s from introductory psychology classes were run in a counterbalanced design (half received 45 db. first and half, 80 db. first). The apparatus and materials were the same as those described in Experiment I, except that tests were not conducted in a soundproof room.

The *S*s were again given 25 conditioning trials and 52 test trials, followed by the AD ACL. They then received 15 more conditioning trials, a second set of 52 test trials, and another AD ACL. An attempt was made to duplicate most of the conditions in Experiment I; however, 45 db. was chosen instead of 40 db. because of a higher uncontrollable ambient noise level in the test room.

Results. Consistent with Experiment I, peripheral errors increased with noise (Table 1), $t\ (41) = 1.69$, $p < .10$. Center responses also increased slightly. Because of the within-*S*s design employed, it is somewhat difficult to estimate strength of independent variable effects (omega squared), but the most conservative estimate would be that noise accounted for 2% of peripheral-error variation, and essentially zero center-response variation.

The AD ACL subtests General Activation and Deactivation-Sleep apparently were not influenced by noise, but substantial noise effects were observed for the High Activation and General Deactivation subtests, $t\ (41) = 2.53$, $p < .02$; $t\ (41) = 4.42$, $p < .001$. Although the activation measures indicated a noise effect, the activation change scores were not correlated with the perceptual-performance change scores.

Experiment III

Since the generalization differences in Experiments I and II apparently were not related to reported activation, the present experiment was designed to investigate alternative individual-difference measures. To investigate the possibility that noise was creating activationlike changes not sensed by the AD ACL, 2 anxiety trait measures were included. Also, *S*s were asked to rate and verbally describe their reactions to the noise.

Method. As in Experiment I, the experimental design was a between-*S*s type; it included one 45- and one 80-db. condition. Sixty-eight male and female introductory psychology students were used. The apparatus and procedure were the same as in Experiment I, except that *S*s were again tested in a nonsoundproof room.

In addition to the AD ACL, the present experiment employed the Manifest Anxiety Scale, a shortened version of the S-R Inventory of Anxiousness, and 2 5-point rating scales on which *S*s could rate the extent that noise generally disturbed their concentration and, specifically, the degree to which the experimental noise influenced their performance. Finally, one question requested a paragraph description of how the experimental noise disturbed performance.

Results. Similarly to Experiments I and II, high noise resulted in increased peripheral errors (Table 1), $t\ (66) = 2.42$, $p < .01$. Center responses also increased, but not to a statistically significant degree. The omega-squared index indicated that 7% of the variation in peripheral errors could be accounted for by noise, while less than 1% of the center-response variation was due to noise.

The AD ACL High Activation subtest may have been influenced by noise, $t\ (66) = 1.69$, $p < .1$, but the other subtests showed small changes. Again, none of the AD ACL scores was reliably related to peripheral errors or center responses.

Ratings by *S*s indicated greater interference from the 80- than the 45-db. condition, $t\ (66) = 2.80$, $p < .01$, but these ratings were not correlated with errors. The other individual-difference measures did not predict peripheral errors or center responses in any reliable and consistent way. Only 56% of the *S*s in the 80-db. condition indicated that noise

interfered with their reactions to the light. Although there was no obvious consistency in *Ss'* verbal explanations of how the sound interfered, one provocative note is that several *Ss* said the noise interfered by making them tense and nervous, while several others said it interfered by making them sleepy and drowsy.

Discussion. Consistent results from all 3 experiments clearly demonstrate that loud noise (i.e., 80 db.) increases spatial stimulus generalization. Furthermore, this effect is primarily due to increased peripheral errors, not increased general responsiveness. Comparisons of the strength of effects of noise between peripheral errors (incorrect responses) and center responses showed that the peripheral-error changes were substantially greater than center-response changes in all 3 experiments. The influence of noise on generalization seems to be the same as special instructions continually prompting *Ss* to speed their responses (Harleston, 1961), and it may be equivalent to such variables as anxiety and drive (Mednick & Freedman, 1960).

However, contrary to expectations, stimulus generalization was not obviously related to [illegible] activation. Although the AD ACL has been shown to substantially correlate with psychophysiological measures and to reliably predict activation-inducing independent variables (Thayer, 1967; Thayer & Moore, 1972), the activation measures did not consistently predict the observed perceptual-performance effects. This is true even though certain AD ACL subscales apparently monitored noise effects reliably in one experiment. Other activation-related individual difference measures, particularly 2 measures of anxiety, did not predict generalization effects either.

Nevertheless, the similarity of the present noise-[illegible] generalization effects to previously demonstrated effects caused by speed-up instructions suggests the common construct of activation. Several [illegible]

states has been demonstrated elsewhere [illegible] Moore, 1972), and it creates substantial [illegible]tions in predicting behavior without [illegible]priate individual-difference measure[illegible]

The present experimental task and [illegible] an interesting possibility for testing [illegible] noise and activation level on attentional s[illegible] Broadbent (1971) has proposed that [illegible] arousal result in the focusing of attenti[illegible] peripheral to central cues when peripheral [illegible] unimportant.

In order to demonstrate selectivity in th[illegible] results, it would be necessary to show [illegible] responsiveness to the center stimulus and [illegible]duced responsiveness to peripheral lights under [illegible] activation conditions. Although loud noise [illegible] produce more responses to the center stimu[illegible] all 3 experiments, there was not reduced responsive[illegible]ness to peripheral cues; rather, as described abo[illegible] [illegible] greater degree than center responses. The presen[illegible] [illegible] Broadbent's (1971) expectations. However, 2 points lead to caution in direct application of these results. First, the nature of the present experimental task [illegible] have introduced confounding psychomotor performance effects in addition to the expected percept[illegible] attention effects. Second, Broadbent and his associates have used higher noise levels to produce arousal than those employed in the present research

* The authors wish to thank [illegible] concerning the relationship [illegible] and attentional selectivity.

THE NONADDITIVITY OF PERSONALITY IMPRESSIONS

MICHAEL H. BIRNBAUM[1]

University of California, Los Angeles

Ratings of the likableness of persons described by 2 adjectives showed con- [illegible] effect of either adjective varied directly with the likableness of the other [illegible] theoretical question of whether interactions were due to nonlinearity in the [illegible] inconsistent with additive models, confirming the interpretation that the interactions are "real" and should not be scaled away. Theoretical and methodological implications are discussed.

[illegible]

fulfillment of the requirements for the PhD [illegible] from [illegible]

[illegible] overall impression [illegible] would be described by both adjectives, and rate how much he would like such a person.

Figure 1 provides a schema for the analysis of impression formation. The 2 stimulus adjectives are referenced by the indices, i and j. The psychological representations of the adjectives, s_i and s_j, are combined by the integration function, I, to form the psychological impression, Ψ_{ij}, which is transformed by the response function, J, to the overt response, R_{ij}.

There are 3 problems to be solved: (*a*) finding the appropriate stimulus representation (s), (*b*) determining the integration function (I), and (*c*) finding the

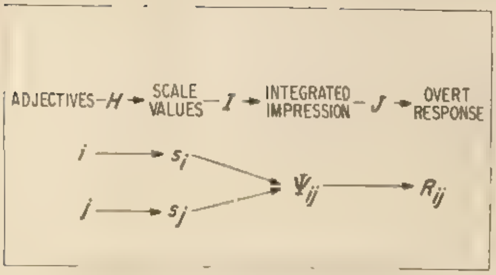

FIGURE 1. Schema for discussing research on information integration.

relationship (J) between the overt responses and the integrated impressions. Any theory of impression formation must deal, at least implicitly, with all 3 of these problems.

ADDITIVE AND CONSTANT-WEIGHT AVERAGING MODELS

A simple linear model provides an example of such a theory. The adjectives are assumed to be represented as single values on a likableness continuum. The I function, defined on all adjective combinations, would be a linear combination of the values of the adjectives:

$$\Psi_{ij} = w_0 s_0 + w_1 s_i + w_2 s_j, \qquad [1]$$

where w_1 and w_2 are the weights reflecting position in the set, s_i and s_j are the scale values of the adjectives, and $w_0 s_0$ is the postulated initial impression, reflecting what the impression would be in the absence of information.

Anderson (1962) pointed out that if sets of adjectives were constructed according to factorial designs, then the analysis of variance test for interactions provides a powerful test of Equation 1. If the adjectives were to change their meaning nonlinearly in combination, if the I function was nonadditive, or if the judgment function (J) was nonlinear, then significant interactions would be expected. If they were nonsignificant, there would seem to be no reason to postulate such complications. The data for the majority of Anderson's (1962b) 12 *S*s appeared to be in rough agreement with Equation 1.

The *constant-weight averaging model* (Anderson, 1968b) is a special case of Equation 1 that requires the weights to sum to 1; the *additive* model places no restriction on the sum of the weights. Critical tests of averaging vs. adding models (in which the number of items in the set are varied) favor the averaging formulation over the additive (Anderson, 1971, 1974, in press). However, when the number of items in the set is held constant, as in the present experiments, the models are equivalent. Therefore, the present article uses the term *additive* to include both additive and constant-weight averaging models.

Anderson's (1968b) review of the evidence for the constant-weight averaging model concluded that

> The model always fits the data quite well, but there are almost always small, significant discrepancies. Inspection of the data has failed to reveal the origin of the discrepancies; they may reflect some fundamental error in the model, or they may result from remaining shortcomings in the experimental technique [p. 736].

Recent studies have shown large discrepancies from the constant-weight averaging model for several information integration tasks. Interactive models have been proposed to account for these nonadditivities (Anderson, 1972; Birnbaum, 1972a, 1972b, 1973; Birnbaum, Parducci, & Gifford, 1971; Lampel & Anderson, 1968). However, there are 2 possible interpretations of the discrepancies that have been observed in these studies: (*a*) the integration (I) of information is not an additive or simple averaging process, or (*b*) the judgment function (J) is nonlinear. The next section shows how previous conceptualizations cannot differentiate these alternatives.

MODEL TESTING AND MEASUREMENT

Assuming Validity of Responses

When the J function is assumed to be linear, models of impression formation can be tested by comparison of theoretical predictions with the raw data. Functional measurement (Anderson, 1970) finds the

stimulus representation in accord with the model to be tested. These stimulus parameters are then used as the basis for statistical tests of fit. If either the model *or* the response scale was incorrect, it would show up as a significant discrepancy. When the data fit the model, the fit is usually interpreted as joint support for both the model and the response scale.

Ordinal Tests

When the J function is only assumed to be strictly monotonic, it becomes more difficult to discriminate among different models. Conjoint measurement analysis (Krantz & Tversky, 1971) describes conditions that ideal data would have to satisfy to be *ordinally* consistent with the theory. For example, crossover interactions would be ordinally inconsistent with additive models, for no monotonic transformation could make the data fit the model. In this case, everyone agrees that the model should be rejected. It should be noted that ordinal violations of additivity will show up as significant interactions in the analysis of variance. The problem arises when significant interactions occur in the *absence* of ordinal violations.

Assuming Validity of the Model

When the additive model is assumed to be valid, then the analysis of variance tests the linearity of the J function. A nonlinear J function will produce significant interactions even though the underlying integration is additive. In the absence of ordinal violations of the model, it is possible to find a monotonic transformation, J^{-1}, which rescales the data to additivity.

When Both Model and Response Scale are in Doubt

Krantz, Luce, Suppes, and Tversky (1971, p. 445) have taken the extreme view that when discrepancies from additivity can be removed by monotonic transformation, they should be attributed to nonlinearity in the response scale, rather than to nonadditivity of the integration function. However, when a monotonic transformation would bring otherwise contradictory data into line with the model, the status of the model remains uncertain. This procedure *assumes* the validity of the model; hence, the existence of such a transformation does not mean that the model is validated. To resolve this difficulty, it is necessary to place transformations within the scope of psychological theory and to provide additional constraints which determine their appropriate application.

Advances in Model Testing

These 4 experiments provide a progressive sequence that systematically eliminates the additive or constant-weight averaging models. The experiments illustrate novel approaches to model testing that remove the difficulty of deciding whether or not to rescale the data. Since these techniques will be of interest to psychologists in many areas, they are outlined briefly below.

The first 2 experiments apply criteria of stimulus and response scale consistency. Experiment I assumed the validity of a priori values for the adjectives obtained in previous work (Anderson, 1968a) and required that the integration model yield scale values that are linearly related. Experiment II investigated the effects of different response procedures, thought to produce different J functions. By a principle of convergent operationism (Garner, Hake, & Eriksen, 1956), if similar interactions are obtained with different response procedures (operational definitions of Ψ), then the interpretation that the interactions are "perceptual" is enhanced.

Experiment III illustrates how the simultaneous evaluation of 2 or more integration processes can provide the leverage to define the concept of an *appropriate* transformation (Birnbaum, 1972b; Birnbaum & Veit, 1974). *Stimulus scale invariance* requires that the scale values (s in Figure 1) be independent of task. *Response scale invariance* requires that the J function be independent of task.

In Experiment III, *S*s performed 2 in-

tegration tasks, rating the difference in likableness between the 2 adjectives as well as the likableness of a person described by the combination. Since the same stimuli and response scale were employed for both tasks, response scale invariance requires that the *same* J-inverse transformation be applied to both tasks. The stimulus scale convergence criterion defines an *appropriate* rescaling of the combination ratings as one which *both* makes an hypothesized model fit the data *and* leads to the derivation of scale values that agree with those derived from the difference task.

Although rescaling of the data might make the model fit a single set of data, the transformation that reduces the interactions implies which psychological differences are greater than or equal to others. Experiment IV obtained direct ratings of these differences, and it tested whether these ratings are qualitatively consistent with the transformation that makes the data additive.

Experiment IV required only the ordinal information in the data to reject the additive and constant-weight averaging models. This leverage was provided by a compound integration task in which *S*s rated the difference in likableness between pairs of hypothetical persons, each described by a pair of adjectives. The ratings can be rescaled to fit the subtractive model; this rescaling may or may not make the additive model of impression formation fit. Thus, difference judgments can be used as a basis for response rescaling to provide a scale-free test of the constant-weight averaging model of impression formation.

Experiment I: Test of Additive Models

The first experiment was designed to uncover the nature of the discrepancies previously observed. Although the basic procedures were similar to those of the research described by Anderson (1968b), these were modified to permit a clearer assessment of the expected interactions. Thus, only 2 factors were employed, but each was represented by a greater number of levels covering a wider range. This permitted a greater variation of within-set range.

Method

The *S*s were presented with pairs of personality-trait adjectives and were instructed "your task is to imagine a person who would be described by *both* of the traits and judge how much you would like such a person." The *S*s recorded their judgments in numerical form, using 1 of 9 ratings for each pair: 1 = dislike very very much, 2 = dislike very much, 3 = dislike, 4 = dislike slightly, 5 = neutral (neither like nor dislike), 6 = like slightly, 7 = like, 8 = like very much, and 9 = like very very much.

Subjects. The *S*s were 300 University of California, Los Angeles, undergraduates fulfilling a requirement in introductory psychology. One hundred different *S*s served in each replicate of the experiment.

Stimuli. The adjectives were taken from Anderson's (1968a) list of 555 common personality-trait adjectives. Each stimulus replicate consisted of a set of 25 adjective pairs produced from a 5 × 5 (Adjective A × Adjective B) factorial design. The 5 levels of likableness of each adjective factor were separated by steps of approximately 1.28 on Anderson's 0–6 normative scale. The adjectives are printed (with normative values in parentheses) in the margins of Figure 2.

Procedure. The 25 adjective pairs were printed in 1 of 6 random orders on the same page with the instructions and the labeled response scale. The adjectives in each pair appeared side by side, with the adjective from Factor A on the left for half of the forms. The *S*s were instructed to read through the entire list before beginning to record their ratings.

Results and Discussion

Additive and constant-weight averaging models. The 3 panels of Figure 2 show the mean judgment of each adjective pair, averaged over all *S*s within the replicate. The mean judgments are plotted as a function of the normative value for the adjective from Factor A, with a separate curve for each adjective from Factor B. The slope of the curves represents the effects of the Factor A adjective. The vertical differences between the curves represent the effects of the Factor B adjective. According to additive or constant-weight averaging models, the curves in each panel should be parallel; that is, the effect of one adjective should not

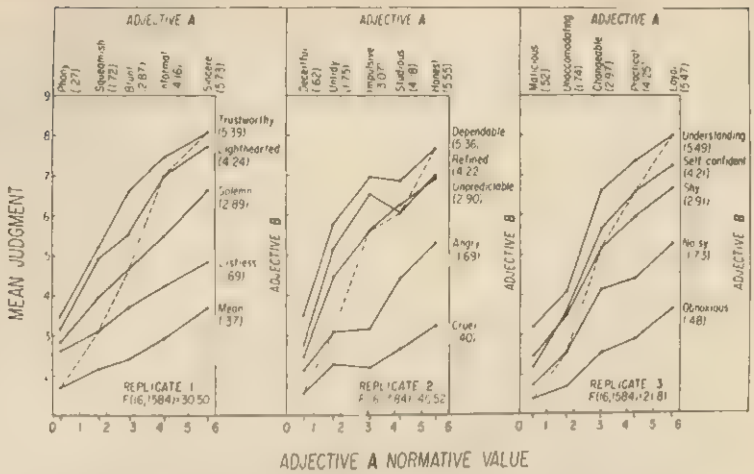

FIGURE 2. Mean ratings of likableness of pairs of adjectives: Experiment I. (Anderson's, 1968a, normative values for individual adjectives are listed above and to the right of each panel.)

depend upon the particular adjective with which it is paired. Instead, the curves in each panel diverge to the right; the effect of either adjective appears to be proportional to the likableness of the other adjective describing the same person.

This divergence was characteristic of the data for most of the individual *S*s: 88%, 88%, and 89% of the *S*s in the respective replicates showed this form of interaction. In Experiments I–IV between 85–95% of the single *S*s resembled the group data. The A × B interactions are highly significant for each of the replicates; *F* values for these interactions are indicated in the panels of Figure 2. Of course, the *F* is much larger when the data from all 3 replicates are combined, F (16, 4752) = 72.80. If the response scale of this experiment is assumed to be valid, the interactions shown in Figure 2 can be interpreted as evidence against the additivity of impressions.

Although the A × B interaction varies between stimulus replicates, F (32, 4752) = 8.28, this higher order interaction is small in comparison with the similarity of the nonadditivities. There are, however, a few peculiarities that appear to depend upon the meanings of the particular adjectives. For example, SELF-CONFIDENT & MALICIOUS is less likable than SHY & MALICIOUS although SELF-CONFIDENT is more likable than SHY in combination with other traits. A SELF-CONFIDENT, malicious person may be perceived as more likely to carry out malicious actions than a SHY one. But the divergent interaction occurs in all 3 replicates and represents the main source of difficulty for the additive models.

Multiplicative model. The multiplicative model, $\Psi_{ij} = s_i s_j$, predicts that the curves in each panel should be a diverging fan of linear functions. The interaction should be located entirely in the bilinear component (Anderson, 1970). Although the major portion of the variance of the interaction (81.6%, 56.2%, and 86.9% for the 3 replicates) was located in the bilinear component, the residuals were also statistically significant, Fs (15, 1485) = 6.36, 20.68, and 3.26. The nature of the discrepancy can be seen most clearly in the second panel of Figure 2. According to the multiplicative model, the curves should be linear; instead, the upper curves are negatively accelerated relative to the lower curves. The other 2 replicates show the same discrepancy, but to a lesser degree.

Range model. The range model was fit to the data (averaged over replications) following the general procedures outlined in Birnbaum et al. (1971), and using

Anderson's (1968a) normative values as estimates of the scale values. The range model, using just one additional parameter, accounts for some 80% of the variance left unaccounted for by the constant-weight averaging model.

Averaging model with differential weights. The mean absolute discrepancy was only .05, indicating a very good fit to 15 points using 10 parameters. The best-fit estimates of scale values for the 5 levels were 1.49, 3.02, 5.24, 6.48, and 7.83; the best-fit weights were 1.92, 1.18, .67, .73, and .90. Fewer parameters are required with the assumption of the validity of Anderson's (1968a) values and by estimating the weights as a polynomial function of scale value. Although this procedure uses more parameters than the range model, the fit was not as good.

Rescaling. Interactions in the analysis of variance might be due to a nonlinear relationship between the impressions of likableness and the overt responses of the *S*s. Thus, the actual impressions may be additive, but the overt responses may be related only ordinally to the theoretically correct response scale. The possibility of response scaling was investigated using 2 techniques of data transformation.

The first technique assumes that Anderson's (1968a) normative values for the single items are appropriate estimates of the scale values and that judgments of pairs of items of equal value should be linearly related to the judgments of the single items (Birnbaum, 1972a). The transformation is then estimated as a polynomial by a least squares criterion. The advantage of this technique is that although it is capable of producing a radical rescaling, it will not eliminate "real" interactions that depend upon differences in within-set range, if the a priori scales are appropriate. As can be seen in Figure 2, the judgments of pairs of minimal within-set range (connected by dashed lines) are already nearly linearly related to normative ratings of single values. If anything, this function (treated in this procedure as the J function of Figure 1) is slightly negatively accelerated, so that the rescaling that makes it linear would actually increase the magnitude of the divergent interaction.

If the divergent interaction is real, then the distribution of psychological impressions is somewhat positively skewed (as given by the projection of the data points on the ordinate of each panel of Figure 2). Positive skewing would lead to a negatively accelerated judgment function according to range–frequency theory (Parducci & Perrett, 1971). This suggests that contextual effects operating on the J function would tend to counteract the effects of true interactions. Birnbaum et al. (1971, Experiment V), demonstrated that manipulation of the frequency distribution of physical means of sets of psychophysical stimuli influences the form of the interaction between the components in a manner predictable from range–frequency principles of judgment.

The second transformation procedure assumes that the integration is additive (or constant-weight averaging) and attempts to transform the data to fit the additive model (Kruskal, 1965). The monotone analysis of variance (MONANOVA) computer program (Kruskal & Carmone, 1969), applied to the mean judgments, greatly reduced the percentage of total variance in the interaction (from 5.0% to .4%). Thus, the data appear roughly consistent with the constant-weight averaging or additive model at an ordinal level. The fact that the data can be transformed to fit raises a difficult theoretical problem: Is the nonparallelism in Figure 2 due to nonadditive integration of information or to a nonlinear response function?

If the additive model is assumed to be correct, the MONANOVA analysis indicates that the judgments are a positively accelerated function of the impressions. Additionally, it would mean that the scale values for adjectives presented in pairs are a negatively accelerated function of Anderson's (1968a) values for the same adjectives presented singly. The positively accelerated function for J derived from the MONANOVA analysis can be interpreted by range–frequency theory (Parducci & Perrett, 1971) to indicate that

the psychological distribution of stimuli is negatively skewed. Kanouse and Hanson (1972) have also hypothesized that the distribution of evaluative stimuli is negatively skewed, but based their arguments on other considerations.

In short, Experiment I demonstrates that ratings of likableness are inconsistent with the additive models. However, 2 interpretations are consistent with the data. The first assumes that the ratings are valid measures of psychological impressions and concludes that the integration of information is nonadditive. The second assumes the validity of the constant-weight averaging (or additive) model and concludes that the responses are a positively accelerated function of the impressions. Both interpretations can account equally well for the data of Experiment I. Consequently, the following experiments were designed to discriminate them.

Experiment II: Variation of Response Scales

The earlier experiments yielding data more consistent with the additive models have used other procedures for obtaining *S*'s response (see Anderson, 1974, in press). The interactions observed in Experiment I may be due to nonlinearity in the *J* function that depends upon the particular procedure *S* uses to indicate his impressions. Therefore, Experiment II tested the additive models using several different procedures for responding to assess whether the interaction obtained in Experiment I is specific to the 9-category rating scale used in that experiment. Each of the 4 conditions of the present experiment tested a different interpretation of how the interactions might depend upon the method for responding: reversing the scale, endpoint anchoring with 20 categories, linemark responses, and matched pairs.

Although the matched pairs procedure has not been used before, it has the apparent advantage that it does not require a metric response from the *S*. Thus, this procedure avoids the argument that metric responding may induce *S*s to integrate separate implicit responses to the individual adjectives rather than forming an overall impression before responding.

Method

As in Experiment I, *S*s read pairs of personality-trait adjectives and judged how much they would like hypothetical persons who would be described by both adjectives. The conditions differed with respect to the instructions for the response. Each set of instructions was used in a separate small experiment, with different *S*s.

For the reversed scale, 1 = like very very much and 9 = dislike very very much. The *S*s were consequently instructed to rate how much they would *dislike* the hypothetical persons. The 20 *S*s rated the adjective pairs of both Replicates 1 and 2 of Experiment I.

The 20-category scale was anchored by instructions that 1 represented the likableness of a person who would be described by MEAN, PHONY, MALICIOUS, OBNOXIOUS, and LIAR; 20 represented the likableness of SINCERE, LOYAL, INTELLIGENT, UNDERSTANDING, and DEPENDABLE. The *S*s were instructed to judge each adjective pair relative to these end anchors and to assign a numeral between 1 and 20 to represent the appropriate position relative to the end values. The 34 *S*s rated the 25 adjective pairs of Replicate 2.

For the linemark response, *S*s were instructed to indicate each judgment of likableness by making a short vertical mark on a line so that the length between the margin and the mark would be proportional to the likableness. The 46 *S*s in this condition judged the adjective pair of Replicate 2.

The list for the matched pairs procedure was constructed from Anderson's (1968a) normative data. Each pair contained 2 adjectives of equal scale value. The 22 pairs covered the baseline range .35–5.60, in .25-category steps. The 50 *S*s were instructed to judge each of the adjective pairs of Replicate 2 by selecting the pair of adjectives from the list of 22 pairs, "most nearly equal in likeableness to the pair you are judging." The value of *S*'s response was taken to be the normative value of the adjective pair selected by *S*. The 22 pairs are listed in Birnbaum (1972b).

Supplementary scaling. These 22 adjective pairs and the 30 adjectives used in Experiment I were printed in random order. Each of 100 *S*s judged 3 aspects of each adjective or pair: (*a*) the *likableness* of a person who would be described by the adjective or pair, (*b*) the *activity* of such a person, and (*c*) the *range* of likableness of persons who would be described by the adjective(s). The *S*s judged all of the adjectives on one aspect before proceeding to the next task. Nine-point scales were used for all 3 scaling tasks, with 9 = like very very much, very very active, or very very wide range of possibilities.

Results and Discussion

Figure 3 shows the mean responses, averaged across *S*s, in each condition.

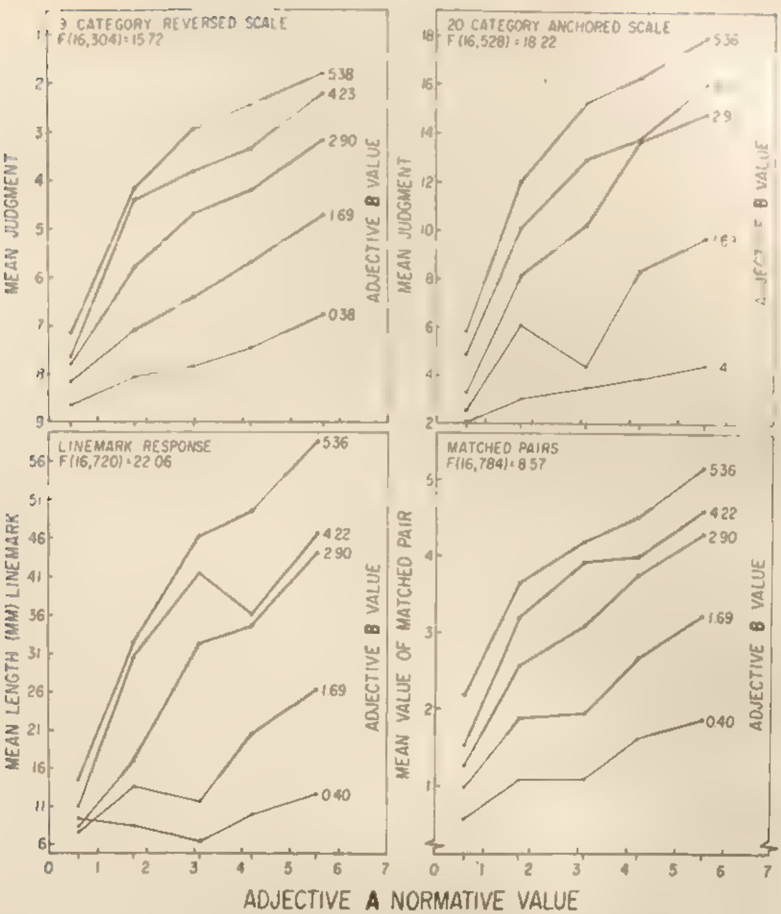

FIGURE 3. Mean judgments of likableness of pairs of adjectives: Experiment II. (Each panel shows results for a different response procedure.)

Additive and constant-weight averaging models again predict parallel curves for each panel. Instead, the interactions are all of the same general form (divergence) as in Figure 2, and the F values listed in each panel show that they are all highly significant.

The ordinate of the upper left-hand panel of Figure 3 has been relabeled for direct comparison with Figure 2. The data show the same interactions, and ratings of "dislikableness" appear to be a linear function (with negative slope) of ratings of "likableness." Since reversing the scale did not reverse the interaction, the deviation from additivity cannot be attributed to anything like preference for smaller numbers. The interaction for the anchored scale (upper right-hand panel) shows the same divergent form as those shown in the other panels and is highly significant. The percentage of variance associated with the interaction is actually larger for the linemarks condition than for any of the other conditions. The positively accelerated relationship between linemarks and category ratings may account for the larger interaction.

The matching procedure assumes that the normative values obtained by Anderson (1968a) are valid estimates of scale values. One check on this technique is to see whether the pairs having minimal within-set range are linearly related to Anderson's scale values. As can be seen by connecting these points (the diagonal) in the lower right-hand panel of Figure 3, this assumption is supported. Never-

theless, the interaction has the same divergent form as the others and is highly significant. The results for this nonnumerical response technique do not support the objection that perhaps *S*'s integration strategy is affected by the numerical response procedures typically used in this type of study. The error terms for this method were greater than for any of the other methods, perhaps because *S*s must judge the pairs of items defining the scale in addition to the usual stimulus pairs.

In summary, the main conditions of Experiment II show that variation of experimental procedures for responding did not eliminate the divergent interaction. Each procedure can be considered an alternative operational definition of the impression. By the principle of converging operations (Garner et al., 1956), the divergent interactions in Figure 3 support the interpretation that *impressions* of personality are nonadditive. In order to retain the additive model, it would be necessary to assume that the responses for all of these procedures are nonlinearly related to the impressions.

Supplementary scaling. One purpose of the supplementary scaling was to check a previous prediction (Birnbaum, 1972a) that items of lower value have narrower dispersions. Successive interval scale values and dispersions (Torgerson, 1958) were obtained for each adjective and adjective pair. Mean ratings were linearly related to Anderson's normative values and to Thurstone scale values derived from the same data. In agreement with the distributional interpretation, Thurstone scale values were positively correlated with dispersion values ($r = .65$). Since each of these dispersions was produced by the differences between the responses of different *S*s to the item, they are probably not the best estimates of the distribution of meaning for the adjectives. Only if it is assumed that different *S*s select a randomly sampled "person" from the distribution of "persons" who possess the trait would the Thurstone dispersion reflect this dispersion directly. Nevertheless, the correlation between value and dispersion seems consistent with this prediction.

Subjective estimates of the range of likableness seem a more direct measure of dispersion. These were highly correlated with mean ratings of likableness ($r = .91$). The plot of this relationship showed that although range is a nearly linear function of likableness for the dislikable traits, neutral and positive traits are all seen as implying similar wide ranges of likablenesses. This finding is consistent with the fact that the interactions in Figure 2 appear to be located in combinations that include dislikable traits. In a post hoc analysis of the 2 × 2 subdesign containing only positive adjectives for Experiment I, the interaction was nonsignificant ($F < 1$). The 2 × 2 subdesign containing the negative traits had a significant interaction, $F(1, 297) = 5.93$.

In summary, the supplementary scaling suggests that adjectives should be represented by distributions, with the lower valued items having smaller variance.

Supplementary test of activity. One interpretation of the crossover interaction observed in Experiment I, Replicate 3 (Figure 2) is that the activity component of the meaning of one adjective can multiply the evaluative component of the adjective with which it is paired. Hence, a SELF-CONFIDENT MALICIOUS person is more actively malicious than a SHY one. Similarly, an IMPULSIVE CRUEL person may be more likely to act cruel than an UNTIDY one (Experiment I, Replicate 2).

This hypothesis—that one adjective can behave like an adverb—was further investigated by having 130 additional *S*s rate the likableness of 36 hypothetical persons, each described by 2 adjectives produced from a 6 × 6 factorial design. The adjectives for the first factor varied in likableness (RUDE, IMMATURE, TROUBLED, DIRECT, INTELLECTUAL, and HONEST). The adjectives for the second factor were relatively neutral in likableness, but 3 were "active" (IMPULSIVE, AGGRESSIVE, and CHANGEABLE) and 3 were "passive" (QUIET, HESITANT, and SHY).

Consistent with the prediction, the likableness effect of an adjective was greater when paired with an active adjective. The interaction was large and significant,

F (25, 3225) = 14.49, and even showed reliable crossovers; for example, HESITANT & HONEST is less likable than AGGRESSIVE & HONEST although HESITANT & RUDE is more likable than AGGRESSIVE & RUDE.

Ratings of the activity of the 30 adjectives used in Experiment I were uncorrelated with ratings of likableness of the same adjectives but were correlated with the Thurstone dispersions (r = .43). The activity hypothesis is not sufficient to account for the overall divergent interactions in Figures 2 and 3, but it appears to explain some of the second-order effects (which would otherwise be called "peculiarities") for particular adjective combinations in Experiment I.

Experiment III: Subtractive Preference versus Additive Combination

Experiment III had the following objectives: (*a*) to evaluate a subtractive model for preference judgments reflecting the *difference* in likableness between 2 hypothetical persons, each described by one adjective; (*b*) assuming that the subtractive model were to fit, to compare scale values for the preference task with those obtained for the usual *combination* task, in which *S*s judge the likableness of a person possessing both traits; (*c*) to use the scale values obtained for the preference task as the basis for rescaling the data from the combination task; (*d*) to use the scale values for the preference task to evaluate Anderson's normative values for single items; and (*e*) to evaluate the effects of a change in instructions for the combination task, in which the adjectives are given equal importance and accuracy.

The subtractive model asserts that preference ratings can be represented as the algebraic differences between the values of the items:

$$\Psi_{ij}{}^{\mathrm{D}} = s_i - s_j, \qquad [2]$$

where $\Psi_{ij}{}^{\mathrm{D}}$ is the psychological difference in likableness (preference for Stimulus i over j), and s_i and s_j are the scale values of these 2 stimuli. If the subtractive model can be fit to the data, then the adjectives can be located as points o[illegible] a unidimensional likableness continuum [illegible]

Two principles of scale converge[illegible] be applied to this experime[illegible] sponse scale invariance: Wit[illegible] set of stimuli and the same r[illegible] cedure, the judgment function [illegible] to be independent of task. (*b*) St[illegible] scale invariance: With the sam[illegible] stimuli, the scale values of the stim[illegible] assumed to be independent of task. [illegible] ciple *a* implies that whatever transforma[illegible] tion is applied to fit the data to [illegible] ditive model for the combination [illegible] should also be applied to the data [illegible] the difference task. Principle *b* impli[illegible] that irrespective of whatever transformations of the responses fit the data for the 2 tasks to their respective models, the scale values derived from the subtractive model should be linearly related to the scale values for the same adjectives in combinations. Stimulus scale invariance can be considered a necessary (but not sufficient) condition for establishing meaningful scales and psychological laws. A failure of scale convergence can provide the leverage for rejecting either the subtractive or additive model, even though the J functions are unknown.

Method

Stimuli. The stimuli were the adjective pairs of Experiment I.

Subjects. The *S*s were 90 University of California, Los Angeles, undergraduates, 30 serving in each replicate.

Procedure. Each *S* performed both tasks, with half of the *S*s in each replicate performing the difference task first. There were no effects of task order.

In the difference task, *S*s were instructed to imagine 2 different people, each described by one of the adjectives of each pair, and then to judge the difference in likableness between the 2 persons. The 9-point scale had labels varying from 1 = like the person (described by the adjective) on the left very very much more than the person (described by the adjective) on the right, through 5 = like both persons equally, to 9 = like the person on the right very very much more than the person on the left.

The procedure for the combination task was in all respects identical to that of Experiment I, except that the instructions were modified to emphasize that the adjectives should be considered

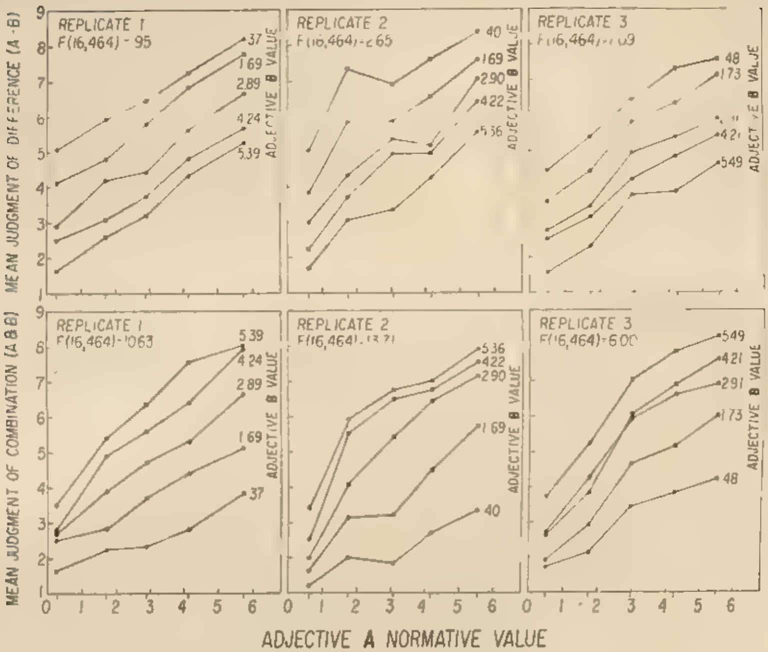

FIGURE 4. Mean ratings of difference in likableness between 2 hypothetical persons, each described by a single adjective (upper panels), and mean ratings of likableness of hypothetical persons, each described by the same 2 adjectives (lower panels): Experiment III.

of equal importance and accuracy, each word having been contributed by a different acquaintance "who knows the person well."

Results and Discussion

Difference task. The upper panels of Figure 4 show the mean judgments of the difference in likableness. Because ratings reflect the difference between Factors A and B, the slopes are positive, but the order of the curves is negative.

Since the subtractive model is a special case of an additive model, the parallelism of the curves supports its validity. Only the interaction for Replicate 2 is significant, and examination of the figure indicates that the interaction is minor and mainly due to one point. Since Anderson's (1968a) normative values are plotted on the abscissa, the near linearity of these functions supports the validity of the normative values as estimates of scale values. Similarly, the vertical separations between the curves are nearly proportional to differences in Anderson's scale values. The good fit of the subtractive model supports the validity of the category rating scale and indicates that the adjectives can be located on a unidimensional likableness continuum.

Combination task. The lower panels of Figure 4 show the mean judgments of the likableness of persons described by both adjectives. The data appear to replicate Experiment I closely, including the peculiarities for ratings of particular adjective combinations. The interactions for this experiment diverge in the same fashion as Experiment I and are highly significant for each replicate, as indicated by the F values printed in the panels of the figure. The F values are smaller than those for Experiment I because there were fewer Ss in this experiment. The change in instructions, emphasizing equal importance and accuracy, appears to have had no discernible effect on the interactions.

Scale convergence. Both the stimulus and response scale invariance assumptions would require that either the subtractive

model for differences or the constant-weight averaging model for combinations must be rejected. Response scale invariance implies that any transformation of the ordinate of the lower panels must be applied to the upper panels as well. Because the subtractive model fit the data directly, any nonlinear transformation would induce an interaction. Therefore, if the validity of the subtractive model and the principle of response scale invariance are assumed, the constant-weight averaging model must be rejected.

The fit of the subtractive model implies that the marginal means for these data constitute an interval scale for the adjectives (Anderson, 1970). However, when the combination data were rescaled to additivity using Kruskal's (1965) MONANOVA, scale values derived from this procedure were nonlinearly related to those for the same adjectives derived from the subtractive model. Therefore, the principle of stimulus scale invariance implies that this transformation would *not* be appropriate.

Further support for the validity of the rating scale is provided by the finding that ratings of homogeneous combinations (adjectives of similar normative value) are nearly linearly related (slightly sigmoidal) to subtractive model scale values. Hence, the assumption of stimulus scale invariance implies that the J function is roughly independent of task. Thus, 3 procedures agree—Anderson's (1968a) normative values, subtractive model scale values, and ratings of homogeneous combinations are all nearly linearly related.

This analysis also indicates that a simple multiplicative model, $\Psi_{ij} = s_i s_j$, would be inappropriate for the combination task; it would incorrectly predict that judgments of adjectives of equal value are a positively accelerated quadratic function of the scale values for the difference model. However, a geometric averaging model (square root of the product of the scale values) would still be consistent with the subtractive model scale values.

The data of Experiment III indicate that with the same stimuli, *S*s, and general experimental procedure, ratings of [illegible]r-ence are consistent with a su[illegible] model, but ratings of combinatio[illegible] again inconsistent with the additive mo[illegible]ls. This suggests that the intera[illegible] due to trivial details of experim[illegible]cedure. If scale values for the adje[illegible]s are assumed to be independent of [illegible]k, the fact that the ratings of homoge[illegible]s combinations are a nearly linear fu[illegible]on of the scale values for the difference ra[illegible]s implies that it would be inappropria[illegible] rescale the ratings of combination[illegible] order to retain the additive mo[illegible] would be necessary either to reje[illegible] subtractive model (in spite of its goo[illegible] to the data in Figure 4), *or* assume t[illegible] *both* the scale values *and* the respo[illegible] function depend upon the task.

Experiment IV: Qualitative Nonadditivity

Experiment IV was designed to provi[illegible] a test of additivity that would requir[illegible] only the ordinal information in the data. The evidence against the additive and constant-weight averaging models obtaine[illegible] in the first 3 experiments is illustrated [illegible] Figure 5A, where the difference in rati[illegible]g between a_2b_2 and a_2b_1 is greater than t[illegible]e difference between a_1b_2 and a_1b_1. An a[illegible]ditive model requires that these differences be subjectively equal. If the J function is assumed to be linear, then differences in judgment are proportional to differences in the impressions; therefore, the divergence (previously shown in Figures 2, 3, and 4) would be contrary to additive models. However, if J were positively accelerated, impressions might be additive. The same ratings have been transformed to parallelism in Figure 5B. Although the difference in rating (Figure 5A) due to the change from b_2 to b_1 depends on whether a_1 or a_2 was in the same set, the difference in psychological value (Figure 5B) is assumed by additive models to be constant.

Experiment IV tested this possibility by asking *S*s to judge directly the differences in likableness between integrated impressions. The success of the subtractive

model in Experiment III suggests that it can be used to infer the impressions of the combinations. It is only necessary to assume that ratings of differences in likableness are strictly monotonic to differences in psychological impressions. If the interaction is real, then the preference for a_2b_2 over a_2b_1 should exceed the preference for a_1b_2 over a_1b_1, as illustrated by the length of the dashed arrows in Figure 5A. If the interaction reflects only a nonlinearity in the J function, however, then the 2 preferences should be equal, as shown by the dashed arrows of Figure 5B.

The matrices in the lower panels of Figure 5 illustrate 2 patterns of data that might be obtained for ratings of the difference in likableness between 2 persons, each described by a pair of adjectives. Figure 5C shows the pattern that would be obtained if the integration of information were nonadditive. Each pair of circled entries is an example of a predicted rank-order comparison. The dashed ar-

MALICIOUS & OBNOXIOUS	5.03	6.35	6.37	[illegible]
MALICIOUS & UNDERSTANDING	3.77	5.00	[illegible]	[illegible]
LOYAL & OBNOXIOUS	3.58	4.85	5.06	[illegible]
LOYAL & UNDERSTANDING	1.98	2.55	2.40	[illegible]

rows represent the same comparison as the dashed arrows in Figure 5A. Since the ratings represent judgments of differences between impressions labeled by the column and the row entries, the direction of the order is reversed below the diagonal. Figure 5D represents the type of pattern that would be obtained if the adjectives combined additively. Each pair of circled entries would be equal. Both matrices in Figure 5 were generated by assuming the subtractive model for preference (Equation 2). However, the rank order of the matrix entries would remain the same if subjected to a strictly monotonic transformation. Thus, the data can be rescaled to fit the subtractive model without precluding the ordinal test for the additive integration models for impression formation (Birnbaum, 1972b).

For example, if the interaction shown in Figure 2 is real, then the judged difference in likableness between someone who is UNDERSTANDING & LOYAL and someone who is UNDERSTANDING & MALICIOUS should exceed the judged difference between someone who is OBNOXIOUS & LOYAL and someone who is OBNOXIOUS & MALICIOUS. But if adjectives [illegible] integrated according to an additive [illegible] constant-weight averaging model, then the 2 differences would be equal.

Method

The *S*s were instructed to judge the [illegible] in likableness between pairs of hypothetical [illegible], each of whom was described by 2 adjectives. Two adjectives were printed on the left side of the page and 2 on the right side of the page. The *S*s were instructed to form impressions of the personalities of the 2 persons before judging the difference in likableness. The 2 adjectives describing each person were described as being of equal accuracy and importance; *S*'s task was to imagine that they were contributed by different, but equally reliable, sources. Judgments were in terms of a 9-point scale, labeled as in the difference task of Experiment III.

Subjects. The *S*s were 195 University of California, Los Angeles, undergraduates, 65 in each of 3 stimulus replicates.

Stimuli. The stimulus for each judgment consisted of 4 adjectives, 2 printed on the left side of the page and 2 on the right. The adjective pairs describing the "person on the left" were produced from a 3 × 3, A × B, factorial design; the adjective pairs on the right were constructed from a 2 × 2, C × D, factorial design. Each person on the left was combined with each person on the right producing a 3 × 3 × 2 × 2, (A × B) × (C × D), factorial design.

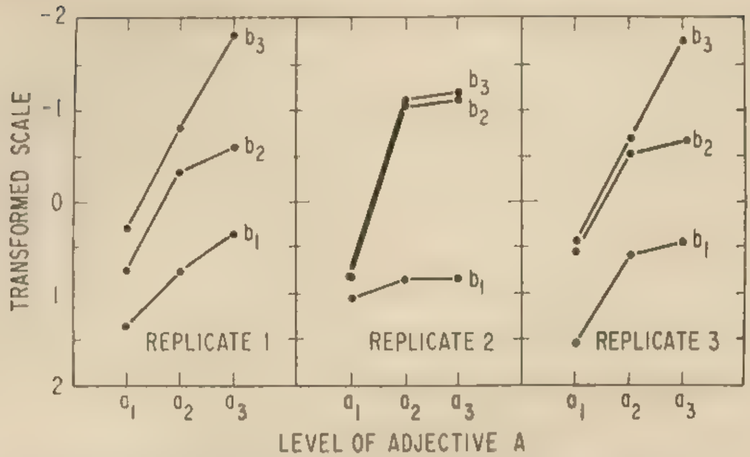

FIGURE 6. Transformed impression values for the person on the left derived from MONANOVA applied to difference ratings. Experiment IV (The 3 levels of subscripts refer to low, medium, and high likableness adjectives of Experiment I. For example, a_1 = PHONY, a_2 = BLUNT, and a_3 = SINCERE, for Replicate 1. To assess metric information in mean ratings, compare this figure with Figure 2.)

The basic idea of the stimulus construction can be understood by consideration of Figure 2. For the third replicate, the adjectives were a_1 = MALICIOUS, a_2 = CHANGEABLE, a_3 = LOYAL, b_1 = OBNOXIOUS, b_2 = SHY, b_3 = UNDERSTANDING, c_1 = MALICIOUS, c_2 = LOYAL, d_1 = OBNOXIOUS, and d_2 = UNDERSTANDING. With respect to Figure 5C, the last entry in the first row (9) would represent the rating of the difference in likableness between someone who is LOYAL & UNDERSTANDING and someone who is MALICIOUS & OBNOXIOUS. Nine additional cells in the design were constructed for each replicate by pairing each person on the left with an additional person on the right who was INFORMAL & LIGHTHEARTED. Therefore, the entire design represents a 9 × 5 factorial design with the factors representing the person on the left and the person on the right (see Birnbaum, 1972b).

Procedure. The 45 trials were printed in 1 of 3 different random orders in booklets with different page orderings for different *Ss*. The *Ss* read through the entire list before beginning to record their judgments.

Results and Discussion

The mean judgments of difference in likableness are presented in Table 1 for that part of the design illustrated in Figure 5. Comparison of the rank order of the ratings with the direction of the differences for the circled values shows that the pattern resembles that of Figure 5C representing an interaction: Differences in rating from Experiments I, II, and III predict the ratings of differences in the present experiment.

The crucial comparisons (circled entries in Figure 5D), which must be equal for the additive or constant-weight averaging model, are significantly in the direction predicted by the interactions in Figures 2–4 for all 3 replicates, Fs (1, 64) = 71.13, 115.88, and 89.54, respectively. The individual ratings by single *Ss* show the same pattern of rank orders for these crucial comparisons as the mean judgments in the table. Of the 195 *Ss*, 81 were in perfect ordinal agreement with the interaction obtained in the first 3 experiments for all 4 comparisons. Only 12 *Ss* showed a greater number of rankings in the direction opposite from that predicted by the interaction, compared with 170 *Ss* whose rankings were in the direction predicted by the interactions obtained in Experiment I. These results are clearly inconsistent with the additive model which would predict an equal split of these rankings between the 2 directions.

The larger, 9 × 5 design was used to test the subtractive model for preferences between combinations. The subtractive

model also predicts parallelism, and the data appeared roughly parallel when plotted. However, statistically significant interactions were obtained for each stimulus replicate, Fs $(32, 2048) = 3.72$, 4.98, and 5.10 for Replicates 1, 2, and 3, respectively. Application of MONANOVA to these ratings of preference reduces the interaction to less than 1% of the total variance, so it is apparent that the preference ratings are at least ordinally consistent with the subtractive model.

Following the application of MONANOVA to the 9×5 subtractive model design, the derived impression values for the combinations were inconsistent with the additive and constant-weight averaging models. Figure 6 plots the impression values derived from the MONANOVA transformation for the 9 persons on the left. Since these were produced from a 3×3 factorial design of adjectives, the nonparallelism of these scale-free values refutes the additive models of impression formation. Similar results were obtained for the 2×2 design for persons on the right.

In summary, the minimal assumption that the preference ratings are monotonically related to subjective differences leads to the conclusion that the additive and constant-weight averaging models must be rejected. Comparison of scale-free values in Figure 6 with the scale-dependent ratings in Figures 2, 3, and 4 shows that ratings contain metric information that correctly describes the divergent interaction.

Krantz et al. (1971, pp. 445–447) have argued that if an interaction can be removed by monotonic transformation, then it should be attributed to the rating scale and should not be given a psychological interpretation. However, Experiment IV shows that this procedure could lead to erroneous conclusions. Although the interaction obtained in Experiment I could be removed by monotonic transformation, ratings of differences in impression are predictable from the differences in ratings. This indicates that the interactions are of psychological significance. Rescaling those data to parallelism would be inappropriate, as demonstrated by the qualitative contradictions of Experiment IV.

However, the ratings also appear to contain some nonlinearity that reduces the apparent magnitude of the interaction for nonnegative items. It would be improper reasoning to conclude that nonnegative items combine additively based on the lack of interaction in the ratings. The scale-free values in Figure 6 appear to show a continued divergence. Nonlinearity in the response scale may actually make nonadditive data appear additive. The procedures of Experiment IV avoid the rescaling problems and provide a truly scale-free test of the additive models.

General Discussion

This research demonstrates that impressions of likableness cannot be represented as simple sums or constant-weight averages of the values of the adjectives. Instead, one bad trait results in an unfavorable overall impression with the other trait having less influence. This effect reflects a real psychological interaction and cannot be attributed to the response scale.

Some of the early research on impression formation concluded that the constant-weight averaging model could give a reasonable fit to ratings of adjective combinations. The parallelism prediction appeared to be roughly satisfied, and this finding was interpreted to validate both the model and the rating scale. Systematic deviations did occur in this research, but were often attributed to experimental difficulties or nonlinearity of the response scale. However, it is now clear that the constant-weight averaging model is not an appropriate general description, but may give a reasonable approximation when the stimulus range is restricted and the experimental design lacks power.[3]

[3] An alternative view might maintain that the constant-weight model is descriptive of impression formation, but only under limited experimental circumstances. The E would be advised to carefully select adjectives, instructions, response procedures, and other conditions to minimize the nonparallelism. When the data appear parallel, this view contends that E would have the right to conclude that the parallelism jointly supports the constant-weight model and the response scale. However, this approach seems unsatisfactory for several reasons. First, the present research shows that different response procedures, "equal impor-

Theoretical Implications

It is useful to consider a set of conditions that yield the parallelism prediction to consider what nonparallelism might mean. The following conditions underlie the parallelism prediction of the averaging model: (*a*) the integration function is an averaging process; (*b*) the adjectives within each factor have equal absolute weight; (*c*) the adjectives do not change value nonlinearly in combination, nor do the weights depend upon the particular stimulus configuration; and (*d*) the J function is linear. Based on a single experiment such as Experiment I, nonparallelism could be interpreted as evidence to disprove at least one of the premises. Without further constraints, it would be impossible to specify whether nonparallelism was due to a nonadditive I process (Conditions *a–c*) or a nonlinear J function (Condition *d*). These experiments provide the leverage to indicate that the nonparallelism is *not* attributable to the J function. There are several remaining possibilities: The integration function may not be an averaging process, the stimulus parameters may depend upon the configuration, or the weights may not be equal for the adjectives.

The differential-weight averaging model (Anderson, 1971, 1972, 1974) can account for the interactions by allowing the weight of an item to depend upon its scale value. Differential weighting requires many more parameters and seems unnecessarily complicated to fit the simple divergence interactions. The model can account for a wide variety of interactions, making it difficult to disprove. However, with large enough designs, there are degrees of freedom left over to permit tests (e.g., Anderson, 1972; Birnbaum, 1973). Configural weighting (Birnbaum, 1972b), in which the weight of an item depends in part on its rank within the set, requires fewer parameters and gives a slightly better fit to the data.[4]

The configural-weight model predicts steady divergence for Figures 2, 3, 4, and 6. The differential-weight model is more flexible and could account for reconvergence, among other patterns. It is thus of theoretical interest to ask if the curves show any evidence of reconvergence. The scale-dependent ratings of Figure 2 appear nearly parallel for nonnegative traits. However, the scale-free values in Figure 6 show steady divergence for Replicates 1 and 3. The ratings may contain a small scale-end effect that reduces the apparent interaction. The bulge in Figure 2, Replicate 2 is apparently due to IMPULSIVE multiplying the effect of the other adjective, rather than having less weight on its own. Since there is no evidence for more than a simple divergence, the existing data cannot test between differential and configural-weight models. Methods for distinguishing these models have been suggested by Birnbaum (1973).

Methodological Implications

Previous conceptualizations of the stimulus concatenation problem have not separated the

tance and accuracy" instructions, and different selections of adjectives all yield similar divergent interactions. If the model is to be deemed correct, then it must apply under very special conditions indeed. Second, since it is possible to manipulate the form of J, it follows that selection of experimental procedures could lead to an "experimental rescaling" of the data. Thus, it should be possible to select end anchors and filler stimuli to reduce the interaction in the analysis of variance. Therefore, it would be inappropriate to select experimental procedures that yield parallel data and then conclude that the parallelism is joint support for model and response scale. That parallelism could result from a combination of nonadditive I and nonlinear J is not merely an untestable philosophical possibility but represents a plausible hypothesis that can be tested by the procedures of Experiment IV.

[4] An averaging mechanism can be analogized to a balance plank and fulcrum. In the differential-weight model, each adjective corresponds to a weight (w) placed at a certain location (s) on the plank. The integrated impression (Ψ) is the location where the fulcrum must be placed so that the plank will balance. This location is the weighted average, $\Psi = \sum w_i s_i / \sum w_i$. The configural-weight averaging model assumes that the weight of a stimulus depends upon its rank within the set to be judged. For 2 stimuli, the simple range model (Birnbaum et al., 1971), $\Psi_{ij} = .5(s_i + s_j) + \omega|s_i - s_j|$, can be rewritten as a configural-weight model, $\Psi_{ij} = (.5 + \omega)s_i + (.5 - \omega)s_j$, when $s_i > s_j$. This model can also be represented by a balance plank mechanism; however, the configural-weight model does not require each location on the plank to have its own weight. For 2 stimuli in the set, there would be only 2 weights, one for the lower valued item, and one for the higher valued item. The same weight can be placed at any location on the plank, if it holds the same rank. This model becomes a *minimum* model when $\omega = -.5$, a *constant-weight* model when $\omega = 0$, and a *maximum* model when $\omega = .5$, and can describe a family of simple convergent or divergent interactions.

J and I functions of Figure 1. This article offers a conceptualization that separates these problems. The propriety of rescaling the data has been uncertain in previous work. Functional and conjoint measurement (Anderson, 1970; Krantz et al., 1971) both allow for monotone transformation, but differ in their outlook about when transformation is appropriate.

Krantz et al. (1971, pp. 445–447) reanalyzed the data of Sidowski and Anderson (1967) and concluded that since the interaction could be eliminated by a monotonic transformation of the mean ratings, the original authors were incorrect in attributing psychological significance to their findings. An investigator following this rescaling procedure with the data of Experiment I would have erroneously concluded that the additive model was an appropriate description of impression formation. The present research, by demonstrating that data transformation can lead to erroneous conclusions, provides a warning against this practice.

Anderson[5] originally attempted to rescale the data for ratings of the severity of disturbed behaviors and to attribute the nonadditivity to the rating scale, but he has recently reinterpreted the same data as evidence for the configurality of clinical judgment by fitting these data to an averaging model with differential weights (Anderson, 1972). The latter interpretation assumed the linearity of the J function.

The present research supports this attitude toward rating scales, but it also provides scale-free constraints that make the interpretations of Krantz et al. (1971) and Anderson (1972; see, also, Footnote 5) matters for experimentation rather than assumption.

In Experiment IV it would be possible to distinguish multiplicative from additive models on the basis of ordinal information (see Figure 5). The simple view of conjoint scaling would not allow this distinction, since a monotonic (logarithmic) transformation of a positive product yields a sum. By assuming that ratings of differences are monotonically related to subjective differences, the I function can be separated from the J function. Experiment IV allows rescaling, but rescaling does not preclude the possibility of testing the I function.

Although the rating scale contains metric information, it does not seem appropriate to assume that J is linear in every experiment. The J function can be predictably nonlinear. It depends upon contextual effects that are explainable (Birnbaum et al., 1971; Parducci & Perrett, 1971). A nonlinear J function could result in 2 possible errors: (a) nonadditive data when the underlying impressions are additive, or (b) additive data when the impressions are nonadditive. Thus, the decision to rescale or not to rescale cannot be convincingly settled without further constraints, such as those applied in Experiments III and IV.

Conclusions

Impressions of likableness cannot be represented as simple sums or averages of single values of the adjectives. They appear to be a predictable, but nonadditive function of the component values. The data show consistent, regular deviations from additivity that are similar for different selections of adjectives. When one adjective is dislikable, the person is rated as dislikable, and variation of the other trait has less effect.

Differential or configural weighting of the more dislikable traits can account for the interactions. Representation of the stimuli by distributions could explain why the adjectives are integrated by a nonadditive function: It is less likely for a person possessing a dislikable trait to be likable than for a person with a likable trait to be dislikable.

Finally, this research illustrates that rating scales contain metric information that should not be uncritically scaled away. The procedures employed in Experiments III and IV provide constraints that allow a model to be tested without having to assume the validity of the rating scale.

April 1974

Beginning in 1975 the *Journal of Experimental Psychology* will appear as four independently edited and distributed sections:

The **Journal of Experimental Psychology: Human Learning and Memory** (Lyle E. Bourne, Jr., Editor) will publish experimental studies on fundamental acquisition, retention, and transfer processes in human behavior.

The **Journal of Experimental Psychology: Human Perception and Performance** (Michael I. Posner, Editor) will publish experimental studies designed to foster understanding of information processing operations and their relation to experience and performance.

The **Journal of Experimental Psychology: Animal Behavior Processes** (Allan R. Wagner, Editor) will publish experimental studies concerning the basic mechanisms of perception, learning, motivation, and performance, especially as revealed in the behavior of infrahuman animals. The studies should make significant contributions to general behavior theory.

The **Journal of Experimental Psychology: General** (Gregory A. Kimble, Editor) will publish experimental articles in any of the three areas represented by the above sections, when the articles involve a longer, more integrative report leading to an advance in knowledge that is judged to be of interest to the entire community of experimental psychologists. The section will include but not be limited to articles such as those that have appeared as *Journal of Experimental Psychology* monographs and as chapters in contemporary books of "advances." Republication of a limited number of data may be permitted if necessary to make the article complete and definitive.

In some instances it may be difficult for the author to decide whether one of the above listed sections or the *Journal of Comparative and Physiological Psychology* is most appropriate for a given manuscript. The author should weigh the essential implications of the research rather than the specific techniques or subject population employed. Is the central message concerned with the issues and concepts of behavior theory (*JExP*), or with the biological substrates of behavior (*Journal of Comparative and Physiological Psychology*)? Is the study primarily addressed to theory of human behavior (*JExP: Human Learning and Memory* or *JExP: Human Perception and Performance*) or to theories equally or more relevant to infrahuman subjects (*JExP: Animal Behavior Processes*)? Is the major emphasis on the acquisition, retention, or transfer of new information, concepts, or problem-solving strategy (*JExP: Human Learning and Memory*) or on the organization or control of structures or mental operations, where the acquisition of new skills is only incidental (*JExP: Human Perception and Performance*)?

Manuscripts should be sent directly to the Editor of the relevant section at the address listed below. In cases where an Editor believes a manuscript is clearly more appropriate for an alternative journal of the American Psychological Association, he may redirect the manuscript with the approval of the author. A final action taken by one of the Editors will be final for all sections of *JExP*.

Manuscripts should be submitted in triplicate and according to the instructions contained in the *Publication Manual* of the American Psychological Association.

Authors should note that limitations on total pages make it necessary to restrict publication to those papers that in the opinion of the Editors make a notable contribution to the literature. Preference can be expected for sets of interrelated experiments that are definitive or provocative.

Addresses for the 1975 Editors-Elect are as follows: *JExP: Human Learning and Memory*, Lyle E. Bourne, Jr., Department of Psychology, University of Colorado, Boulder, Colorado 80302; *JExP: Human Perception and Performance*, Michael I. Posner, before June 1, 1974, same as Allan R. Wagner, after June 1, Department of Psychology, University of Oregon, Eugene, Oregon 97403; *JExP: Animal Behavior Processes*, Allan R. Wagner, Department of Psychology, Yale University, 333 Cedar Street, New Haven, Connecticut 06510; *JExP: General*, Gregory A. Kimble, Department of Psychology, University of Colorado, Boulder, Colorado 80302.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive galley proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., 175 Fifth Avenue, New York, New York 10010; University Microfilms, Ann Arbor, Michigan 48106, or Princeton Microfilm, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

CARDIAC ORIENTING DURING "GOOD" AND "POOR" DIFFERENTIAL EYELID CONDITIONING[1]

LOIS E. PUTNAM, LEONARD E. ROSS, and FRANCES K. GRAHAM[2]

University of Wisconsin—Madison

The relation between orienting responses (ORs) and acquisition of a differentially conditioned eye blink response was studied in a group of 10 *Ss* showing good differential conditioning and a group of 10 *Ss* who failed to condition differentially. With Good conditioners, the predictions of OR theory were confirmed. Orienting, measured by heart rate (HR) deceleration, increased during acquisition and habituated as conditioning stabilized. With Poor conditioners, an OR-interference effect was found which is consistent with OR theory but was unexpected on the basis of most previous work. Another unexpected result was the occurrence of HR accelerations which were larger to a signaled than to an unsignaled unconditioned stimulus (UCS). It was suggested that both findings could be explained by the effects of orienting on processes active during short as opposed to long CS-UCS intervals and on skeletal conditioned responses (CRs) as opposed to autonomic CRs that are components of the orienting system.

A major reason for interest in the orienting response (OR) is its presumed relation to learning processes. Pavlov initially believed that the pattern of overt physical reactions which he termed the "investigatory" or "orienting" reflex had little importance for learning, but he later noted that conditioning proceeds best in the presence of an OR if it is neither too strong nor too weak. He also noted that the OR tends to disappear as conditioning is established (Lynn, 1966; Razran, 1961). The more fully articulated theory of orienting developed by Sokolov (1963) hypothesizes two generalized systems of responses with opposed functions, an OR which enhances stimulus reception and a defensive response system (DR) which attenuates the effects of stimulation. The relation of these systems to changes occurring in learning was described for two paradigms—classical conditioning of the vasomotor response to shock and the conditioning of an instructed motor response. In both cases, a vasomotor OR appeared on initial pairings of conditioned stimulus (CS) and unconditioned stimulus (UCS), intensified on subsequent pairings, persisted until the conditioned response (CR) stabilized, and disappeared on later trials. After vasomotor conditioning to shock was accomplished, both CS

[1] This study was supported by Research Grants [illegible] and HD01490, by Research Scientist Award K3-MH21762, and by Training Grant HD00117 from the U.S. Public Health Service. Computer services were provided through Grant FR00249 to the Laboratory Computer Facility and through a National Science Foundation grant administered by the University of Wisconsin Research Committee. Portions of this paper were presented at meetings of the Society for Psychophysiological Research, St. Louis, Missouri, October 1971.

[2] Requests for reprints should be sent to Leonard E. Ross or Frances K. Graham, Department of Psychology, University of Wisconsin—Madison, Madison, Wisconsin 53706.

and UCS elicited a stable vasomotor DR. Since the instructed motor response situation did not employ an aversive UCS, a DR was not elicited and, after conditioning was stabilized, vasomotor responses disappeared entirely (Sokolov, 1963, pp. 172 173, 185; Vinogradova, 1965).

Findings obtained from these two paradigms constitute the primary evidence that an OR is a prerequisite for normal conditioning and that the OR changes during the course of conditioning. However, both paradigms have limitations. Instructions are a means of manipulating attention and may thus elicit a different OR pattern than would occur with the traditional conditioning situation. With an autonomic conditioning paradigm, the measures of OR and CR may not be independent. As Morgenson and Martin (1968) have pointed out, when the same response measure indexes both the OR and CR, relationships between them may be due more to general responsiveness within systems than to any role of the OR in conditioning. Although the occurrence of changes in the direction of cephalic vasomotor responses, depending on whether an OR or DR is elicited, may exempt the Soviet studies from this criticism, the existence of OR DR differentiation by vasomotor responses has not been unequivocally replicated by Western investigators (Graham, 1973). In any case, the conditioning studies of Western investigators who have been concerned with OR changes have mainly employed the galvanic skin response (GSR) or the peripheral vasomotor response, neither of which distinguishes between ORs and DRs. These studies are clearly vulnerable to the objection of possible OR and CR confounding unless latency criteria are used to separate the responses and, even then, to the objection that any OR-learning association is due to the reactivity of the particular response system. The objection is especially pertinent to studies concluding that ORs, [illegible]dexed by the GSR on initial trials, predict fac[illegible]ilitated GSR conditioning (e.g., Maltzman & Mandell, 1968).

[illegible]espite the obvious advantages of study- [illegible] and CR in separate response systems and of using a [illegible] of de- pendent on verbal instruct[illegible] [illegible]re ap- pear to be no studies of hu[illegible] [illegible] which a classically conditioned [illegible] motor response and an OR DR [illegible]tiating autonomic response have [illegible] [illegible]igated concurrently. This parad[illegible] [illegible]sed in the present study. The eye[illegible] [illegible]sponse to air puff was the to-be-co[illegible] [illegible]ed re- sponse, and orienting was [illegible] [illegible]ed by heart rate (HR) deceleration. [illegible]t rate deceleration appears to meet [illegible] [illegible]riteria of an OR and HR acceleration [illegible] [illegible]riteria of a DR (Graham, 1973; Jacks[illegible] 1972). Since acquisition of a differenti[illegible] [illegible]CR is less affected than a simple CR [illegible] gen- eralized arousal effects (Prokasy, 1[illegible]), the eye blink response was differentia[illegible] con- ditioned. While OR theory predicts rela- tively unambiguous OR changes in response to the positive CS (CS+) as conditioning progresses, it is less clear what changes in the OR should be expected wi[illegible] [illegible] nega- tive CS (CS−). If differen[illegible] [illegible]did con- ditioning is to occur, both [illegible] [illegible]ditioned stimuli should presumably [illegible] [illegible]ienting, and changes in orienting mi[illegible] [illegible] expected to follow a similar course, p[illegible]bly with less pronounced orienting an[illegible] [illegible]ore rapid extinction to the nonrein[illegible]d CS−. Sokolov (1960, p. 221) gives an [illegible]ample of more rapid extinction of ori[illegible]ng to the negative stimulus, but the sit[illegible]ion is not directly comparable to the pres[illegible] one since differential conditioning was preceded by simple conditioning.

In addition to investigating HR changes during differential eyelid conditioning, the present study also compared these changes with HR responses to the conditioned and unconditioned stimuli when they were unpaired. Finally, the relation of orienting to successful conditioning was studied by selecting two groups of *S*s who differed markedly in how well they achieved differential eyelid conditioning. If the OR plays a role in facilitating acquisition, "good" conditioners should show the expected pattern in response to CS+, i.e., initially increasing HR decelerations which would habituate as differential eyelid conditioning reached asymptote. "Poor" conditioners,

on the other hand, might show either unusually large and persistent ORs or smaller, less stable ORs. The latter finding would be in line with Maltzman's conclusion that low-OR *S*s are poorer conditioners (e.g., Maltzman & Mandell, 1968).

Method

Subjects. Fifty undergraduates, receiving experimental "points" for their participation, served as *S*s. Five additional *S*s were tested and discarded in order to complete groups of Good and Poor differential conditioners. Of these five *S*s, three failed to meet a criterion of producing at least five CRs, and two were tested to complete the Poor conditioning group, but showed good differential conditioning. Two other *S*s were also discarded, one due to equipment failure and one for a heart anomaly.

Apparatus. The subject-testing room contained an upright ophthalmologist's chair which faced a screen displaying the fixation point—a black, circular, cardboard disc 8.5 cm. in diameter. A rectangular patch of light (85 × 50 cm.), projected on the screen, provided the only illumination.

Recording and stimulus generating equipment were located in a separate room having intercom communication with the *S* room. Two Hewlett-Packard ABR audio oscillators (Model 200 CDR) produced pure tones of 800 and 2,100 Hz. whose rise and decay times ($\approx 10\ \mu s.$) were controlled by a Grason-Stadler Model 829C electronic switch. A Grason-Stadler 901B noise generator provided continuous background white noise which, with tones, was presented binaurally to *S* through Sharpe HA 10A earphones. Intensity of tones and noise was determined from matches of four judges who adjusted the earphone-presented noise to the loudness of free-field white noise, measuring 65 db. re .0002 microbars on the C scale of a General Radio 1551C sound-level meter, and adjusted the earphone-presented tones-over-noise to the loudness of a 1,000-Hz. free-field tone 85 db. above the judges' mean threshold. Stimulus durations, interstimulus intervals, and intertrial intervals (ITIs) were controlled by Tektronix timing equipment and an Ohrtronics tape reader. Tones were automatically triggered on the positive slope of the first electrocardiographic R-wave occurring after the ITI had elapsed.

Movement of the *S*'s right eyelid was recorded using a standard potentiometer–polygraph apparatus (Wilcox & Ross, 1969) and heart rate, detected by a lead II placement of Beckman biopotential electrodes, was tape recorded and computer read.

Design and procedures. Five treatment groups of five males and five females each, to which *S*s were assigned randomly until full, included two differential eyelid conditioning groups (Good and Poor conditioners) and three control groups (Unpaired, Two-Tone, and One-Tone). Subjects retained in

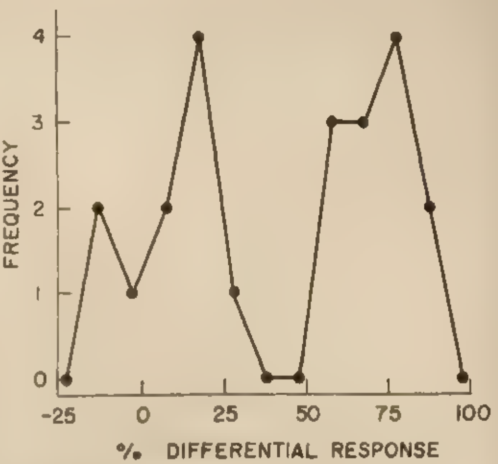

FIGURE 1. Distribution of differential eyelid conditioning performance.

the Good group showed 55% to 90% differential conditioning on the last half of the conditioning trials (percentage CRs on the last 20 CS+ trials less percentage CRs on the last 20 CS− trials), while *S*s in the Poor group ranged between −15% to 25%. The distribution of percentage difference scores for all *S*s tested, including the two discarded Good conditioners, appeared to be bimodal, as illustrated in Figure 1.

Conditioning *S*s received 40 CS+ and 40 CS− trials with an ITI of 18 to 30 sec. from CS onset to CS onset. A Gellerman presentation order, repeated every 20 trials, provided that each block of 10 trials contained equal numbers of CS+ and CS− trials and that neither stimulus occurred more than three times in succession. The UCS was a 100-msec. puff of .75 psi compressed air delivered to *S*'s right cornea and coterminous with the 900-msec. tone CS+. Six of the Good conditioners received a 2,100-Hz. CS+ and an 800-Hz. CS− and four received the reverse pattern. In the Poor conditioning group, four *S*s had the higher frequency tone as CS+.

Three other groups provided control comparisons. An *Unpaired* group received 40 tones and 40 unpaired puff presentations with the temporal scheduling identical to that of puff and CS− in the conditioning groups. Procedure for a *Two-Tone* group also retained the order and temporal intervals of trials in the conditioning groups but omitted the air puff. A sensitization control procedure with random interspersion of the UCS among both tones was not feasible since the mean intertone interval would have had to be lengthened to allow time for HR response recovery. A third control group, the *One-Tone* group, received only 40 tones on the same schedule as CS− in the paired group, and thus had an ITI ranging from 36 to 60 sec. Frequency of the tones was balanced within each group.

Instructions to all *S*s indicated that reactions "to certain distracting stimuli" were being investigated

and that heart rate, along with other responses, would be recorded. Eyelid responses were not mentioned explicitly and, as the eye blink recording headset was positioned, *S* was informed only that it would be used to record "responses." The *S* was cautioned to sit quietly and was warned that receiving credit for participation was contingent on remaining awake.

Results

Eyelid conditioning. Percentage responding to CS+ and CS− is shown in 5-trial blocks in Figure 2. Consistent with previous work in this laboratory, a CR was defined as the first pen deflection of at least 2 mm. (1 mm. eyelid closure) occurring in the interval from 200 msec. after CS onset until UCS onset. Good conditioners showed asymptotic responding to CS+ (96%) by Trial Block 5 (Trials 41–50) and achieved considerable differential responding (64%) by Trial Block 3 (Trials 21–30). Asymptotic differential responding of approximately 75% was reached by Trial Block 4. Poor *S*s, on the other hand, showed only a small increase in responding between Trial Blocks 1 and 8 and virtually no differential responding. Statistical tests over the last three trial blocks confirmed that Good *S*s responded significantly more to CS+ than to CS−, $t\ (9) = 13.96$, $p < .001$, that Poor *S*s did not respond differentially, $t\ (9) = 2.18$, $p > .05$, and that the differential responding of the Good group was significantly better than that of the Poor group, $t\ (18) = 6.88$, $p < .001$. The Good–Poor differences could not be ascribed to differing numbers of *S*s classified as voluntary responders since classification, according to the Hartman and Ross (1961) criteria, indicated that there were four voluntary responders in the Good and three in the Poor group.

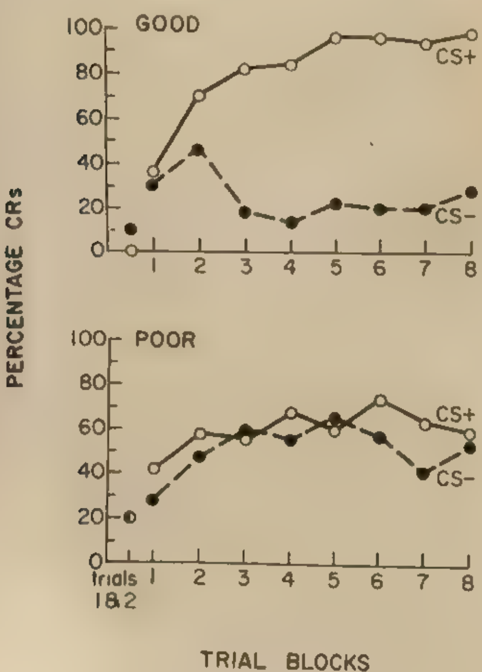

FIGURE 2. Percentage of conditioned responses for Good and Poor conditioners in blocks of five CS+ and five CS− trials.

Comparison of heart rate responses in conditioning and control groups. The differential conditioning procedure also produced highly significant HR responses which were time locked to the onset of both CS+ and CS− in both Good and Poor conditioning groups. These responses, averaged over all trials, are shown in Figure 3 for differences between HR during the first second before stimulus onset and HR on each of 6 sec. following onset. The 1-sec. averages are the bpm rate during all full and partial beats, weighted according to the fraction of the second occupied by each. A 6-sec. poststimulus period was selected for illustration and analysis since it was the longest period during which a single trend accounted for the major part of the variance and because differences from prestimulus were rarely reliable beyond this point (Putnam, 1972). Differences in prestimulus level, between groups were not significant and did not change differentially across the experimental session.

As Figure 3 illustrates, HR responses during the 6-sec. poststimulus period were generally triphasic with an initial deceleration lasting for 2 sec., a subsequent phase of acceleration also lasting for 2 sec., and a slower recovery phase. In the control groups, the accelerative phase did not always increase HR beyond prestimulus, and the response was, on the whole, less regular and less pronounced. A comparison of responses to "CS−" tones showed that

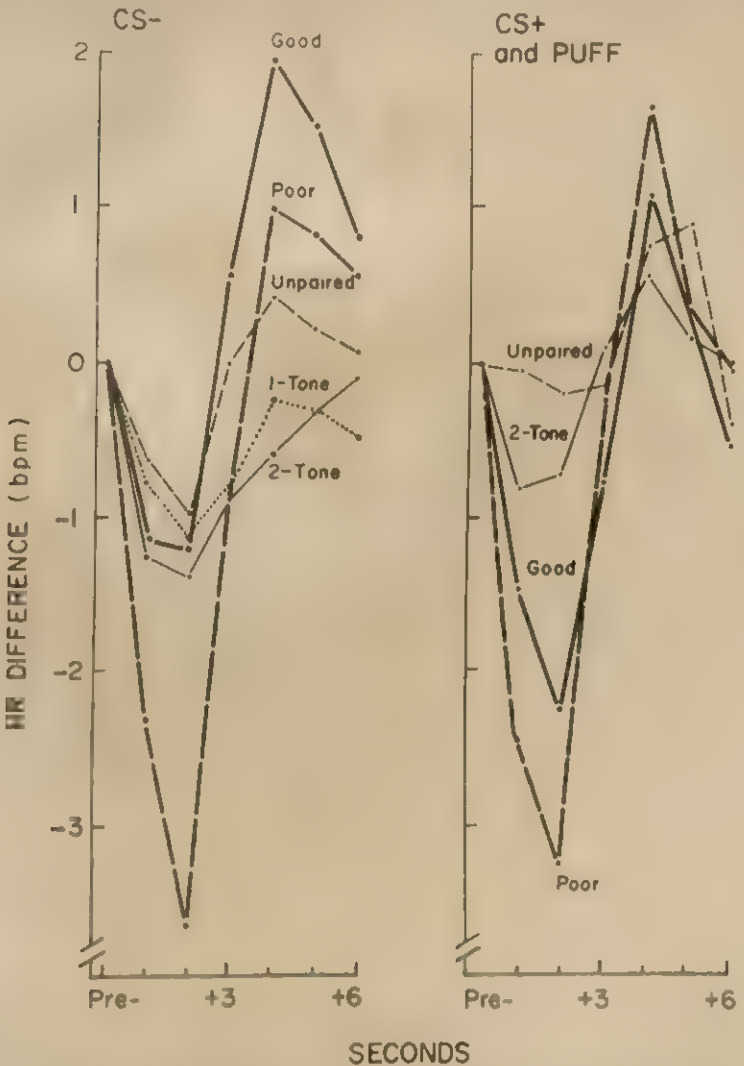

FIGURE 3. Mean heart rate (HR) responses to CS− and to CS+ alone, puff alone, or paired CS+ and puff, for each paired and control group.

differences among the five groups in overall cubic trend were significant (Table 1, Col. A) and were largely due to the paired-control comparison. The trend in each of the control groups, compared individually with the conditioning groups, was also significantly different but the controls did not differ from one another. When the three response components were tested separately by measuring changes over the first 2 seconds, over Seconds 2 to 4, and over Seconds 4 to 6, differences among groups and between paired and control groups were significant during the initial deceleration (Table 1, Col. B) and the following acceleration (Table 1, Col. C) but not during the recovery phase (Table 1, Col. D). Each of the control groups, considered separately, also differed from the conditioning groups in the degree of acceleration, but only the Unpaired group differed in initial deceleration. Again, there were no significant differences among control groups. There was also no significant dif-

ference among groups in the changes across trials, pooled into blocks of eight trials each.

The relatively large accelerations to CS in the conditioning groups were unexpected. Since the acceleration was significantly larger than in the control group given both air puff and tone unpaired, sensitization could not account for the full effect. Further, the conditioning and the unpaired groups also differed in their response to the puff. When puff was unsignaled, it elicited a significantly smaller acceleration than when it was preceded by CS+, F (1, 27) = 11.34, $p < .01$.

Comparison of heart rate responses of Good and Poor conditioners. While the HR response during conditioning differed from control group response both in initial deceleration and in the subsequent acceleration, significant differences between Good and Poor conditioners were confined to the initial 2-sec. period of deceleration which presumably reflects orienting (Table 1).

Poor conditioners were not deficient in orienting but, rather, they showed large, stable ORs which did not differ following CS+ and CS− and which did [illegible] habituate. The relative stability of [illegible] responses to CS−, as well as the consiste[illegible] group difference in magnitude of decel[illegible]n, is illustrated in Figure 4. In con[illegible] responses to CS+ (Figure 5) show[illegible] considerably more variation across tr[illegible] blocks although they were clearly less [illegible] than responses to puff in the [illegible]red group. When decelerative respo[illegible] to both CS+ and CS− and to each st[illegible]lus alone were analyzed for changes [illegible]oss blocks of eight trials, the differenc[illegible] between Good and Poor conditioners wer[illegible] reflected in a significant Groups × Stimul[illegible] × Linear Trials effect when both stimuli were included in the analysis (Table 2, Col. [illegible]) and in a significant Groups × Linear Trials effect for response to CS+ (Table 2, Col. B). Only the Groups effect was significant in response to CS− (Table 1, Col. C).

The finding of greatest interest was [illegible] change in the decelerations elicited [illegible] CS+. Both Good and Poor conditio[illegible]s showed a similar increase in deceler[illegible]n over the first three trial blocks but, on [illegible]er

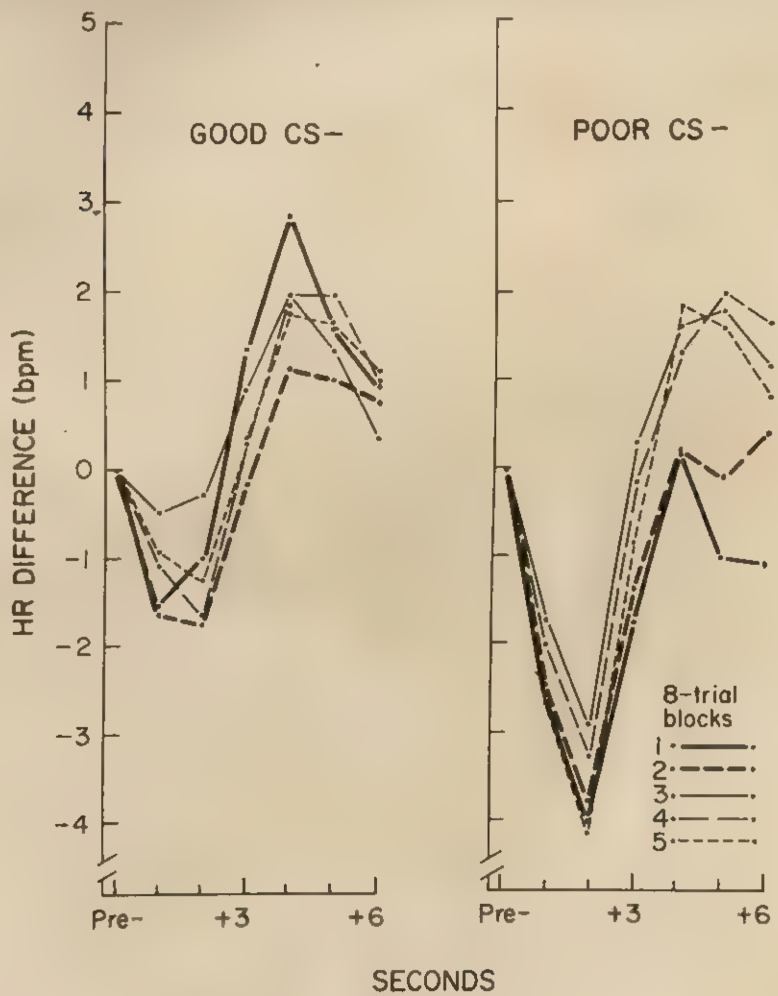

FIGURE 4. Heart rate (HR) responses of Good and Poor conditioners to CS− in five trial blocks of eight trials each.

trials, Poor conditioners continued to give large decelerations while the response showed habituation in the Good conditioning group. These changes can be seen more clearly in Figure 6, which also shows the average decelerative response of those Poor conditioners who avoided the puff on at least 18 of the final 20 CS+ trials by giving a CR coincident with the UCS. Although there were only four subjects in this category, their failure to show any habituation seems to rule out the possibility that ORs of Good conditioners habituated because they were able to avoid the puff. The temporal correspondence between orienting and conditioning is illustrated in Figure 7 which shows the differential eyelid responding of Good conditioners superimposed on their HR deceleration data. It is evident that the period of maximum deceleration corresponds roughly to the time when differential eyelid conditioning reached an asymptote.

For comparison with studies that have described the learning behavior of *S*s categorized as high and low orienters on the basis of some measure of initial orienting, such as response to the first CS, differential conditioning scores of all *S*s were correlated with deceleration to the first

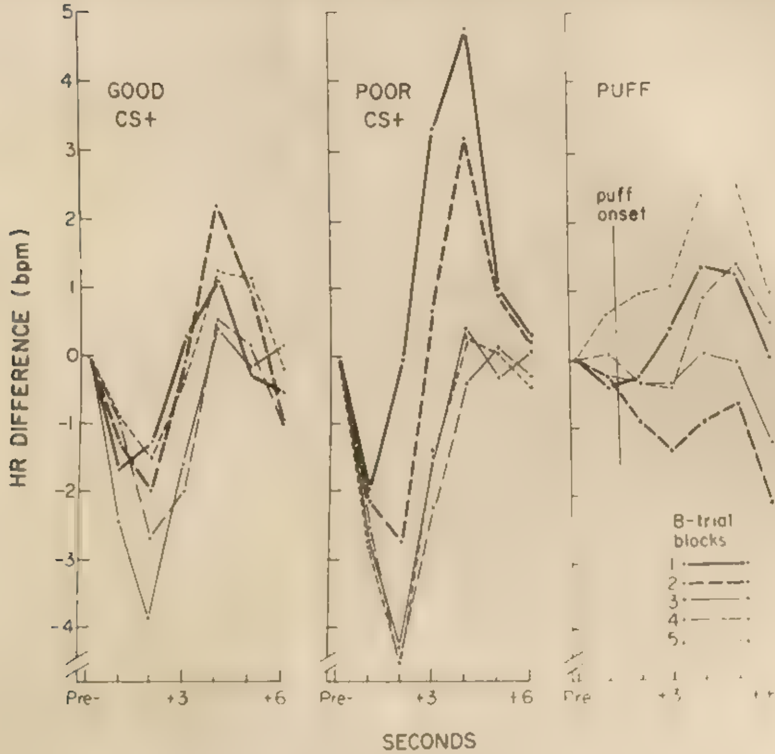

FIGURE 5. Heart rate (HR) responses of Good and Poor conditioners to CS+ and of Unpaired *S*s to air puff in five trial blocks of eight trials each.

CS− and to the first CS+. Neither correlation was significant and they differed in direction (Pearson product-moment $r = -.30$ for first CS− and $r = +.36$ for first CS+).

Discussion

The present study of the relation between orienting, measured by HR deceleration, and learning, measured by acquisition of a differentially conditioned blink response, confirms the descriptions of Soviet investigators (e.g., Sokolov, 1963; Vinogradova, 1965). The OR intensified during acquisition and habituated as conditioning stabilized. Similar results have also been reported in a recent study of HR changes accompanying conditioning of the rabbit's corneoretinal potential (Powell, 1972). Since the Soviet studies providing the best empirical basis for the OR-learning relation either conditioned an autonomic response and thus confounded OR and CR measures, or employed an instructed motor response and thus might have imposed attentional requirements specific to a "voluntary" task, the present results place on a firmer basis the generalization that during learning first increases and then declines while a response increases and stabilizes. rise and fall during learning is also of inter because it suggests that the common finding of similar inverted-U functions in autono conditioning studies may reflect changes in orienting rather than in a learning process

Two other findings of the present study that *S*s failing to condition had large, stabl ORs and that HR accelerations to the UCS were larger to a signaled than to an unsignaled UCS, stand in contrast to most previous work. The existence of larger ORs in Poor than in Good conditioners, both on the first trial and throughout conditioning, is compatible with Soviet versions of OR theory which emphasize that very marked orienting, as well as very weak, interferes with conditioning, but the finding does not agree with Western versions that propose only a positive relation between orienting and conditioning (e.g., Maltzman, 1967). Maltzman views the evidence of a positive relation and the absence of evidence of any interfering effects of high OR on learning as important for the argument that orient-

ing responses are not measuring a generalized arousal or drive state. The argument is reasonable but it is questionable that the previously existing empirical data permit a distinction between arousal and OR effects on learning.

A major flaw in the evidence for a solely positive OR-learning relation not due to arousal is that a number of studies have classified *Ss* into high- and low-OR groups on the basis of only a single trial which has sometimes been the first habituation and sometimes the first UCS trial (e.g., Maltzman, 1967). As Zeiner and Schell (1971) point out, the response to a noxious UCS qualifies as a DR. Base levels of skin conductance have also been employed (Maltzman & Mandell, 1968) as a measure of the tonic OR but might equally well be considered a measure of arousal (Malmo, 1959). A second major problem with the evidence is that studies have not adequately controlled for general reactivity effects. Many have measured CR acquisition,

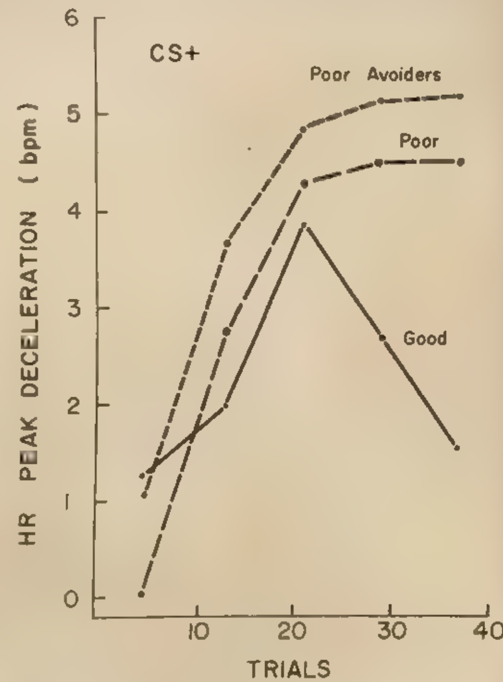

FIGURE 6. Changes over CS+ trials in the peak heart rate (HR) deceleration (prestimulus HR less Second-2 HR) of Good conditioners, Poor conditioners, and Poor avoiders.

which is more likely than differential conditioning to reflect arousal. Even differential conditioning may not rule out activation effects if OR and CR are measured by the same re-

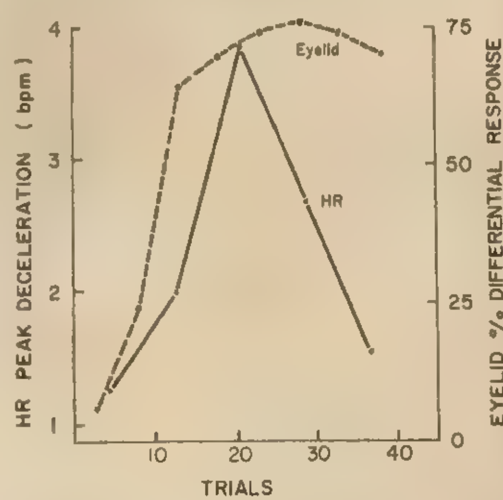

FIGURE 7. Change over trials in the relation between differential eyelid responding of Good conditioners and their peak heart rate (HR) decelerations to CS+.

sponse system and there are *Ss* who fail to respond to both CS+ and CS− in a given trial block. In such cases, there is no measure of whether discrimination is or is not present and their inclusion as instances of no discrimination artifactually lowers the discrimination score. Since low-OR *Ss* are more likely, on the basis of a response reactivity factor, to have no-response trials, reactivity could thus affect the OR-differential conditioning relation as well as the relation of orienting to CR acquisition. Zeiner and Schell (1971) provide an example of this in showing that a positive relation between a GSR-OR and differential conditioning of first-interval GSR responses disappeared when discrimination was measured only on trials yielding some nonzero response.

While much, if not all, of the data purportedly showing a positive OR-learning relation may thus reflect the effects of a DR, arousal, or specific response reactivity rather than an OR, these effects could not have produced the OR-learning relation of the present study since the OR was measured by HR deceleration, which is *not* a measure of arousal, and learning was measured by the differential conditioning of a response in a different system. However, findings of a significant negative relation between the OR and learning appear to be nonexistent in the Western literature, except for the present study, and it is possible that there are critically important differences between how orienting affects processes developing during conditioning with a short as opposed to a long CS–UCS interval.

Paradigm differences may also be important in accounting for the second discrepant finding of the present experiment, that HR accelerations were larger in response to a signaled than to an unsignaled UCS. A number of studies, generally measuring GSR, have found that unconditioned response (UCR) amplitude is smaller, not larger, in response to a signaled UCS (e.g., Kimble & Ost, 1961; Kimmel, 1967; Peeke & Grings, 1968). Since one interpretation of UCR diminution is that a response to a signaled UCS "is due to a carryover of the response processes begun during the inter-stimulus interval [Grings, 1969, p. 607]," it might be thought that while a unidirectional response like GSR would be interfered with by a prior response, a bidirectional system like HR might be enhanced, if only by virtue of an initial level effect. A recent report of UCR diminution with HR as the response measure (Lykken, MacIndoe, & Tellegen, 1972) makes it unlikely that the explanation lies solely with GSR–HR differences, but an alternative is suggested by considering differences in the length of the CS–UCS interval.

The Lykken et al. (1972) study, in common with GSR studies of UCR diminution and many OR-learning studies, employed a shock UCS and a relatively long CS–UCS interval, initiated 5 sec. before shock onset by the first of two successive CSs. In contrast, the present study employed a CS–UCS interval of only 800 msec. which would require that any preparatory processes be mobilized very quickly. Just what this implies for HR changes is problematic but there is evidence that the cardiovascular system participates both in orienting and in preparations for action and that preparations for action result in HR acceleration (e.g., Chase, Graham, & Graham, 1968). Since HR reflects only one aspect of cardiovascular preparations, is slow relative to skeletal responses, and shows lag as a result of feedback to the heart from blood pressure, volume, and O_2 changes, HR changes associated with mobilizing for rapid action would be expected to outlast the action and thus might summate with the UCR. This hypothesis, of an interaction between length of the CS–UCS interval and the type of UCR measured, receives support from another recent study (Furedy & Klajner, 1972) which also employed a short CS–UCS interval (500 msec.) and also obtained a larger UCR to a signaled UCS when the response was a cardiovascular change, peripheral vasomotor constriction. There was no signaling effect when GSR was measured.

The argument, then, agrees with Grings (1969) that the signaled UCR reflects a carry-over of response processes begun with the CS but suggests additionally that whether the UCR is increased or decreased depends upon the length of the CS–UCS interval and the particular response that is measured. These same factors may also determine whether an orienting response, with which brief suspension of movement is associated (Obrist, Webb, & Sutterer, 1969) interferes with or facilitates the occurrence of a particular CR. With short CS–UCS intervals, a prolonged, pronounced OR may not be required in order to establish an association between two stimuli in close temporal proximity and, if it does occur, might be expected to interfere with execution of a skeletal response such as blink. With longer CS–UCS intervals, prolonged orienting may be more important in establishing an

association between stimuli more widely separated in time and even if it were very pronounced would not interfere with an autonomic CR which was itself part of the orienting complex.

PRAGMATIC NORMALIZATION:

FURTHER RESULTS FOR SOME CONJUNCTIVE AND DISJUNCTIVE SENTENCES[1]

SAMUEL FILLENBAUM[2]

University of North Carolina, Chapel Hill

On a paraphrase task involving pragmatically extraordinary sentences *S*s normalized two sorts of disordered conjunctive sentences as well as disjunctive sentences involving "perverse" threats more than half the time. Later when comparing their paraphrases with the source sentences they were often unable to detect differences in meaning. These results were interpreted in terms of a basic assumption made by many *S*s that messages are sensible, that what is described in messages must conform to the customary order and connection among events, and that apparent anomalies can be attributed to inadequacies in the encoding of the messages.

The tendency to normalize connected discourse or stories in memory has been well known since at least the time of Bartlett (1932). It may be the case that such normalization involves not so much or not only memorial processes, but may largely be a consequence of the way in which strange material is initially interpreted and stored, such that extraordinary descriptions are transmuted into ones more mundane and commonplace, given knowledge of the ways things usually transpire, and a strong presumption of the sensibleness of the material encountered. The present research constitutes a replication and extension of part of an earlier study (Fillenbaum, 1971) in which it was found that on a paraphrase task verb order was often permuted for disordered conjunctive sentences, normalizing them and assimilating the order of events described to conventional order. It is an extension in two regards: (*a*) in that (*i*) a new kind of ordered conjunctive sentence is examined in addition to the kind studied before, and (*ii*) a class of strange disjunctive sentences ("perverse" threats) is also studied, and, perhaps more important, (*b*) in that we also s[illegible] determine whether *S* could detect [illegible] changes in his paraphrases, by havin[illegible] review each of his paraphrases at the en[illegible] and having him say whether there was any difference in meaning between the original sentence and his paraphrase, and, if so, to indicate what sort of difference was involved.

Method

There were 40 sentences to be paraphrased. There were 5 filler items at the start and then, in randomized order (*a*) 10 ordered conjunctive sentences in normal order (e.g., "John got off the bus and went into the store"), (*b*) 10 ordered conjunctive sentences with normal order reversed, these sentences being extraordinary but semantically coherent (e.g., "John dressed and had a bath"), (*c*) 4 ordered conjunctive sentences with normal order reversed, these sentences violating temporal entailment relations between their main verbs (e.g., "John finished and wrote the article on the week end"), (*d*) 5 disjunctive sentences involving commonplace threats (e.g., "Stop that noise or I'll call the police"), (*e*) 5 disjunctive sentences involving conditional threats that were "perverse" in that the consequent clause indicated that the speaker would *not* bring about some undesirable event commonly to be expected in the circumstances (e.g., "Don't print that or I won't sue you"), plus a single "perverse" warning, the sentence "Get a move on or you will catch the bus."

Each of the 51 *S*s, who were college students meeting a class requirement for an introductory psychology course, was run individually being given a deck of 3 × 5 in. cards each containing one of the sentences to be paraphrased, and a blank deck for writing down his paraphrases. The instructions, which were the same as the version two (strong) instructions used in the earlier study (Fillenbaum,

[1] This work was supported in part by U.S. Public Health Service Research Grant MH-10006 from the National Institute of Mental Health. The writer is indebted to R. Hall for his aid in gathering and analyzing the data.

[2] Requests for reprints should be sent to Samuel Fillenbaum, University of North Carolina, Psychometric Laboratory, Chapel Hill, North Carolina 27514.

1971), stressed that the task was to paraphrase or rephrase "the sentences as accurately as you can, conserving meaning as completely as possible" and that *S* was not "to improve the sentences or make them more sensible, but to *paraphrase* them, rewording each in a way that captures its meaning as accurately as possible." After *S* had finished the paraphrase task at his own pace he was told that he would have to go through his paraphrases, that he would be asked "about the remaining differences IF ANY" between each sentence and its paraphrase, and that if he did "see some shred of difference" to say what seemed to be involved. For each item *S* was then shown the original sentence and his paraphrase and asked "Is there any difference in meaning between the sentence and your rewording?" and if this question was answered "yes," *S* was asked "What sort of difference?" After running through all the items in this fashion if *S* had actually changed the meaning of the sentences in his paraphrases and noticed this at all during the review of the items (which was the case for most *S*s), he was confronted with this fact, reminded of the instructions to preserve meaning, and asked "How come?"

The analysis of paraphrases was relatively straightforward. For each conjunctive sentence one could determine whether or not the order of verb phrases had been maintained. Change in the order of verb phrases for the disordered conjunctive sentences almost always resulted in normalizing the sentences. In addition there were occasional paraphrases which did not change the unusual order of verbs but which elaborated or emended the sentences in such fashion as to turn them into sensible, normal sentences. The disjunctive sentences, threats, were paraphrased in various ways perhaps most commonly as conditionals. One could generally unambiguously determine whether or not these paraphrases normalized meaning. Thus, for example, given "Clean up the mess or I won't report you," both (*a*) "If you don't clean up the mess I'll report you" and (*b*) "If you clean up the mess I won't report you" may be regarded as changing and normalizing the original sentence, while both (*c*) "If you clean up the mess I'll report you" and (*d*) "If you don't clean up the mess I won't report you" may be regarded as conserving some of the strange properties of the original sentence.

The judgments *S*s made on reviewing their paraphrases, as to whether or not these differed in meaning from the original sentences, could be coded simply as "different" or "same." The observations *S*s made when they did judge a paraphrase to be different from its source sentence, and the various things said by way of explanation or self-justification at the end, when confronted with the fact that their paraphrases had often involved meaning changes, were found to be codeable in a limited number of categories (see results below).

Results and Discussion

For normally ordered conjunctive sentences meaning was preserved in 99% of the paraphrases (with 90% judged same in meaning and 9% different in meaning) and was perverted in 1% of the paraphrases (with all of these judged different in meaning). For disordered conjunctive sentences violating a contingent relation meaning was preserved in 36% of the paraphrases (with 31% judged same in meaning and 5% different in meaning) and normalized in 64% of the paraphrases (with 22% judged same in meaning and 42% different in meaning). For disordered conjunctive sentences violating an entailment relation meaning was preserved in 30% of the paraphrases (with 28% judged same in meaning and 2% different in meaning) and normalized in 70% of the paraphrases (with 43% judged same in meaning and 27% different in meaning). For normal conditional threats meaning was preserved in 99% of the paraphrases (with 95% judged same in meaning and 4% different in meaning) and perverted in 1% of the paraphrases (with all of these judged different in meaning). For "perverse" conditional threats meaning was preserved in 46% of the paraphrases (with 40% judged same in meaning and 6% judged different in meaning) and normalized in 54% of the paraphrases (with 34% judged same in meaning and 20% different in meaning).[3]

It is clear that ordered conjunctive sentences in normal order and normal conditional threats are hardly ever perversely paraphrased, and that in each case paraphrases that preserve meaning are overwhelmingly regarded as doing just that. For these sorts of sentences when *S*s claim that paraphrases change meaning the most common ground given is that change in a particular single word led to a change in sentence meaning. Results for the two sorts of disordered conjunctive sentences

[3] These results, insofar as comparable, are very similar to those obtained earlier (Fillenbaum, 1971) where meaning was preserved in 96% of the paraphrases of normally ordered conjunctive sentences, but for only 39% of the paraphrases of disordered conjunctive sentences violating a contingent relation. In a previous (unpublished) study it was found that paraphrases preserved meaning for 99% of normal threats, but for only 43% of "perverse" threats.

and for the "perverse" conditional threats are quite different. For the disordered conjunctive sentences 64% (contingent relation violated) and 70% (entailment relation violated) of the paraphrases involve normalization, while for the "perverse" conditional threats 54% of the paraphrases involve normalization (the results for the single "perverse" warning are roughly similar to those for "perverse" threats and will not be mentioned further). The differences in normalization for the three kinds of strange sentences do not reach significance when proportions of normalization of each sentence kind are contrasted for each S by means of sign tests.

Turning next to judgments of whether or not paraphrases changed the meaning of the various kinds of strange sentences, we find that for disordered conjunctive sentences where a contingent relation between verbs has been violated normalizing paraphrases are detected almost twice as often as not (the figures are 42% and 22%), while for disordered conjunctive sentences where an entailment relation between verbs has been violated normalizing paraphrases are detected less often than they are overlooked (the figures are 27% and 43%). The difference in detection rates is significant ($p < .01$) when proportions of detection of normalizing changes for the two kinds of sentences are contrasted for each S by means of a sign test, indicating that Ss are responsive to differences in the semantic properties of these two kinds of disordered sentences even though the actual percentages of normalizing paraphrases are quite similar (64% and 70%). For "perverse" threats we find that paraphrases that normalize the source sentences are detected less often than they are overlooked (the figures are 20% and 34%), and that the detection rate for these normalizing changes is significantly less than that for normalizing changes for disordered conjunctive sentences violating a contingent relation ($p < .05$), and no different from that for normalizing changes for disordered conjunctive sentences violating an entailment relation. Given considerable conceptual differences between the disordered conjunctive sentences and the strange disjunctive sentences it is difficult to say anything as to the interpretation of differences in detection rate for normalizing changes.

Consider next what Ss say is involved when they do detect differences between strange source sentences and their paraphrases of them. For disordered conjunctive sentences of the two kinds studied we find that the great majority of comments refer to order change, change in temporal sequence, and change in causal sequence, with 85% of the comments for sentences where a contingent relation is violated and 65% of the comments for sentences where an entailment relation is violated falling into these three categories. These comments are quite realistic for it is just these sorts of changes that have occurred in the meaning normalizing paraphrases. If we consider the comments made when paraphrases of "perverse" threats are judged to be different from the source sentences, we again find some use of the above three categories but now the most common observation is that the paraphrase is a sentence opposite in meaning to its source. Again such comments are quite realistic, for normalization of "perverse" threats characteristically involves just that, see, e.g., the difference between the source sentence "Clean up the mess or I won't report you" and a paraphrase such as "If you clean up the mess I won't report you."

The results just presented raise two questions: (*a*) If Ss can detect differences between their paraphrases and the source sentences with regard to such significant matters as changes in temporal and causal order and changes which result in opposite meaning, then why did they provide such misleading paraphrases, given strong instructions to preserve and conserve meaning and warnings against attempting to improve or make the sentences more sensible? (*b*) If Ss cannot detect such substantial differences between the source sentences and their paraphrases then what might be responsible for such obtuseness or blindness? What is empirically true, and presupposed in both of the above questions, is the fact that extraordinary sen-

tences are often pragmatically normalized in the paraphrases, and one needs to ask (*c*) why this should be so.

It seems plausible that the same general answer holds for all three questions. Even in the peculiar circumstances of the psychological laboratory *S*s seem to be acting on the basic assumption that *what is described in discourse will be sensible*, that what is described will conform to the customary order of events and will satisfy normal qualitative and causal relations between events or actions. If a sentence is encountered which appears to violate this assumption one may consider it to be a clumsy, inadequate phrasing or description, and turn it into a more appropriate version in one's paraphrase. Thus what is taken as awry or extraordinary is not the world, but the linguistic account of it. As to why *S*s should have provided normalizing paraphrases when they *could* detect significant differences between these and the source sentences, it may be that as far as *S*s are concerned a difference detected is not so much one between descriptions of two different sorts of events as one between two different descriptions of the same event, with the paraphrase expressing properly what is *intended and badly expressed* by the original sentence. Finally, why might *S*s have failed to notice differences between the source sentences and their normalizing paraphrases? This may just constitute further testimony to the strength of the basic assumption, such that the original "malphrased" sentences and their own "improved" versions are really regarded as amounting to the same description of sensibly ordered and organized events.

The above suggestions while speculative find support in the comments *S*s made at the end, by way of explanation and justification for their paraphrases. Of the 51 *S*s 10 or 11 hardly ever changed meaning in their paraphrases, so we need to consider only the responses of the other 40 *S*s.[4] Comments which claimed (*a*) that the paraphrases made things clear and more sensible, (*b*) that the paraphrases put things into natural order, (*c*) that the original sentences violated expectancies, (*d*) that the original sentences were illogical, and (*e*) that they knew what the original sentences were trying to say and so they said it, account for the responses of 25 of these *S*s. All of them appear to be claiming, in one way or another, that their paraphrases somehow put more adequately what was badly phrased in the original sentences. In addition there were 7 *S*s who said that they misread or read incorrectly the original sentences, which suggests, if their comments are taken at face value, that they may not even have noticed the strange properties of the original sentences, and that in the very act of reading and coping with them they corrected or normalized these sentences. Thus for 32 of the 40 *S*s there is some evidence for the operation of the assumption that what is described in discourse must be sensibly organized. One further observation is worth reporting, almost every one of the 40 *S*s who was trying to explain or justify his (normalizing) paraphrases seemed in part inarticulate, and was considerably flustered. It seemed as though it was somehow very important for *S*s to adjust things to conventional order and sequence, and to exhibit the normal relations among events, so as to say what the speaker of the source sentence must have intended or meant.

People may make the basic assumption that sentences are sensible just because they believe that the events of which such sentences purport to be accounts occur or are organized in characteristic ways, and that it is much more likely that the world that is being described is the commonplace one and that the description is burdened with the errors and malapropisms of the speaker than that extraordinary events are being

[4] In the earlier study there were consistent individual differences, with some *S*s normalizing the majority of the disordered sentences and others hardly normalizing any (Fillenbaum, 1971). In the present study similar results were obtained both with regard to whether or not strange source sentences were normalized and with regard to detection of such changes.

accurately and faithfully presented. It is as though people focus not on linguistic messages per se, but on the information they embody or appear to convey, considering and assimilating this information in relation to their preexisting knowledge of the ways of the world.

MODALITY DIFFERENCES IN RECOGNITION MEMORY FOR WORDS AND THEIR ATTRIBUTES

KIM KIRSNER[1]

University of Western Australia, Nedlands, Australia

[illegible] Experiment I, 20 Ss gave recognition responses for which accuracy and reaction time data were collected. In Experiment II, 20 new Ss gave [illegible] items [illegible]. Intramodality recognition performance was superior to [illegible] performance [illegible] modality report data [illegible] The results were thought to be consistent with a [illegible] explanation of recognition facilitation and the modality report data.

When a person hears or sees a word, one possible assumption is that the word is immediately translated into its semantic form. That is, the meaning of the stimulus is extracted and retained while normally redundant information about the physical characteristics of the stimulus are lost. From the viewpoint of a model of memory, it is of interest that information concerning the physical nature of the stimulus may be retained for a period of time apparently beyond that which is necessary for semantic analysis. The present study was implemented with a view to (*a*) establishing the longevity of this representational storage and (*b*) gaining some insight into the coding processes involved in the retention of the representational as distinct from semantic attributes of verbal stimuli.

The present study used a modification [illegible] Feghtenman (1961). In their procedure, Ss were exposed to a series of words within which each item was repeated once, at one of several possible retention intervals. The technique was modified here so that an item could be repeated in the same modality (e.g., visual visual—VV) or in the alternative modality (e.g., auditory visual—AV) on the 2 presentations. Two distinct questions are considered. The first question concerns the duration of persistence of modality-specific information in memory. In the present paradigm this may be inferred from the duration of intramodality facilitation in recognition performance, for example, from the presence of an advantage for VV relative to AV. The second question follows Mann (1970) in adopting a direct approach in which S is required to [illegible] modality of presentation of each item recognized as *old*. The distinction between recognition facilitation and knowledge about modality of presentation may be important in that, in one case, the information may facilitate recognition even though it is not directly accessible, whereas, in the other case, the information may be directly accessible without benefiting recognition performance per se.

In experiments that have used words as stimuli, research has shown that auditory [illegible]tation is associated with better performance than visual presentation over a variety of memory tasks. However, the duration of this auditory superiority appears to be technique dependent, ranging

[1] [illegible]

from the last 2–3 serial positions in free recall (Murdock & Walker, 1969) to as many as 7–10 serial positions or seconds in probe recall (Murdock, 1967) and recognition memory (Kirsner & Craik, 1971). As the auditory advantage was found over all sampled serial positions in the probe recall and recognition experiments, the present study was designed to sample recognition performance over a substantially longer set of serial positions.

The position with regard to visual persistence for linguistic stimuli is complicated. On one hand, it has been widely assumed, following Sperling (1967), that apart from transient retention in an iconic form there is little or no visual persistence for linguistic stimuli. In line with this conclusion a number of mixed-modality studies using discrete-trial recognition and probe recall procedures have found no evidence for short-term visual persistence (Burrows, 1972; Kirsner & Craik, 1971; Murdock, 1967). Against this, however, results from clinical and shadowing studies using recall as well as *same different* techniques have found evidence that visual information for 1–3 letter stimuli persists for up to 25 sec. (Kroll, Parks, Parkinson, Bieber, & Johnson, 1970; Parkinson, 1972; Parks, Kroll, Salzberg, & Parkinson, 1972; Warrington & Shallice, 1969). One possible explanation of the inconsistency may be that visual persistence is masked in mixed-modality studies by a short-term auditory component. If this is so, then a longer sampling period may be required in order to reveal visual facilitation effects. This condition is met in the present study, wherein performance was sampled over a range of 31 intervening items in the continuous list.

The purpose of the experiments reported here was to explore the duration and characteristics of representational persistence in audition and vision. Experiment I compared performance, as measured by both accuracy and recognition reaction time (RT), for intra- and intermodality recognition decisions. Experiment II also provided data on recognition accuracy and, in addition, required *Ss* to report the modality of first presentation for recognized items.

Method

Subjects. Twenty undergraduate *Ss* from the University of Toronto *S* pool were used in each experiment. They were naive with respect to the experiment and were paid for their services on completion of the single session. All *Ss* were tested individually.

Design. The experiments were conducted using a within-*Ss* design for the 2 × 2 × 6 factorial combination representing test modality (auditory or visual), similarity (same or different modality on first and test presentations), and lag (1, 2, 4, 8, 16 and 32). Lag = 1 refers to an immediate repetition with no intervening items.

The *Ss* were presented with a continuous series of 772 items. The first 52 items were intended to absorb short-run practice effects and were not considered in the analyses. The 720 critical items comprised 360 words presented twice each, with 15 replications within each of the 24 experimental conditions. Each replication of the 24 *test* trials was completed within a concealed block of 48 consecutive trials, and the experimental conditions were ordered differently within each replication.

The words, drawn from a pool of common, 2-syllable nouns of 5, 6, 7, or 8 letters, were presented at a rate of 4 sec/word. Visual items were exposed for .5 sec. and were followed by a blank interval for the remaining 3.5 sec. of the intertrial interval. This was followed immediately by an auditory item or another visual item in accordance with the predetermined sequence. Two formats were drawn up, each format constituting a random sample from the word pool. Each format was presented to 10 *Ss* in each experiment.

Procedure. The visual items were prepared in lowercase on an IBM Selectric typewriter. For presentation, the list was inserted in the typewriter; the list was advanced by a solenoid attached to the return button. A Shibadan television camera was focused on the return carriage, and *Ss* viewed the stimuli on a Shibadan monitor. The typewriter was advanced twice for each visual word, once to bring the item onto the screen and once to introduce the blank phase. The screen remained blank during presentation of the auditory words.

Auditory items, previously recorded in a female voice at intervals appropriate to the mixed-modality sequence were presented through a loudspeaker located immediately above the television screen from one track of a stereo tape recorder. The auditory and visual sequences were synchronized by feeding tones, located for the visual sequence, from the second auditory track through a speech relay to the solenoid of the typewriter. A Uher duoplot system was used to start a millisecond clock at the onset of each auditory and visual word.

In Experiment I, *Ss* were required to decide whether or not each word had occurred before in the list. They responded by saying *yes* or *no* on each trial in the continuous list. The RT was measured from the onset of each word, and the clock

was stopped by S's vocal responses amplified from a microphone signal.

In Experiment II, *Ss* were required to say *same*, *different*, or *no*. If a word had occurred before in the list, *Ss* said *same* or *different* contingent on their decision as to whether or not the word had been presented in the same physical form on the 2 occasions. The *Ss* said *no* if the word had not appeared in the list before. The RT was not measured in this experiment.

RESULTS

Recognition accuracy. The recognition data for the inter- and intramodality combinations are presented in Table 1. As there was no significant effect attributable to the task variable, the accuracy data are shown pooled across *Ss* in the RT and modality judgment experiments. Each value is therefore based on 600 observations representing 15 observations per *S* for the 40 *Ss* in the RT and modality judgment experiments.

The auditory comparison reveals an advantage for AA relative to VA for all 6 retention intervals. An analysis of variance (ANOVA) (Task × Similarity × Lag) showed that the main effects of similarity, F (1, 38) = 17.3, $p < .001$, and lag, F (5, 190) = 34.7, $p < .001$, were significant. There were no other significant effects (at the .05 level). Thus, the tabular and statistical evidence are consistent with the conclusion that the AA advantage does not diminish over the sampled range of retention intervals.

The visual comparison shows a consistent advantage for VV at the 4 longest retention intervals and some inconsistency at the 2 shortest intervals. An ANOVA (Task × Similarity × Lag) showed that the main effects of similarity, F (1, 38) = 4.8, $p < .05$, and lag, F (5, 190) = 30.5, $p < .001$, were significant. The Similarity × Lag interaction was also significant, F (5, 190) = 8.7, $p < .001$, indicating that the VV advantage increases significantly at the longer retention intervals. There were no other significant effects.

An overall ANOVA (Task × *Ss* × Test Modality × Similarity × Lag) was completed in order to test the hypothesis that the advantage found for the intramodality conditions followed different retention functions in audition and vision. The critical Test Modality × Similarity × Lag interaction, F (5, 190) = 6.7, $p < .001$, showed that this was the case.

The overall performance level was similar in the 2 experiments. The mean detection and false alarm rates were 91.0% and 10.5% in Experiment I and 92.9% and 6.6% in Experiment II. Thus, the data show that recognition performance was not impaired by the additional input and output demands associated with the judgment task in Experiment II.

Recognition reaction time. The results presented in Table 2 show recognition RT for correct recognition decisions for the 4 modality combinations. The values are based on not less than 233 observations per point.

For the auditory comparison, the recognition RT data show a pattern similar to that for recognition accuracy. The auditory-auditory combination enjoys a consistent advantage at most retention inter-

VV	713	764	797	763	774	805	769
AV	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

Note. Abbreviations: AA = auditory auditory, VA = visual-auditory, VV = visual visual, and AV = auditory visual.

vals, however, unlike the accuracy data, the AA advantage is reversed at the longest retention interval and substantially reduced in magnitude at the shortest interval. An ANOVA (Similarity × Lag) showed that the AA advantage, $F(1, 19) = 9.4, p < .01$, lag effect, $F(5, 95) = 31.4, p < .001$, and the Similarity × Lag interaction, $F(5, 95) = 5.1, p < .001$, were all statistically significant.

The visual comparison supported the accuracy data with a clear VV advantage at the longest retention intervals and a lesser advantage at the shorter intervals. An ANOVA showed that the effects of similarity, $F(1, 19) = 14.0, p < .01$, lag, $F(5, 95) = 8.8, p < .001$, and Similarity × Lag interaction, $F(5, 95) = 2.5, p < .05$, were significant.

To summarize, the evidence shows that recognition performance is sensitive to the modality manipulation. In the case of auditory persistence, the tabular data indicate an AA advantage relative to VA at the 5 shortest retention intervals for both accuracy and recognition RT. The recognition RT data indicated that auditory persistence might be limited to a period of less than 2 min. or 31 intervening items, but this may be due to technique-specific or sampling factors. The data clearly supported the conclusion that there is an overall advantage for VV relative to AV and suggested that, if anything, this may be enhanced at long retention intervals.

Knowledge of modality of presentation. The data presented in Table 3 show the proportion of correct judgments for each combination of the experimental conditions. The data are necessarily conditionalized on correct recognition. The results of Experiment II show an advantage for the intramodality conditions, particularly at long retention intervals. An ANOVA (Test Modality × Similarity × Lag) showed that the main effects of Similarity, $F(1, 19) = 11.4, p < .01$, and lag, $F(5, 95) = 27.9, p < .001$, were significant. The Test Modality × Similarity × Lag interaction, $F(5, 95) = 5.5, p < .001$, was also significant.

There are 2 possible sources of artifact in the modality judgment data; first, *S*s could improve their performance by giving more *no* responses when uncertain about modality of first presentation and, secondly, *S*s might give more *same* responses to items in one or both modalities. The finding that accuracy was greater in the modality report group appears to preclude the general criterion effect.

The response bias problem is more complicated. The false alarm data presented in Table 3 indicate a tendency to give more *same* than *different* responses, particularly for visual items. A signal detection analysis was implemented to give an unbiased estimate of modality knowledge. In this analysis, the d' statistic was calculated separately for each condition for each *S*. The hit rate was the number of correct modality judgments expressed as a proportion of the number of correct detections within each condition. The false alarm rates were calculated from the allocation of *same* and *different* judgments to new items. For this purpose it was assumed that the population of new items was

TABLE 3

Proportion of Correct Modality Judgments as a Function of Modality Combination and Lag

Modality combination	Lag: 1	2	4	8	16	32	*M*	False alarms[a]
AA	99.7	99.7	97.9	91.7	89.2	80.0	93.0	3.4
VA	98.3	90.7	96.3	89.2	86.0	77.7	89.7	3.1
VV	99.0	92.3	94.7	89.9	87.3	86.0	91.5	3.9
AV	98.3	99.7	94.6	85.3	84.9	76.7	89.9	2.7

Note. Abbreviations: AA = auditory–auditory, VA = visual–auditory, VV = visual–visual, AV = auditory–visual.
[a] For example, 3.4 and 3.1 indicate the proportion of *same* and *different* responses, respectively, given to new auditory items.

divided equally into *same* and *different* events. Thus, for the VV condition, the false alarm rate was the number of *same* judgments given to new visual items. The same procedure was adopted for *different* judgments. The d' values were 4.04, 3.94, 3.96, and 3.96 for the AA, VA, VV, and AV modality combinations, respectively. An ANOVA completed on the d' values showed that the main effect of similarity was not significant ($F < 1$), but the Test Modality × Similarity × Lag interaction, F (5, 95) = 4.1, $p < .01$, remained significant. Thus, the effect of this calculation was to eliminate the overall advantage associated with the intramodality conditions.

Discussion

The results show that information about modality of presentation remains in memory for a period that must be considered in minutes rather than seconds. This is evident from both the direct evidence that *S*s can give reliable judgments about modality of presentation over a 2-min. period, and from the indirect evidence that recognition performance is facilitated when a word is presented in the same modality on the presentation and test trials.

Detailed analysis of the recognition data indicated some asymmetry in the retention of auditory and visual material. Auditory persistence was at a maximum over short retention intervals of 16 items (64 sec.) or less, but the data did not consistently support the view that auditory persistence was of limited duration. Visual persistence, on the other hand, appeared to be masked at short retention intervals but was present under all conditions at retention intervals beyond 4 intervening items or 16 sec. Unlike recognition, however, the modality judgment data showed that when response biases were controlled there was no evidence of either (*a*) asymmetric retention of auditory and visual information or (*b*) an advantage attributable to the presentation of a word in the same modality on the presentation and test trials.

The most important theoretical questions concern the way in which modality information is encoded and stored in memory and how it is retrieved and used in the recognition and modality report situations. There appear to be a number of possible explanations of the data, ranging, at one extreme, from the view that they are influenced by an extended form of sensory memory, to the view that recognition facilitation as well as modality knowledge is based on abstract information stored in long-term memory.

As argued by Serfass and Dong (1972), the fact that *S*s can remember input modality is not readily explained by reference to information-processing models such as those advanced by Atkinson and Shiffrin (1968), Morton (1969), or Sperling (1967). Certainly, it appears true that these models have neglected the processes involved in storing attributional information about an item in favor of an analysis of the operations involved in the identification and retention of the item per se. However, it may be more appropriate to address modality report data to the question of memory for attributes raised by Underwood (1969). In this context the modality report data may not be critical for any one model of attribute retention.

Hintzman, Block, and Inskeep (1972) have considered 2 explanations of attribute report data. The first of these is that an attribute is encoded as an abstract proposition, associated with the meaning of the word, and bearing only a referential relationship to the stimulus conditions. The second is that attribute information is retained as a literal copy of the perceptual experience. The present data bear on these issues at a number of points. First, as Hintzman et al. have argued, if the modality information is stored as an abstract attribute it should make no difference to recognition whether or not an item is re-presented in the same modality. In this respect the present results clearly support the literal or "representational" position. Furthermore, the asymmetric relationship between auditory and visual persistence in recognition may be adduced as evidence against the view that modality information is encoded only in an abstract form. It is possible, however, that attribute information is encoded and used in different ways for recognition and attribute report. Thus, modality report could be based on abstract information even though recognition facilitation is determined in some other way.

The abstract explanation of the report data received some support from the finding that modality knowledge is generally insensitive to the similarity manipulation. Unlike recognition, performance on the modality report task is not facilitated in the same modality condition. On the other hand, there is evidence that performance on the between-modalities

attribute is superior to performance on within-modalities attributes. This trend was reported by Hintzman et al. (1972), and is apparent in a comparison between the results of the present experiment and the results of (*a*) an analogous visual experiment using 2 type fonts (Kirsner, 1973), and (*b*) an auditory experiment using 2 voices (Craik & Kirsner).[3] Thus, if attribute information is stored only in an abstract form dependent on the verbal unit in memory, then it seems necessary to conclude that the organization of the structure surrounding the word unit is influenced by perceptual as well as linguistic factors.

In summary, it has been argued that (*a*) modality information is stored in a representation form in memory, (*b*) this representational information is used directly in recognition, and (*c*) modality judgments also use information which may be stored in a representational form, but that access to this information is achieved via the word unit. These conclusions are of course tentative, and an accurate description of the relationship between representational and linguistic systems in memory depends on further research.

THE EFFECT OF LEVEL OF DEPTH PROCESSING AND DEGREE OF INFORMATIONAL DISCREPANCY ON ADAPTATION TO UNIOCULAR IMAGE MAGNIFICATION [1]

WILLIAM EPSTEIN [2] AND CYNTHIA L. MORGAN-PAAP

University of Wisconsin—Madison

The *S*s adapted to uniocular image magnification which transformed the preexperimental relationship between objective depth slant and retinal disparity. The adaptation treatment consisted of continuous inspection of a single luminous figure representing for different *S*s three different degrees of perspectival slant. Two levels of depth processing were contrasted: *depth registration*—an activity which diverted *S* from active utilization of depth information—and *depth processing*—an activity that required frequent utilization of depth information. The magnitude of adaptation was found to increase as the discrepancy between perspectival and stereoscopic slant increased and to be greater following depth processing than following depth registration. The results were discussed in the context of an account of adaptation which stresses resolution of informational discrepancy. Other findings in the literature were reinterpreted in the light of the current experiments.

In earlier experiments (Epstein, 1971, 1972a, 1972b; Epstein & Daviess, 1972; Epstein & Morgan, 1970) we showed that the relationship between retinal disparity and perceived stereoscopic depth is modified by a period of exposure to uniocular horizontal image magnification produced by a meridional size lens (MSL). The *S*s, who engaged in binocular visual exploration of a typical indoor environment, while wearing a vertically oriented MSL before one eye, showed subsequent adaptive shifts in depth judgments based on binocular disparity. The shifts were interpreted as evidence that binocular disparity had been recalibrated as a consequence of the pairing of disparity with the nontransformed discrepant information provided by exposure to the normal environment.

The present experiments had three objectives. First, we wished to test a procedure for bringing the adaptation treatment under experimental control. Although the early contemporary research (reviewed by Epstein, 1967, Chap. 9) employed controlled laboratory tests to produce adaptation, e.g., target-marking, much recent work, including our previous work on uniocular image magnification, has favored the less controlled expedient of giving *S* a period of exposure to the normal extralaboratory environment. The advantage of this latter treatment is that it combines all of the nontransformed informational inputs from the environment in joint opposition to the optically transformed input, thus providing optimal opportunity for adaptation. The disadvantages are all those associated with lack of control. Therefore, in Experiment II we set about to demonstrate adaptation to uniocular image magnification with a strictly controlled treatment.

Our second objective was to examine the relationship between the degree of informational discrepancy and the magnitude of the adaptive shift. In the present experiments the discrepancy was between perspective slant and stereoscopic slant. We chose perspective as the source of discrepant input because there is evidence that in the absence of other information, perspectival cues are effective determinants of perceived slant in depth (e.g., Clark, Smith, & Rabe, 1955; Freeman, 1966), and because

[1] This investigation was supported by U.S. Public Health Service Grant MH-16390. The authors wish to thank Krishan D. Broota, S. M. Ebenholtz, and Kenneth Paap for help with various aspects of this investigation.

there is evidence that in a cue-conflict situation perspective can modify the effect of binocular disparity (Gillam, 1968). Despite the aforementioned evidence, Experiment I was designed to assess *S*'s depth judgments in a cue-conflict situation involving disparity and perspective. The choice of perspective is also recommended upon considerations of experimental convenience. It is a simple matter to vary perspectival slant and thus vary the degree of informational discrepancy. In Experiment II, stereoscopic slant, determined by the MSL, was kept constant, while perspectival slant, determined by the figural properties of the target that was inspected during the adaptation period, was varied. The adaptation treatment consisted of exposure to discrepancy between perspectival slant and stereoscopic slant, and the measure of adaptation was the shift in binocular, no-lens, judgment of the apparent frontal parallel plane of a single luminous rotatable test line.

A third objective was to examine the influence of level of processing on adaptation. It now is commonplace that adaptive shifts are greater following self-generated, self-controlled movement than following passive, other-controlled movement. Although a variety of interpretations of this result have been advanced, there is a relatively straightforward account which rarely has been made explicit. On the view that adaptation represents a response to informational discrepancy, it is plausible that the degree of adaptation would depend on the degree of processing of the inputs that are potentially discrepant. If processing of the input has no behavioral significance, because behavior is guided externally, as in the case of passive movement, then processing may be aborted and the informational discrepancy may not be sufficient to motivate adaptation. Accordingly, adaptation following passive activity will be less than adaptation following self-generated activity.

In the foregoing account, the important difference is not between active and passive movement, but between levels of processing; simple registration of input versus processing of the input in the service of a relevant perceptual discrimination. Therefore, in Experiment II we examined the effects of two types of exposure tasks on adaptation to uniocular image magnification. In both tasks the displays, conditions of viewing, and duration of visual exposure were identical. In the *depth registration* condition *S*'s attention was drawn to a task that did not require utilization of depth information; in the *depth-processing* condition *S*'s attention was drawn to a task that required processing of depth information. Our expectation was that *depth processing* would lead to greater adaptation.

Experiment I

Prior to the investigation of our principal questions it was necessary to assess the responses of the perceptual system to the discrepancy between perspectival and stereoscopic slant. What is the apparent slant in depth of a target whose retinal perspectival correlates and retinal-disparity correlates are not in agreement? To answer this question, judgments were secured of the apparent slant of frontal parallel projections of a rectangle rotated in depth about its vertical axis, presented under three conditions of viewing: monocular viewing (M), binocular untransformed viewing (B), and binocular viewing with MSL before one eye (MSL). On some trials in the MSL condition, the direction of the theoretical rotation of the frontal plane induced by the MSL, i.e., the direction of stereoscopic slant expected in the absence of conflicting input, was consistent with the direction of perspectival slant; on other trials, the directions of perspectival and stereoscopic slant did not agree. With these variations in mind, the specific questions to be resolved in Experiment I were the following: (*a*) In the absence of discrepant input (Condition M), will the perspectival cue determine apparent slant-in-depth reliably? (*b*) When normal access to binocular disparity is available (Condition B), will the effect of perspective be attenuated? (*c*) When the discrepancy between stereoscopic slant and perspectival slant is accentuated (Condition MSL), is

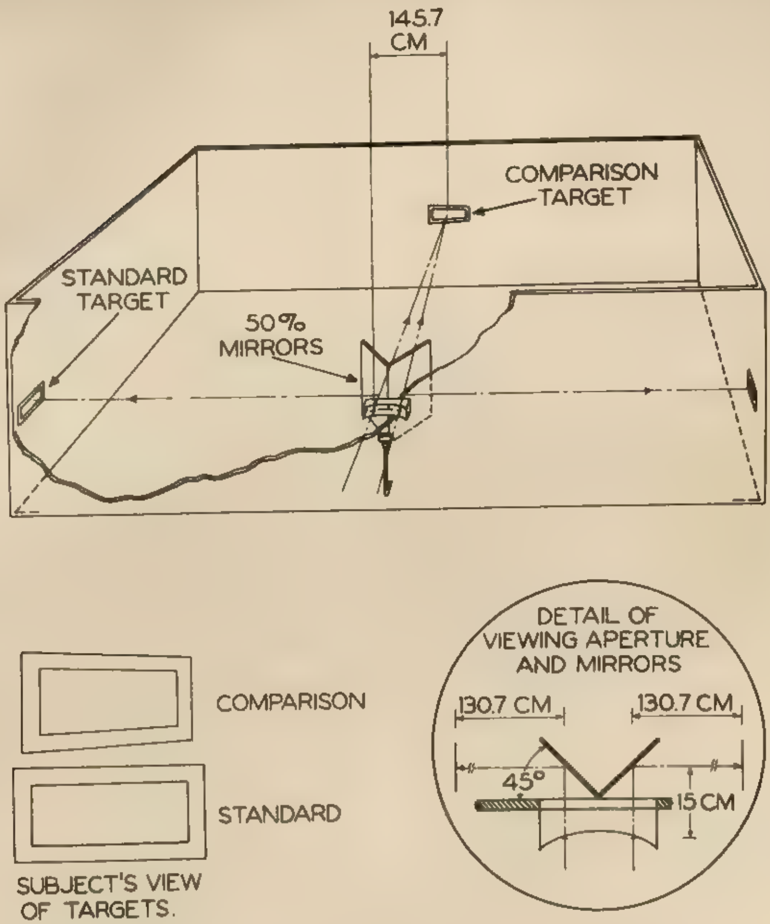

FIGURE 1. Arrangement for presenting stimuli. (Explanation is in text.)

the result a perceptual compromise or does one or the other of the two inputs dominate completely?

Method

Apparatus. Figure 1 shows the arrangement for presenting the stimuli. The *S* always viewed two targets simultaneously, one above the other: a monocularly viewed standard presented to the left eye and a comparison which was presented for either monocular or binocular inspection as the experiment required. The comparison target was 145.7 cm. directly in front of *S*. The 50% mirrors just inside the viewing aperture at 45° angles allowed the monocularly seen standard to appear at the same distance and directly below the comparison. The standard and comparison targets were equivalent in subjective brightness. Even though the monocular target was viewed only with the left eye, a mirror was placed in front of both eyes so that both eyes would receive similar amounts of light. The *Ss* viewed the targets through an aperture 13.75 × 6.25 cm. while supported by a chin rest.

Stimuli. The targets were photographic negatives of a 20.4 × 10.2 × 1.9 cm. rectangle, photographed at slants of −60° to +60° in 10° steps. A 20.4 × 10.2 cm. rectangle subtends a visual angle of 8° × 4° at the viewing distance used. The targets were placed in slots in front of frosted glass and were back-illuminated. They appeared to *S* to be luminous white against a totally black background. In addition, there was a horizontal line target, 20.4 × 6 cm. The line was cut into a black surround and when back-illuminated like the other targets, it too appeared to be a luminous white against a black background.

Lens. A 6% meridional size lens and two plain glasses ground by the American Optical Company were used.

Design. Twelve presentation orders were generated from a Latin square. Each of the 12 slants of the comparison (±10° to ±60°) appeared in each serial position only once and each slant was preceded by and followed by every other slant only

once. The zero-slant rectangle was always the first and the last comparison target in each viewing condition. It was the only target presented twice. The standard was always a rectangle, a zero-slant target. Slant estimates were secured for each comparison relative to the standard. Every *S* judged all comparison slants under each of the three viewing conditions in succession: M, B, and MSL. The order of viewing conditions was determined randomly for each *S*.

Procedure. The *S* was seated with head in a chin rest, at the viewing aperture. The viewing aperture was parallel with the forehead and eye level was at the height of the midpoint of the aperture. First the effectiveness of the MSL was determined. This was accomplished by presenting the horizontal line for binocular inspection in the place where the comparison targets would later be seen. The monocular standard was also in view and *S* was instructed to provide an estimate of the slant of the line relative to the standard using a reproduction procedure:

> You will see a rectangle and a horizontal line, one above the other. The rectangle will be of zero slant, that is, parallel to your forehead. Your task will be to reproduce the apparent visual slant of the line relative to the rectangle; that is, to draw an angle which corresponds to the apparent angular separation of the rectangle and the line. I am only interested in how slanted the line appears to be, and you need not worry about where it actually is.

The *S* was given a clipboard with sheets of paper attached to it. Each sheet showed a circle 11.75 cm. in diameter with a small dot marking its center and a line drawn through its center bisecting the circle. Demonstrations of drawings of the line to reproduce the angular rotation of the horizontal line were provided.

Throughout the entire experiment *S* wore an American Optical trial frame. For the screening test a plain glass was inserted in one frame while the other had the 6% MSL. The MSL eye was the one subsequently to be used in the MSL condition for that *S*. The *S* observed the line and rectangle for 45 sec. before responding. The 45-sec. viewing time was chosen because the stereoscopic effect of the MSL is not immediate (Seagrim, 1969). The lights were then turned on, *S* removed the glasses, and then drew the apparent angular rotation of the horizontal line on the top sheet of paper.

Then *S* was exposed to the three viewing conditions and the succession of 14 targets in each condition. In Condition M, *S* wore a plain glass before the left eye and an eye patch over the right eye, in Condition B the trial frame had two plain glasses (PG), and in Condition MSL the MSL was before one eye and a PG was before the other. Half of the *S*s wore the lens before the right eye and half before the left eye. The following instructions were read:

> You will see two rectangles, one above the other. The top rectangle will be changed in slant from trial to trial at random but the bottom will always be a rectangle of zero slant, that is parallel to your forehead. Your task will be to reproduce the apparent visual slant of the top rectangle relative to the bottom rectangle, that is, to draw an angle which corresponds to the apparent angular separation of the two rectangles. I am only interested in how slanted the top rectangle appears to be, and you need not worry about where it actually is.

The room lights were turned on while *S* reproduced the angular rotation of the comparison and changed the targets. After each reproduction *S* moved the response sheet so that preceding reproductions were not open to inspection by *S*.

Subjects. The 24 *S*s were University of Wisconsin undergraduates. Persons who normally wore framed glasses were not selected but wearers of contact lenses were accepted. To secure these 24 *S*s, 34 were tested. Ten were rejected because they did not exhibit an MSL effect when viewing the horizontal line.

Results and Discussion

On the screening test, slant estimates of the horizontal line were 30.83° ($SD = 9.09°$) for the 12 *S*s who wore the MSL before the right eye, and also 30.83° ($SD = 8.16°$) for the 12 *S*s who wore the MSL before the left eye. The theoretical geometric effect (Ogle, 1964) for the 6% MSL at an observation distance of 145.7 cm. is 51°5′. Therefore, in estimating the slant of an objectively frontal parallel horizontal line in the absence of veridical slant cues *S* should estimate it as being slanted 51°5′ with the side in front of the lens farther away. Although no *S* exhibited the full effect, all 24 *S*s did exhibit large effects in the predicted direction. The principal data are summarized in Table 1. Analysis of variance showed that neither MSL eye (left or right) nor condition of viewing (M, B, or MSL) were significant sources of variance. However, the effect of degree of perspectival slant was highly significant, F (6, 132) = 769.13, $p < .001$. Table 1 shows that each interval of increased perspectival slant was accompanied by a corresponding increase in estimated slant. Also significant was direction of perspectival slant, F (1, 22) = 6.05, $.025 > p > .01$, although this effect was much smaller than the effect of magnitude of slant. The targets designed to appear with the left side farther away were

...erally estimated at larger slants than ...rgets of the same magnitude slanted with ...right side farther, although the differ-...s between a left- and right-slanted ...get of the same magnitude was small. Also significant was the Direction × Magnitude of Slant interaction, F (6, 132) = ...69, $.05 > p > .01$, and the MSL Eye × ...ection × Magnitude of Slant inter-...on, F (6, 132) = 2.45, $.025 > p > .01$.

The three questions that Experiment I ... designed to answer have been answered ...quivocally. Under the experimental ...ditions, perspectival input had significant and systematic effects on perceived slant depth. The effectiveness of the perspectival input was in no way modified by conflicting stereoscopic slant depth. Perspectival slant was clearly dominant.

Experiment II

The results of Experiment I provided a ...asis for inferring the degree of informa-...ional discrepancy that will be present during an adaptation period in which Ss are exposed to a constant stereoscopic slant coupled with varying degrees of perspec-...ival slant. Consider the case of an S who spends 10 min. in binocular inspection of one of the comparison stimuli of Experiment I while wearing an MSL before one eye. Suppose that the geometric effect of the MSL is a 60° rotation. If the inspection figure is a rectangle (zero slant), the discrepancy between perspectival and stereoscopic slant will be 60°, but if without changing the MSL, the inspection figure is changed to a 60° projection in the same direction as the MSL-induced slant, the discrepancy will be reduced to zero. And by choosing an intermediate projection, e.g., 30°, an intermediate degree of discrepancy is introduced. This plan was followed in Experiment II. Three groups of Ss were tested for adaptation to uniocular image magnification following a period of inspection of one of the perspectival projections used in Experiment I. It was expected that the magnitude of the adaptive shift would be larger the greater the degree of discrepancy, despite the fact that disparity was transformed to the same degree

TABLE 1

Mean Estimates of Slant of Comparison Targets under the Three Viewing Conditions

Comparison	Monocular	Binocular: With MSL[a]	Binocular: Without MSL	Grand M
0°	0	0	0	0
10°	9.50	9.31	9.08	9.30
20°	20.40	19.25	19.00	19.55
30°	29.38	28.75	28 75	29.00

60°	56.63	57.50	57.04	57.00

[a] MSL = meridional size lens.

for all Ss. Each S adapted twice, once in the *depth-registration* condition and once in the *depth-processing* condition.

Method

Apparatus. The apparatus used in Experiment I was employed in Experiment II with a few alterations. The viewing distance to the comparison target was increased from 145.7 cm. to 154.48 cm. The slot where the standard target was shown in Experiment I was covered and not used in Experiment II. Only the comparison target area was used to present the adaptation figures. At a distance of 101 cm. to the left of the chin rest used to look at the targets in Experiment I, a second chin-rest and head-clamp arrangement was set up on the same level as the first chin rest. At a distance of 154.48 cm. a rotatable electroluminescent line, 29 × .5 cm., was located. The height of the line was at S's eye level. The line could be rotated in the horizontal plane on a vertical axis about a pivot point which remained fixed directly in front of S. The position of the line could be read to an accuracy of .5° of rotation. A reading of 180° signified that the line was perpendicular to S's line of sight, that is, in the frontoparallel position; a reading over 180° indicated that the left side was rotated back; a reading under 180° indicated that the right side was rotated back. The chin rest and head clamp inhibited large head movements by S. In order to increase the range of discrepancies that could be studied in our experimental arrangement, an 8% MSL was used in Experiment II. At the viewing distance of 154.58 cm. the geometric effect of the MSL is an apparent rotation of 60°. The trial frame used in Experiment I was used again in Experiment II.

Stimuli. The inspection figures presented to S during the adaptation period were the 0°, 30°, and 60° figures previously used in Experiment I.

Design. Three independent groups of 20 Ss were tested. Each S was exposed to only a single adaptation figure, but each S participated in both adaptation activities. Within each group, half of the Ss

had the depth-registration activity on the first day and the depth-processing activity on the second day, while the other *S*s had the two adaptation activities in reverse order. The two adaptation sessions were separated by 48 hr. Half of the *S*s in each group wore the MSL before the right eye during the adaptation period and half wore the MSL before the left eye. The adaptation figures and the MSL eye were always paired together in such a way that perspectival slant and stereoscopic slant were in the same direction.

Procedure. All *S*s followed the identical preadaptation procedure. First, *S* made eight judgments of the frontoparallel position of the electroluminescent line. The *S* was seated at the chinrest and head-clamp arrangement and viewed the electroluminescent line binocularly in total darkness. The first four judgments were made wearing the trial frame with PG in both frames. The second four judgments were made wearing the trial frame with a PG in one frame and the 8% MSL in the other. Two of the settings of each set of four started with the line at 155° and two with the line at 205°.

The *S* instructed *E* to adjust the position of the line until it appeared parallel with her forehead. Head movements were explicitly discouraged. In order to reduce the tendency to make judgments based on line length rather than slant depth, *S*s were told to disregard the length of the line and judge exclusively on the basis of the line's orientation relative to her forehead. This instruction was necessary since, with a predicted geometric effect of 60°, apparent line length could become a confounding variable.

Following the preadaptation tests, the glasses were removed and then *S* moved to the other chin rest. The *S*s in the *depth-registration* condition heard the following instructions:

> This stage of the experiment is concerned with signal detection. We wish to learn whether the ability of an observer to detect a faint signal varies over a ten-minute period of observation of a simple unstimulating visual field. When you look into this box you will see a luminous four-sided figure in an otherwise dark background. At infrequent and irregular intervals a faint light will be flashed inside the figure. The light will appear in one of the four corners. The corners at which the light will appear have been selected randomly, so it will not be possible for you to predict where the signal will appear. When you have detected a signal press one of the four buttons to show its location in the figure.

The *S* was shown how to use the response box buttons. The glasses were restored with the MSL still in place and then she observed the figure and responded for 10 min. The *S*s in the *depth-processing* condition heard the following instructions:

> This stage of the experiment is concerned with another form of depth judgment. We wish to learn whether the depth at which objects app[ear] varies over a ten-minute period of continuo[us] observation. When you look into this box [you] will see a luminous four-sided figure in an ot[her]wise dark background. At infrequent [and] irregular intervals a faint light will be flash[ed] inside the figure. The light will appear in [one] of the four corners. The corners at which th[e] light will appear have been selected randomly so it will not be possible for you to pred[ict] where the signal will appear. Each time a ligh[t] flashes I want you to answer two ques[tions] about the corner in which the light appear[s]: (*a*) Does the corner, that is, the corner wh[ere] the light appeared, appear nearer, farther [or] equal in distance from you as the corner to [the] right or left? (*b*) Does the corner app[ear] nearer, farther, or equal in distance from yo[u] as the corner below or above it?

An example was presented and when *S* understo[od] the procedure, the glasses were restored with th[e] MSL in place and she observed the figure and re[s]ponded for 10 min.

The light flashes were brief and appeared [at] random times at intervals ranging from 30 sec. [to] 90 sec. in randomly ordered corners. After the 10-min. adaptation activity, *S* kept her eyes closed while *E* changed the lenses and while she returned to the other chin rest. All *S*s made two PG postadaptation judgments of the frontoparallel position with the electroluminescent line. Forty-eight hou[rs] later, the procedure was repeated with the second adaptation activity.

Subjects. Sixty undergraduates from the sa[me] population that provided *S*s for Experiment I serv[ed] in Experiment II. Twenty *S*s were assigned to each of the three adaptation figures. Since the principal objective of this investigation was to examine the recalibration of binocular disparity as a stimulus for perceived depth we could use as *S*s only observers who gave evidence of effective use of disparity prior to the introduction of the experimental treatment. To secure 60 *S*s who satisfied this requirement it was necessary to test a total of 97 *S*s. Twenty-four were rejected because the mean of the 4 frontoparallel PG settings deviated from the true frontoparallel by more than ±10°; 11 were rejected because of failure to exhibit an MSL effect of at least 20°; and 2 were dropped due to a failure to return for the second day of testing. With the exception of the latter 2 *S*s, all rejected *S*s were terminated before the initiation of the adaptation period on the first day. None of the retained *S*s wore framed corrective glasses but several were regular users of contact lenses and these *S*s continued to wear the contact lenses throughout the experiment.

Results

Preexposure plain glass judgments. The results are summarized in Table 2. The

TABLE 2

Mean Preadaptation Setting of Frontal Parallel, Mean Shift, and Percept Adaptation: Depth Registration First; Depth Processing First

Level of processing	0° adaptation figure			30° adaptation figure			60° adaptation figure			Average % adaptation
	Pre M	Shift M	% adaptation	Pre M	Shift M	% adaptation	Pre M	Shift M	% adaptation	
Depth registration first										
Depth registration	181.02	19.48	56.86	179.78	14.40	46.58	180.38	10.90	34.48	45.97
Depth processing	180.72	26.22	74.24	180.85	22.65	74.20	180.48	16.88	53.50	67.31
Depth processing first										
Depth registration	179.58	16.50	49.80	180.60	11.40	35.21	180.55	6.90	21.31	35.44
Depth processing	180.52	24.52	69.84	179.92	15.52	49.05	180.65	9.62	30.43	49.77

mean preexposure frontoparallel judgments, based on the four settings, show that *S*s were highly accurate. A between-*S*s (adaptation figure and MSL eye), within-*S*s (adaptation activity) analysis of variance of the preexposure settings showed no significant main effects or interactions.

Preexposure meridional size lens judgments. The MSL produces an apparent rotation of the frontal plane, so that when the electroluminescent line is objectively in the frontoparallel position, the side on the same side as the lens appears farther back. Therefore to adjust the line to the apparent frontoparallel plane the right side of the line must be moved forward when the right eye is exposed to the lens and the left side of the line must be moved forward when the left eye is exposed to the lens. As noted earlier, the predicted geometric effect is 60°.

All *S*s made adjustments in the predicted direction. When the line was judged to be in the frontoparallel position, the mean MSL settings differed from the mean PG settings (the MSL effect) by 34.38°, 31.47°, and 32.93° for the groups assigned to the 0°, 30°, and 60° adaptation figures, respectively. A between-*S*s (adaptation figure and MSL eye), within-*S*s (adaptation activity) analysis of variance was computed to determine whether the groups differed before the start of the different adaptation treatments. There were no significant main effects. There was one significant interaction: Adaptation Figures × Adaptation Activity, $F\ (2, 54) = 3.42$, $p < .05$.

Postadaptation judgments. Table 2 shows the mean postadaptation plain glass shift (difference between the pre- and postadaptation judgments) and the percent adaptation for the three adaptation figures and the two adaptation activities. Adaptation is evident if at the removal of the MSL *S* judges the line to be frontoparallel when the line is set to produce the same disparity that was produced by the MSL. Therefore, the effect will be a deviation of judgments of frontoparallel from the preadaptation frontoparallel, with the side of the line on the same side occupied formerly by the MSL set farther back.

All *S*s showed aftereffects in the predicted direction with mean shifts ranging from 6.90° to 26.22°. The degree of shift depended on the inspection figure and the type of adaptation activity. The effect of these variables is readily discerned in Figure 2 which presents percent adaptation averaged over the two orders in which the two adaptation activities were experienced. Figure 2 shows that the magnitude of the adaptive shift decreased as the perspectival slant of the inspection figure increased and that for all inspection figures the adaptive shift was greater following the depth-processing activity compared to the depth-

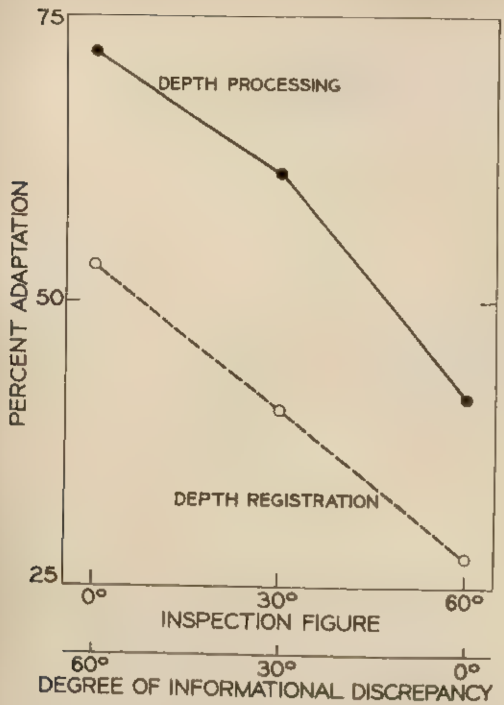

FIGURE 2. Percent adaptation for three inspection figures (degree of discrepancy) and two types of adaptation activity averaged for the two orders.

registration activity. The average percent adaptation was 63%, 51%, and 35% for the 0°, 30°, and 60° inspection figures, respectively. The average percent adaptation was 64% and 45% for the depth-processing and depth-registration activities, respectively. A between-*S*s (adaptation figure, MSL eye, and order of adaptation activity), within-*S*s (adaptation activity) analysis of variance was performed on the percent adaptation data. The main effects of adaptation figure, F (2, 48) = 19.88, $p < .001$, MSL eye, F (1, 48) = 4.76, $p < .05$, adaptation activity order, F (1, 48) = 15.10, $p < .001$, and adaptation activity, F (1, 48) = 90.48, $p < .001$, were significant. There were no significant interactions. The effect of MSL eye was due to the slightly greater adaptation for *S*s who wore the MSL before the left eye. The order of activity effect was due to the fact that the passive–active order resulted in greater adaptation than the reverse order.

Discussion

Experiment II showed that for a con transformation (enhancement) of bin disparity the magnitude of the adaptive varied as a consequence of variations of spectival slant of the adaptation figure. Th are no strictly analogous observations in literature. However, our findings can related to the results of experiments that h varied the degree of optical transformat e.g., degree of optical tilt (Ebenholtz, 1966 degree of sideways displacement (Efstath 1969). In these cases, the adaptive shift been found to increase as the magnitude of t optical transformation has increased. Th present findings strongly suggest that the essen tial variation, common to both procedures, i a variation in the degree of informational discrepancy. The magnitude of discrepancy can be varied by manipulating the degree of optical transformation or by varying the informatio correlated with the nontransformed input The effect is comparable. Nevertheless, ou procedure has the advantage of avoiding confounding due to unwanted variations in th ocular system that may be associated with vari ations of the degree of optical transformation

The model of adaptation to uniocular imag magnification which we have advanced in our earlier reports (Epstein, 1971, 1972a; Epstein & Morgan, 1970), and which has been ind pendently formulated by Wallach (Wallach & Frey, 1972a) in accounting for adaptation in volving the oculomotor cues, has a ready explanation for the dependence of magnitude of adaptation on degree of informational discrepancy. In the present instance, the claim is that binocular disparity has been recalibrated or reevaluated as a consequence of being continuously paired with a dominant, discrepant input. The degree of disparity imposed by the MSL acquires a new significance for perceived depth, one which is consistent with the dominant perspectival slant. The farther apart are the two slants, the greater must be the shift in the significance of disparity if the prevailing degree of disparity is to become equivalent in its effect on perceived depth to the effect of perspective.

It is important to note that in our formulation, the directing factor in the relationship between the discrepant inputs is not that one elicits veridical percepts and the other, being transformed, elicits nonveridical percepts. In the present experiment, since the target was in fact frontoparallel, both inputs induced non-

veridical percepts. The directing factor in our experiment was cue dominance. As Experi[illegible] showed, under our conditions per[illegible]al slant was dominant. Accordingly, [illegible]ity was recalibrated. The direction of [illegible]ift, therefore, is determined by dominance, not veridicality. Of course, if the dominant input is untransformed and yields veridical [illegible]on the adaptive shift in the subordinate [illegible]ll be toward veridicality. That shifts [illegible]eridicality have been the rule in the [illegible]f adaptation is a coincidence of the [illegible]ental designs that have been favored. [illegible]imple matter to demonstrate "counter[illegible]ptation" (Wallach & Frey, 1972b) or "maladaptive adaptation" (Canon, 1971), in which the shift is from veridical to nonveridical perception. All that is required is to pair a subordinate nontransformed input with a dominant transformed input.

The vital role of cue dominance as the directive factor in adaptation may also explain the way in which selective attention effects adaptation to informational discrepancy. Canon (1970) exposed S to an intermodal discrepancy between visual and auditory localization. During the adaptation period, S tracked a moving target presented in both modalities, under instructions to attend to the visual input ignor[illegible] the auditory input, or vice versa. Follow[illegible]he adaptation period, measures of locali[illegible]tion were secured with auditory input and visual inputs separately. Canon found that adaptation was restricted almost entirely to the unattended modality. If we may assume that selectively attending to a cue or to the input from a specific modality confers dominance to the attended cue or modality, Canon's finding can be understood. Dominance relationships among cues or modalities are no doubt well-established by preexperimental perceptual experience, perhaps on the basis of probabilistic considerations similar to those proposed by Brunswik (1956). But dominance in a given situation may be affected by contemporary or situation-specific factors, in Canon's (1970) case, distribution of attention. This result is all the more significant because it seems likely that without selective attention visual localization dominates auditory localization (Weerts & Thurlow, 1971), so that if our interpretation is correct, selective attention is able to reverse preexperimental dominance relationships.

The 60° inspection figure in Experiment II was selected because in this case perspectival slant and stereoscopic slant matched. Accordingly, informational discrepancy was assumed to be absent and significant adaptation was not expected. However, the experimental results showed that although the 60° inspection figure yielded the smallest shift the adaptation effect was significant. This result may suggest that a portion of the adaptive shift is not a response to informational discrepancy, just as in the case of tilt adaptation a part of the total adaptive shift may be attributed to Gibson-type normalization (Morant & Beller, 1965). A more likely explanation of the occurrence of significant adaptation to the 60° figure is that motion parallax, arising from unavoidable small head movements during the 10-min. adaptation period, offset perspectival slant and introduced a discrepancy between motion parallax slant and stereoscopic slant. This difficulty would not be present in Experiment I because S was not required to maintain the head in a stationary position for any extended time. When we retested eight high adapters selected from the Ss of Experiment II some time after the conclusion of Experiment II, using a modified procedure which reduced head movements to the practical minimum, the adaptive shift in response to the 60° figure was reduced. Nevertheless, since adaptive shifts were not totally eliminated the question remains open.

The other principal finding of Experiment II is that an adaptation activity that requires depth processing yields greater adaptation than passive registration of depth. The effect of processing level may be attributable to two related factors: (*a*) depth processing may supply an added motive for resolution of the informational discrepancy, inasmuch as the requirement to localize the target may compel the visual system to opt for one outcome, and (*b*) depth processing may enhance the potency of the dominant cue by encouraging S to utilize the cue. Although the experimental results clearly show an enhancement attributable to depth processing it is also clear that adaptation occurs even when S is directed away from the relevant discriminations. Of course, the procedure did not purport to control S's processing completely, only to introduce a difference in level of processing. It seems likely that in the depth-registration condition Ss did engage in a degree of depth processing.

It should be understood that we are not claiming that depth processing is a necessary condition for the occurrence of adaptation to transformed disparity. Even were depth processing absent completely, the fact that dis-

crepant inputs are present is likely to be sufficient to produce some adaptation. The situation is analogous to that which prevails in the case of the difference between passive and active movement. While adaptation usually is greater following active movement, significant adaptive shifts do occur following passive movement (e.g., Mack, 1967; Singer & Day, 1966). According to our argument, adaptation is greater following active self-generated movement for reasons similar to those we offered in explaining the effect of level of processing in the present experiment. Nevertheless, adaptation following passive movement will occur as long as informational discrepancy is present.

EVIDENCE FOR SEMANTIC ANALYSIS OF UNATTENDED VERBAL ITEMS[1]

MARILYN C. SMITH[2] AND MARY GROEN

Scarborough College, University of Toronto, Toronto, Ontario, Canada

Are unattended verbal materials stored in short-term memory solely in terms of their sensory features, or do they receive some semantic analysis? To answer this question, *S*s received dichotic presentation of lists of words, with the 2 lists being selected either from the same or from different categories. The *S*s were instructed to attend to only one ear, and ignore the other. Following list presentation, a probe was presented, with *S*s indicating if that probe had been presented in the attended list. Probe type was varied as to category similarity with the attended or unattended lists. It was found that when a probe item was presented that had been an actual item in the unattended channel, long latency and high error rates were found if the category of the unattended item was the same as the attended list, but not if they differed. This was interpreted as indicating that unattended materials receive some semantic analysis.

Several recent studies have pointed to the existence of short-term memory (STM) storage for unattended verbal items (Davis & Smith, 1972; Norman, 1969; Peterson & Kroener, 1964). However, there is some ambiguity concerning the extent to which this material is processed prior to storage. Glucksberg and Cowan (1970) argued that it is only the sensory features of the stimulus, rather than semantic or categorical information about it which is held in STM. This conclusion was based upon 2 findings. In a shadowing task, where narrative passages were dichotically presented, digits were occasionally presented to the unattended ear. When *S*s were later asked if a digit had been presented, homophones of digits that occurred in the narrative such as "too" and "for" were incorrectly identified as digits. This indicates that context had no effect, and that information about meaning was therefore not being extracted from the unattended channel. Secondly, *S*s were instructed to report if there were any instances where they believed a digit had been presented, but were unable to recall exactly which digit it was. However, it was found that unless a specific digit was reported, *S*s reported that no digit had occurred. There was thus no apparent memory for the category *digit* that was separate from specific item occurrence. This is in contrast to memory-attended events, where *S*s can report, correctly, that a category member (e.g., a digit or a word) has occurred without being able to report the identity of the specific item.

Some data of Treisman (1964) support this contention. When an unattended message was the same as the one being shadowed, all *S*s noticed this identity when the time separation was sufficiently short. The critical time interval depended upon whether the shadowed or rejected message was leading. When the relevant message was leading, identity was noticed with an interval up to 4.5 sec., whereas when the irrelevant message was leading, it was only 1.4 sec. Treisman considered these durations to be a measure of STM for the 2 kinds of materials. The important finding with regard to the question of semantic analysis of unattended input relates to the differences she found in the memory duration of attended and unattended messages as a function of the nature of the material employed. When the relevant message was leading, the interval for noticing

[1] This research was supported by National Research Council of Canada Grant APA-191 to Marilyn C. Smith.

identity was 4.5 sec. for prose. This corresponds to about 12 words, the usual memory span for this type of material. However, when *S* was shadowing isolated words, the critical lag was much smaller, about 6 words. Thus, memory in the attended channel is a function of meaning. On the other hand, the number of words by which the irrelevant message led when identity was noticed did *not* depend upon the kind of material used at all, suggesting that semantic analysis was not occurring.

Other studies, however, provide evidence that some semantic analysis of unattended events is done. Lewis (1970) found that unattended material that was semantically similar to the attended material (synonyms) caused *S*s more difficulty in a shadowing task than did semantically dissimilar items. Similarly, Davis and Smith (1972) found that the dichotic presentation of a list of nonsense words which *S*s were instructed to ignore did not cause as much interference in the recall of a list of attended words as did the presentation of a to-be-ignored list of real words.

In the study reported here, a reaction time (RT) paradigm introduced by Sternberg (1966) was employed to study the question of semantic analysis of unattended material. In this procedure, *S*s are presented with a list of words to remember (memory set) followed by a probe item. The task is to determine whether the probe item had been presented as a member of the memory set. It generally has been found that RT increases linearly with the size of the memory set, and that the slope of the function is the same whether or not the probe was one of the presented items. Sternberg interpreted these results as indicating that *S*s perform a serial exhaustive scan of the items in memory.

Recent elaboration of this procedure has indicated that in some situations *S*s may be capable of categorizing the items in the memory set so as to reduce the required search time. De Rosa and Morin (1970) found that when the memory set consisted of a set of consecutive digits, the time required to determine that the probe digit was not a member of this set increased as the difference between the arithmetic value of the presented stimulus and the highest (or lowest) digit in the memory set increased. Lively and Sanford (1972), presenting lists consisting either of digits or of letters, found that the time to decide that a probe item was not a member of the memory set was faster if the probe was a member of the other category to that employed in the memory set. Further evidence for such categorization of items is presented by Smith and Abel (1973). They presented a list of items drawn from several categories followed by a probe consisting of a category name. It was found that the time required to decide whether the given category had been represented in the memory set varied directly with the number of categories, rather than with the actual number of items. All of these studies suggest that upon presentation of the memory set, some categorization of the list items occurs.

The above experiments employed only memory sets to which *S*s were attending. Does the same kind of category analysis occur for unattended input? To study this, *S*s were dichotically presented with 2 lists of words, one of which they were instructed to ignore. All items within a list were drawn from the same category. By varying whether the unattended list on a given trial contained items belonging to the same category as the attended list, as well as the category from which the probe item was selected, it was hoped that something could be learned about the nature of the semantic analysis of unattended input.

If unattended materials are not semantically analyzed, but have only acoustic representation in STM, as suggested by Glucksberg and Cowan (1970), then category similarity between attended and unattended lists should have no influence on RT to the probe. Any effect of category similarity, on the other hand, would be taken as evidence that some semantic analysis is done of the ignored channel. To get more information about the memory representation for unattended input, several different probe words were employed.

Positive probes (i.e., those requiring a *yes* response) were items that had actually been presented in the attended channel. Negative probes were selected from (*a*) the category employed in the attended list, (*b*) the category employed in the unattended list, (*c*) a different category entirely, or (*d*) an actual item in the unattended list. A monaural condition in which the category of the negative probe could be the same or different from the memory set was included for comparison.

Method

Subjects. Five male university students with normal hearing volunteered to participate in this experiment, and were paid for their services.

Apparatus. All lists were recorded using a magnetic Sony (TC-355) 4-track tape recorder, and were presented individually to *S*s through headphones. In recording the lists for dichotic presentation, the 2 channels were matched approximately for loudness. By pressing a voice-operated relay key (Uhr Model F422) before recording each probe word, an inaudible mark was made on the second track of the tape at the onset of the probe. There was a variable delay of 20–40 msec. between actual probe onset and the mark on the tape. During playback, a sensing device, on detecting this mark, triggered a Hunter Klockounter (Model 120A, Series D) which measured RTs to the nearest millisecond. The timer was stopped when *S* manually depressed 1 of 2 microswitch response buttons to indicate his response choice. Because of the distance on the tape recorder between the recording and playback heads, the probe word was not actually heard to begin until 256 msec. after the tape mark had triggered the timer. Thus, this time was subtracted from all recorded RT measures.

Procedure. Six hundred 2-syllable words from 45 different categories were selected from Battig and Montague's (1969) category norms. Only those list words that had been included as category members by at least 5 of the students who established the norms were included. No word was included in more than one category. Prior to testing, *E* read *S* a list of all the words to be used to ensure familiarity with all words and pronunciations.

Each *S* attended 7 sessions over a 4-day period. Two sessions were presented on each of Days 1–3, and the last session was presented on Day 4. On Day 1, *S* received only monaural presentation of the lists, the first session representing a practice session and the second the test. Dichotic lists were presented on Days 2–4, and consisted of 1 practice session followed by 4 test sessions.

In each session, 144 trials were presented. A single trial consisted of the following sequence: a warning signal (metallic tap), a list of 2, 4, or 6 words, another warning signal, and finally, the probe word. A 6-sec. interval elapsed before the beginning of the next trial. In the monaural trials, words and signals occurred at the steady rate of 1/sec. For dichotic trials, one pair of words per second was heard, one word from each tape channel per second. Words in a pair were approximately simultaneous, with the onset of the attended word always preceding the onset of the ignored word by 100–150 msec. Half of the probes were positive; i.e., they were items that had occurred in the preceding list and required a *yes* response. The other half of the probes were negative, requiring *S* to respond *no*. Positive probes were selected from each serial position with equal frequency.

For each *S*, one ear was chosen as the "relevant" ear. Instructions emphasized that he was to attend *only* to that ear, and to ignore materials presented to the irrelevant ear. The *S*s were warned that some probes would occasionally be drawn from the list presented to the irrelevant ear, but that these required a *no* response, and that they would do better in the task if they totally ignored the irrelevant materials. In an attempt to aid *S*s in blocking out the irrelevant ear, the monaural and dichotic attended lists were always presented to the same ear. Further, in the dichotic condition the warning signals and probe words were presented only in the relevant ear. The *S* always made his positive response with the same hand. Each of the 4 possible ear–hand combinations was assigned to each of 4 *S*s. One of the combinations was then randomly assigned to the remaining *S*.

Words within a single list represented only one category. For each trial, a category was selected at random, and then the appropriate number of words was randomly chosen from that category without replacement in a single session. A given word was used only once in the monaural test session, but twice in each dichotic session, once in an attended list and once in an unattended list.

The number of trials in each condition differed for monaural and dichotic sessions. In monaural sessions, half of the negative probes were drawn from the same category as the list items, and half from a different category. Dichotic trials were first subdivided according to the categories of the 2 lists. On half of the trials the lists presented to each ear were from the same (S) category; on the other half, they were from different (D) categories. Fifty percent of the probes were positive. The remaining 50% of the negative probes were subdivided into the following types: (*a*) a member of the same category as the attended list (Types S_1 and D_1); (*b*) an actual item from the ignored list (Types S_2 and D_2); (*c*) an item from a category different from both lists (Types S_3 and D_3); or (*d*) if the 2 lists were from different categories, an item from the same category as the unattended list (Type D_4).

Under Condition S, the first 3 negative probe types were tested with equal frequency. For Condition D, all 4 types were used, again with equal frequency. Samples of each type of probe appear in Tables 1 and 2, together with their frequency of presentation in each session. If the

TABLE 1

negative probe was an actual item from the ignored list, each serial position was tested equally often.

The specific order of conditions within a session was randomized separately for each set of 144 trials. Each session was recorded on a separate tape. Four dichotic test tapes were required in order to test each serial position for S_2 and D_2 probes at least twice for every list length. They were presented in a different random order to each S.

Results

Monaural presentation. A 3 × 3 × 5 analysis of variance was performed on the mean RT data, the factors being list length (2, 4, or 6 words), probe type (positive, negative from the same category as list, and negative from a different category), and *S*s. Incorrect responses were not included in the analysis. The only significant factor found was list length, $F\ (2, 8) = 26.7$, $p < .01$. Probe types, the variable of interest with respect to classification, did not result in significantly different RTs, suggesting that classification was not used as the decision strategy in responding to negative probes. Despite this finding, all *S*s spontaneously reported that probes from different categories were easier to reject.

Dichotic presentation. Mean RTs at each list length as a function of whether the category of the attended and unattended lists are the same or different are shown

TABLE 2

Examples of Probe Types for Dichotic Condition (List Length 4)

in Figure 1. Monaural RT data, in which positive and negative probes have been combined, are also shown for comparison. A 4-way analysis of variance was performed on correct mean dichotic RT measures, the factors being list length (3); probe type, i.e., positive or negative (2); category classification, i.e., attended and unattended lists from the same or different categories (2); and *Ss* (5). Different types of negative probes were combined for this preliminary analysis. Only the effects of list length and category type were significant ($p < .01$). As lists became longer, RT increased, F (2, 8) = 70.6, and responses to probes were made more slowly when both lists were from the same category than when the categories were different, F (1, 4) = 26.7. None of the interactions reached the .05 level. A replication of the analysis of variance using median scores yielded the same results.

It can also be seen in Figure 1 that monaural RT was faster than dichotic RT at all list lengths. This effect did not reach significance at the .05 level, perhaps because monaural trials always preceded dichotic trials, and *Ss* were thus not as well practiced. Least squares linear regression equations were calculated for the 3 functions. They are shown in Figure 1. The slope for the 2 dichotic conditions, 44.7 msec. per list item for same category lists and 41.4 msec. for different category lists, indicate that the 2 functions are essentially parallel. Both are slightly steeper than the monaural condition (33.7 msec. per item).

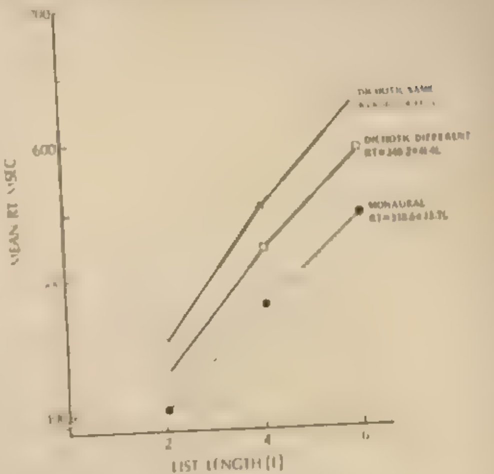

FIGURE 1. Reaction time (RT) for monaural and dichotic conditions.

Mean correct RT for each of the 7 negative probe types as a function of list length is shown in Figure 2. An independent analysis of variance of the various types of negative probes was carried out to clarify the interpretation of the observed differences. The S_2 probes, i.e., those in which an actual item from the unattended list was presented under the condition where both lists were from the same category, were not included in the analysis because of the large number of errors that occurred in this condition. The remaining 6 probe types were examined in a Probe Type × List Length × *Ss* factorial analysis of variance design. Both probe type, F (5, 20) = 5.5, $p < .01$, and list length, F (2, 8) = 21.5, $p < .01$, were found to be significant variables. For this analysis, only correct responses of less than 2 sec. latency were included in determining means.

All sets of paired comparisons of probe types were made by the least significant difference test. When a .05 level was assumed, the 6 probe types fell into 2 different groups. No differences were found for S_1, D_1, and D_2 items. These 3 types were all responded to more slowly than S_3, D_3, and D_4 probes, with the latter 3 not being differently responded to.

To summarize the data in Figure 2, the slowest negative RTs were made to actual items from the unattended list in the condition where both lists were drawn from the same category. Collapsing across list length, mean RT for the S_2 condition was 713 msec. The second longest RTs were found when a probe was presented from the unattended list, the 2 lists being drawn from different categories (D_2), and in those conditions where the negative probe was from the same category as the attended list, regardless of category similarity of the 2 lists (S_1 and D_1). The mean RTs for these 3 conditions were 544, 534, and 547

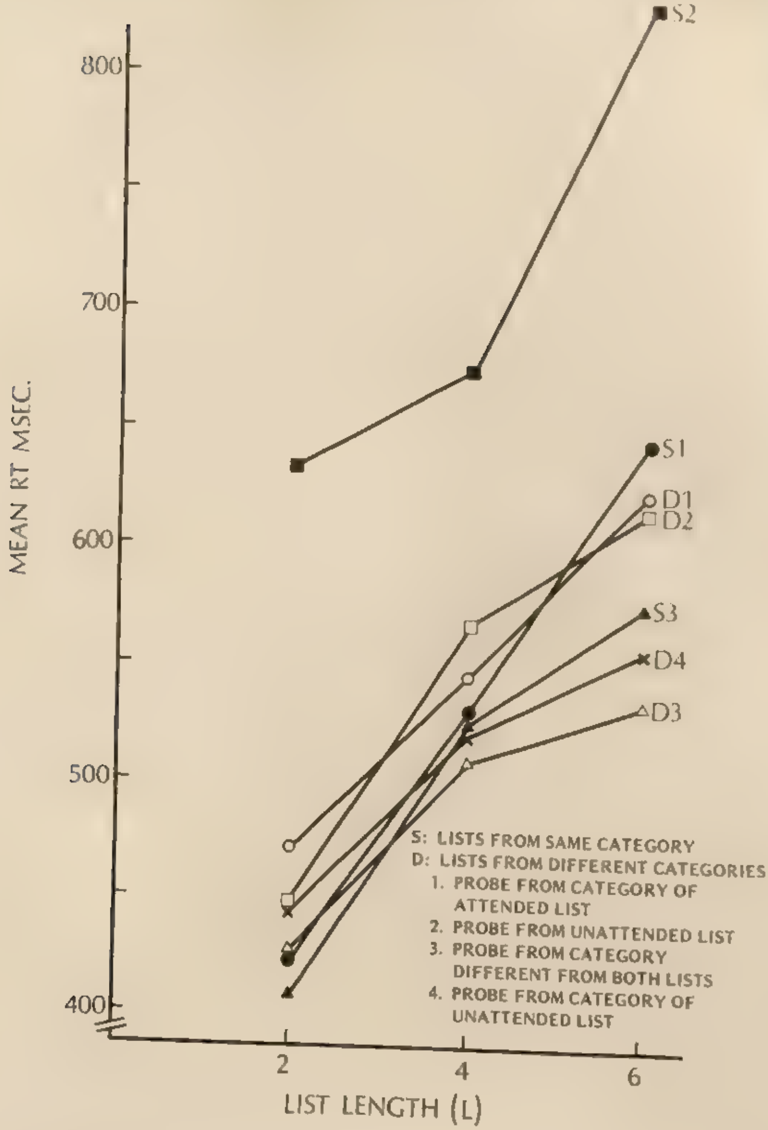

FIGURE 2. Negative reaction times in dichotic condition for each probe type.

msec., respectively. Finally, the fastest negative responses occurred in the 3 conditions in which the probe was drawn from a different category from the attended list, even if that item represented the category of the unattended list, providing it was not an actual item from the unattended list. The mean RTs for these 3 conditions were 505 (S_3), 491 (D_3), and 508 (D_4) msec.

Negative probes that represented actual items from the unattended list (S_2 and D_2) were examined further for serial position effects. Plotting the mean RT as a function of serial position for each list length did not reveal any consistent trends.

Errors. The mean percent errors at each list length are shown in Figure 3. Positive and negative responses have been combined in the monaural condition. Error rate in the monaural condition did not vary as a function of list length, and averaged 3.1%. With dichotic presentation, the errors for negative probes with the exception of the

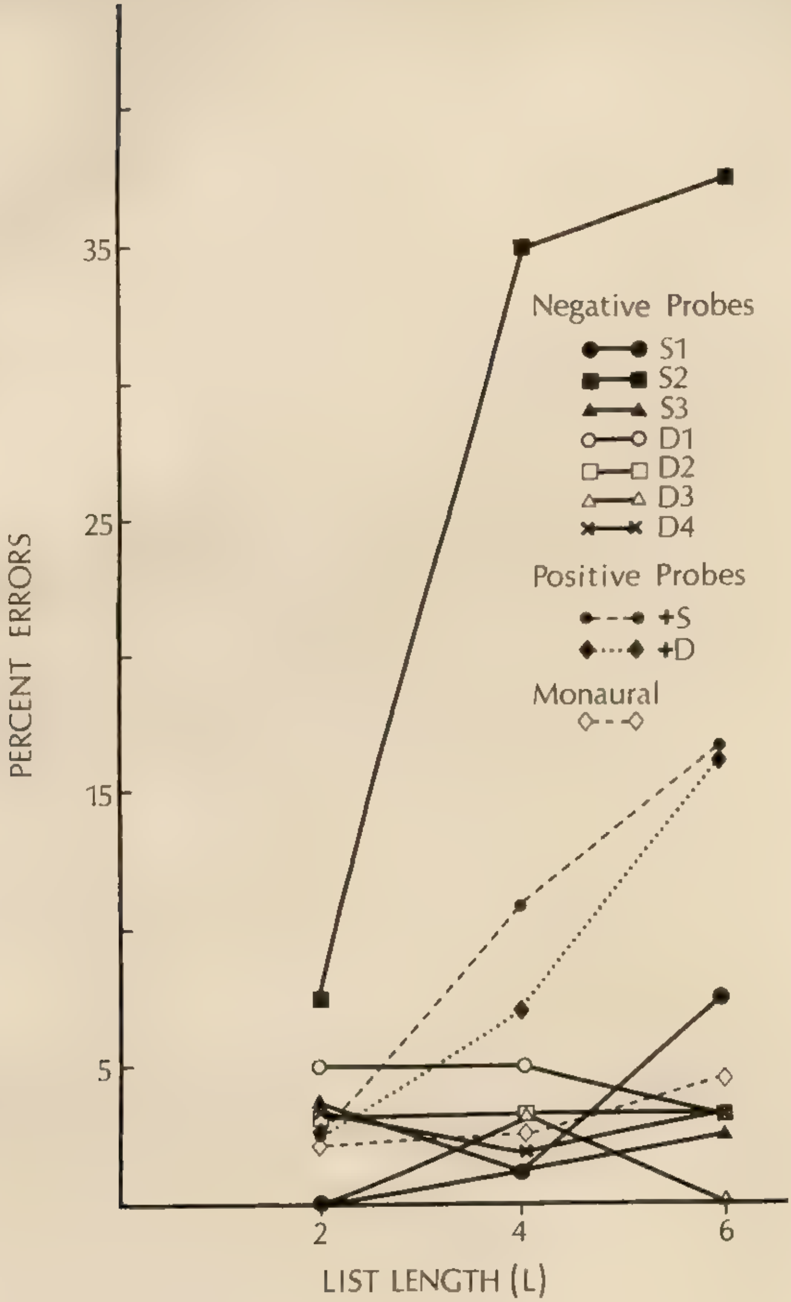

FIGURE 3. Mean percent errors for monaural and dichotic conditions. (Abbreviations: S = same, D = different.)

S_2 condition, were the same as for monaural presentation, in that they did not vary across list length, and averaged 2.9%. For positive responses in the dichotic condition, errors were found to be greater than for negative probes, and to increase with increases in list length.

By far the greatest number of errors occurred in the S_2 condition, where the probe is an actual item from the unattended

list, both lists being drawn from the same category. For List Length 2, error rate was a relatively small 7.5%. However, for the longer list lengths it was approximately 35%, indicating that *S*s have great difficulty distinguishing these items from items in the attended list. In contrast, only 2.8% of the responses to D_2 probes were errors. To determine whether the error rate for the S_2 probe was a function of serial position in the unattended list, error rate was plotted as a function of serial position for each list length. However, no consistent pattern was found.

Serial position effects for positive probes. Mean RT and percent errors for positive probes as a function of serial position were examined for both the monaural and various dichotic conditions. For List Length 2, RT and errors were greatest in Serial Position 2. For List Length 4, a bow-shaped function was found for both RT and errors, with slowest responses and greatest number of errors occurring toward the middle of the list. Finally, at List Length 6, while the RT curve was again generally bowed for the monaural condition, a marked recency effect was found in the dichotic conditions. Similarly , errors were greatest for the items at the beginning of the list, with fewest errors occurring at the later serial positions.

Discussion

The results of this experiment provide evidence that the unattended input is not stored solely in terms of sensory features. Rather, some category analysis appears to take place. The strongest evidence for this conclusion comes from the 2 conditions in which an actual item is drawn from the irrelevant channel and presented as a probe (requiring a negative response). If all unattended items are stored as acoustic representations, as suggested by Glucksberg and Cowan (1970), the category membership of the unattended message should be unimportant. However, it was found that if the items in the unattended channel belonged to the same category as those in the attended list (S_2), RT was far greater than in the condition where the unattended message belonged to a different category (D_2).

The 2 conditions also differed greatly with respect to errors. If a probe, selected from the unattended channel, belonged to a different category from the attended list (D_2), error rate was low, resembling that found for the monaural condition, and did not vary with list length. On the other hand, if the probe was an item that had been presented in the ignored ear and did belong to the same category (S_2), error rate was very high, increasing sharply with list length.

It is of interest to note that the effect of irrelevant list category on either RT or errors is found only when the probe is an actual item from the unattended list. A negative probe from the same category as the unattended list (D_4) is not responded to differently than a probe from a category that was not presented at all (D_3). Hence, category membership of the unattended items is only an important variable when the sensory or acoustic representation of the items are actually present. This would lend support to the conclusion of Glucksberg and Cowan (1970) that there does not appear to be any abstract category representation for unattended items.

The finding that negative probes from the same category as the attended message (S_1 and D_1) are rejected more slowly than words from a different category (S_3, D_3, and D_4), is in agreement with the results of Lively and Sanford (1972). It indicates that categorization occurs for the attended message, with this information being used as a basis for rejection. The failure to find this effect in the monaural condition (i.e., shorter latency for noncategory negative probes) may be due to the fact that unlike the Lively and Sanford study, where only 2 highly learned categories were used (digits and letters), many different categories were employed in this experiment. Since the monaural condition was always presented first, *S*s were less practiced than in the dichotic condition, and perhaps registration of category information was sufficiently variable to eliminate any differences.

FEEDBACK PRECISION AND POSTFEEDBACK INTERVAL DURATION[1]

CECIL A. ROGERS, JR.[2]

University of Arizona

Precision of feedback grain was manipulated in a simple positioning t An optimum was found; an increase in precision past that optimum proc deleterious effects upon rate of acquisition. In a second study, increasing postfeedback interval removed that optimum. The feedback precision eff were then replicated in a timing task. The combined results of the 3 stud were interpreted as supportive of an information-processing approach to t study of postfeedback interval events for simple motor skills. The findi additionally supported specific predictions by Bilodeau and deductions Adams' 1971 theory of motor learning.

Trowbridge and Cason (1932) provided early evidence that increases in feedback precision normally promote rate of acquisition in perceptual–motor tasks. Reviews of the literature by Adams (1971) and Bilodeau (1966, 1969) confirm this relationship for a variety of tasks. Bilodeau did suggest, however, that for any specific task, some optimal level of feedback grain might exist. Increases in precision beyond that level might fail to enhance and could be detrimental to the learning process. Extrinsic feedback might be refined past the point of human response capability or could exceed *S*'s information-processing capacity.

One previous study by Bilodeau and Rosenbach (1953) found few effects from varying feedback grain in a knob positioning task. Since their range of manipulation of feedback precision was somewhat narrow, Experiment I was designed to investigate broader variations of feedback precision in the same task.

The first study was, in essence, a search for Bilodeau's (1966, 1969) predicted optimum. The task and procedures were adapted from Bilodeau and Rosenbach (1953). Their micrometer positioning task met criteria that the amount of intrinsic feedback should be relatively small and that response error measurement should be finely grained.

Experiment I

Method

Subjects. The *S*s were 80 male and female volunteers from introductory psychology classes at the University of Arizona. They were randomly assigned to 1 of 4 groups with the restriction that each group contain equal numbers of each sex.

Apparatus and procedure. A micrometer (Starrett Model 263RL) was mounted behind a black wooden screen so that its turning knob projected through a hole in the center of the screen (Bilodeau & Rosenbach, 1953). The *S*s were seated and their arms were positioned perpendicular to the apparatus, which rested upon a table. The view presented to *S* was that of a black knob on a black background. The body of the micrometer rested behind the screen and was visible only to *E*. Verbal instructions to *S* indicated that he must rotate the knob and learn to stop it at the correct position. One complete rotation of the knob produced a micrometer shaft displacement (not visible to *S*) of .250 unit; the goal response was set at 4 units ± .5 unit. Response error was read directly from the micrometer by *E* before rounding and reporting it orally to *S*. Error was recorded to the nearest .001 unit for all groups. The micrometer was calibrated such that 1 unit equaled 1 in.

Ten acquisition trials were given to each *S*. A single trial consisted of a verbal ready signal followed in 2 sec. by a go signal which was followed in turn by, *S*'s response, oral feedback 43 sec. after the go signal, and the next ready signal 5 sec. after termination of feedback. Duration of feedback was approximately 4 sec. and the total trial cycle was about 55 sec.

[1] This research was supported in part by National Aeronautics and Space Administration Grant NGR-03-002-091 and in part by Tulane University while the author was on sabbatical leave there, 1971–72. The assistance of I. McD. Bilodeau and the data collection aid of John Ireland are appreciatively acknowledged.

[2] Requests for reprints should be sent to Cecil A. Rogers, Jr., Department of Psychology, University of Arizona, Tucson, Arizona 85721.

On the first trial, all *Ss* were told to turn the knob as far as they cared to. If *S* hit the target on a subsequent trial, he was told that his response was correct and that he should try to repeat it on the next trial.

Design. The *Ss* in the 0-order treatment were informed of direction of response error relative to the goal (too short or too far). The 1-digit group also received magnitude information rounded to the nearest whole unit. Response error for 2- and 4-digit groups was reported to the nearest tenth and thousandth of a unit, respectively. For example, an actual response error of +3.214 in. would be reported as "too far," +3, +3.2, or +3.214 units, depending upon feedback condition.

Results and Discussion

Absolute error data were consolidated into 5 2-trial blocks as displayed in Table 1. Variance analyses of Block 1 revealed no significant differences among groups at the onset of practice, F (3, 76) = .40. Subsequent analyses revealed a significant practice effect, F (4, 304) = 72.38, $p < .01$, and a significant feedback grain effect, F (3, 76) = 3.41, $p < .025$. No Feedback × Practice interaction was indicated, F (12, 304) = 1.62. As shown in Table 1, mean response error showed progressive diminution with practice and the increase of feedback precision from 0 to 1 to 2 digits of information. The 4-digit group showed a reversal of this trend by performing more nearly like the 0-digit condition. Examination of Block 5 data revealed a feedback precision effect; F (3, 76) = 3.83, $p < .025$. An unequal interval trend analysis of precision levels at Block 5 indicated a curvilinear component, F (1, 76) = 11.0, $p < .01$. Bilodeau's (1966, 1969) hypothesis was then confirmed in that the most precise level of feedback administered in Experiment I not only failed to produce optimal acquisition rates, but slowed acquisition relative to the 2 intermediate feedback levels.

An analysis of within-trial events suggested a possible mechanism for operation of the feedback grain effects found in Experiment I. Postfeedback interval, from termination of feedback to the next response, was 7 sec. Adams (1971) reviewed the effects of interpolating motor responses in the postfeedback interval and

TABLE 1

Mean Response Error (in in.) for Feedback Conditions over Trial Blocks: Experiment I

Digits of feedback	Trial block				
	1	2	3	4	5
0	5.92	4.91	4.47	3.18	3.14
1	5.86	4.05	2.90	2.33	1.92
2	5.45	4.05	2.63	1.26	.87
4	6.03	4.81	4.17	3.85	2.81

found few effects on motor-skill acquisition. He hypothesized that the interval is primarily one of verbal–cognitive activity by *S*, wherein feedback is processed and a response modification is computed. Adams further suggested that acquisition might be slowed either by interpolating verbal activity in the postfeedback interval or by excessively foreshortening it. If some such minimal information-processing time is required between feedback and the next response, it seems likely that feedback precision would also in part determine optimal interval duration. As precision increases, more information is imparted to *S*. As Adams notes, such precision normally provides *S* with information to make more finely graded responses. However, as *S*'s informational load is increased, more time is required for his selection of a response modification. For a given task, acquisition might then be hindered by very precise feedback combined with a short postfeedback interval. The 7-sec. postfeedback interval in the present study may have been inadequate for the 4-digit condition. The present results considered in the context of Adams' theory suggest a possible interaction between feedback precision and postfeedback interval duration.

Weinburg, Guy, and Tupper (1964) previously demonstrated the deleterious effects of shortening the postfeedback interval while holding grain constant. For one positioning task, they found that 5 sec. was the minimal period required between feedback and the next response. While increases beyond 5 sec. did not aid acquisition, reduction below 5 sec. was harmful.

Experiment II was then designed as a replication of Experiment I, but with the postfeedback interval lengthened. An improvement in the ranking of 4-digit *Ss* might then be expected in the context of Adams' (1971) theory. Bilodeau's (1969, p. 277) position, which emphasizes the information-processing aspects of the postfeedback interval, would also be suggestive of such a finding. Such an outcome would further be consistent with data obtained on postfeedback intervals by Bourne and Bunderson (1963) for concept formation tasks.

Experiment II

Method

Subjects. Sixty undergraduate volunteers from Tulane University were divided into 3 groups of 20 *Ss*. Each group was comprised of an equal number of males and females.

Apparatus and procedure. No change was made in apparatus. Procedure differed from Experiment I only in lengthening of postfeedback interval from 7 to 14 sec., with a consequent foreshortening of the prefeedback period from 43 sec. to 36 sec. The total trial cycle remained 55 sec.

Design. The 0-digit feedback condition present in the first study was omitted from Experiment II. Feedback grains of 1, 2, and 4 digits were administered as in Experiment I to the 3 remaining groups over 10 trials.

Results and Discussion

Mean absolute response error per 2-trial block is shown in Table 2 for the 3 feedback grain conditions. A reordering of rank-order positions obtained in comparison to those found in Experiment I. The relative performance levels of the 1- and 2-digit conditions remained the same, but the 4-digit group improved from worst to best of the 3 conditions. Analysis of Block 1 data indicated no differences among groups early in practice, $F(2, 57) < 1.0$. By Block 5, precision levels differed, $F(2, 57) = 4.05$, $p < .025$. Further analysis of the Block 5 data revealed a linear trend across precision levels, $F(1, 57) = 7.56$, $p < .01$. This linear trend contrasted with the curvilinear trend found in Block 5 of Experiment I. This disappearance of an optimum in Experiment II was consistent with the theories of both Adams (1971) and Bilodeau (1966, 1969) as described above.

The data for the 1-, 2-, and 4-digit conditions from Block 5 of both studies were combined for further analysis. A feedback precision effect, $F(2, 114) = 3.21$, $p < .05$, and an experiment effect, $F(1, 114) = 12.10$, $p < .01$, were found. An Experiment × Feedback Precision interaction was also shown, $F(2, 114) = 5.34$, $p < .01$. That interaction supported the suggested dependency between precision of feedback and postfeedback interval length. On the whole, these findings were consistent with an information-processing approach to the learning of a simple positioning task. Such an approach might further suggest that other variables could be expected to interact with feedback precision and/or duration of postfeedback interval. Information-processing load upon *S* during that interval might vary with response complexity, number of response alternatives, feedback transformations, duration or rate of presentation of feedback, idiosyncratic information-processing strategies, and related variables which are extensively reviewed by both Adams and Bilodeau.

TABLE 2

MEAN RESPONSE ERROR (IN IN.) FOR FEEDBACK CONDITIONS OVER TRIAL BLOCKS: EXPERIMENT II

Digits of feedback	Trial block 1	2	3	4	5
1	5.75	2.79	1.91	1.33	1.22
2	5.27	2.93	1.49	.88	.83
4	4.68	2.00	.88	.68	.54

Experiment III

The phenomenon of a feedback precision optimum found in Experiment I might have been idiosyncratic to the micrometer positioning task. A third study was then conducted with a different apparatus and procedure. An effort was also made to apply a more specific information-processing approach to the present problem. Bernstein, Blake, and Hughes (1968) view

information processing as occurring in 3 successive stages: filtering or detection, processing or stimulus analysis, and response selection. Separate mechanisms are postulated to operate at each stage and rarely operate in parallel (Decker & Rogers, 1973). The most likely locus for operation of feedback precision effects would be in the stimulus analysis and/or response selection stages during the postfeedback interval. By reducing the number of response alternatives to 1, while continuing to present extrinsic feedback at suprathreshold levels, varying precision levels might be studied relative to the stimulus analysis stage alone. A delayed single-choice reaction time task was then chosen for Experiment III. Occurrence of a precision optimum with such a task would then lend limited generality to the phenomenon and associate it in part with the theorized stimulus analysis stage of Bernstein et al.

Method

Subjects. Forty-five undergraduate volunteers from the University of Arizona were randomly assigned to 3 groups without regard to sex. Each was paid for his participation.

Apparatus. A modified Lafayette reaction time apparatus (Model 322B) was interfaced with an electronic timer (Hewlett-Packard Model 522B). Onset of the single blue stimulus light activated the timer. Depression of a telegraph key terminated elapsed time measurement and provided offset of the light. The calibrated timer measured elapsed time to the nearest .00001 sec.

Procedure. The *S*s were seated before a table with the index finger of their preferred hand resting upon a telegraph key. They were instructed that their task would be to learn to wait, following onset of the light, for a specific interval prior to depressing the key. Following a response, feedback was presented for direction (too soon or too late) and magnitude (in seconds) of timing error. Target time was set at 9 sec. ± .5 sec., but *S*s were not so informed. Ten trials were provided. The event sequence consisted of a verbal ready signal followed in 2 sec. by onset of the stimulus light, followed in turn by *S*'s response, feedback 36 sec. after the ready signal, and the next ready signal 5 sec. after termination of feedback. Feedback duration was about 4 sec., providing for a total trial cycle of 45 sec. When *S* responded during the target interval, he was told that he was correct and should repeat his performance on the next trial.

Design. Feedback grain was varied among the 3 groups. The 1-digit group received error rounded

TABLE 3

MEAN TIMING ERROR (IN SEC.) BY FEEDBACK CONDITION AND TRIAL BLOCK: EXPERIMENT III

Digits of feedback	Trial block				
	1	2	3	4	5
1	7.16	4.87	2.63	1.49	1.54
4	5.89	1.91	1.24	1.05	.89
8	7.24	2.87	2.12	1.77	1.45

to the nearest whole second. The 4-digit group was given feedback rounded to the nearest .001 sec., while 8-digit *S*s received feedback refined to the nearest .0000001 sec. In the latter group, the last 2 feedback digits were taken from a random numbers table because the timer was only accurate to 6 digits.

Results and Discussion

Table 3 presents mean absolute response error for each feedback condition over 5 2-trial blocks. No differences among groups were found in Block 1, F (2, 42) < 1.0. Further analysis indicated a practice effect, F (4, 168) $= 41.75$, $p < .01$, and a Practice × Feedback Precision interaction, F (8, 168) $= 2.43$, $p < .05$. No simple precision effect was found, F (2, 42) $= 2.07$. Examination of Block 5 data showed a curvilinear trend over precision levels, F (1, 42) $= 10.0$, $p < .01$, as was found in Experiment I. Optimal feedback precision was the 4-digit condition. Maximum precision produced intermediate level performance with the 1-digit group ranking lowest. The feedback precision effect found in Experiment I with the positioning task was then replicated for the timing task. The optima for the 2 task–procedure combinations were different despite a 7-sec. postfeedback interval for both studies. The higher 4-digit optimum obtained in Experiment III may have resulted from any number of differing variables between the 2 studies, including the shorter trial cycle and simplified response demand characteristics in the timing task. The deleterious acquisition effect of excessively precise feedback in the third study was less severe than in the first, perhaps for similar reasons. On the whole, Experiment III findings lend limited

generality to the feedback optimality phenomenon. The existence of such an optimum, in a task where extrinsic feedback was at suprathreshold levels and response selection demands were low, suggests that the information-processing mechanism affected may operate in part during the stimulus analysis stage described by Bernstein et al. (1968).

Further extension of the Bernstein et al. approach to simple skills tasks would suggest that the detection stage operates roughly between onset and offset of feedback. This feedback duration interval occurs between pre- and postfeedback intervals but has rarely been extracted or examined in simple positioning tasks. Previously established signal detection variables would presumably operate during this feedback presentation interval. Occurring next, during the early part of the postfeedback interval, would be the stimulus analysis stage. Its minimal length would be determined by feedback characteristics, long- and short-term verbal and motor memory demands, and possibly cognitive or problem-solving requirements in some tasks. Bernstein's response selection stage would occur last in the postfeedback interval, provided such time were available. The Bernstein et al. formulations may represent a convenient vehicle for deriving increasingly specific hypotheses as to the nature, duration, and sequencing of postfeedback interval events in simple motor-skills tasks. Such a microscopic analysis of within-trial events follows directly from the suggestions of bo[illegible] Adams (1971) and Bilodeau (1966, 1969) th[illegible] simple motor tasks have strong verbal-[illegible]nitive components active during the p[illegible]tfeedback interval.

PRODUCTION, ESTIMATION, AND REPRODUCTION OF TIME INTERVALS DURING INHALATION OF A GENERAL ANESTHETIC IN MAN[1]

NILLY ADAM,[2] ANGELINA D. CASTRO, AND DONALD L. CLARK

School of Medicine, University of Pennsylvania

The internal clock model for time judgments of short intervals describes adequately the relations among the methods of estimation, production, and reproduction observed under normal conditions. Since general anesthetics affect time productions by slowing of this hypothesized clock, this study investigated whether the relations predicted by the model would hold during inhalation of a general anesthetic—fluroxene. Six *S*s estimated, produced, and reproduced 3-40-sec. intervals before and during fluroxene inhalation. The model predicted the results from the majority of *S*s, thus supporting the internal clock concept. The anesthetic increased the slope of the production function and accordingly decreased the slope of estimation, leaving the slope of reproduction unchanged, thus maintaining the predicted relations among the methods. An alternative model, viewing time judgments as depending on memory content, could not account for the effects of the anesthetic on time reproductions seen with some *S*s.

The 3 most common measurement methods of time perception are estimation, production, and reproduction. The relationships among time judgments obtained through these 3 methods have been the subject of numerous investigations (for reviews, see Adam, 1971; Bindra & Waksberg, 1956). The most explicit formulation of these relationships was put forward by Carlson and Feinberg (1968). They based their reasoning on the assumption of a "clock" underlying time perception. Presumably, *S* uses the same clock to judge time intervals measured by these methods.

In estimation, the slope of the function depicting time estimates against objective time gives the ratio of the subjective to the objective clock. That is, in the function $T_E = k_E t_o$, where T_E = time estimates, t_o = objective time, and k_E = the slope or the ratio of the number of "subjective" seconds per each "objective" second.[3] Thus, if *S* receives a 2-sec. stimulus which he estimates as being 1 sec. long, his subjective/objective ratio is .5 and accordingly the obtained function $T_E(t_o)$ should subtend 26°30′ (arctan .5).

In production, *S* is expected to keep the same subjective/objective ratio as in estimation, although this is not necessarily so. If the same ratio is used, then when the function of time production—$T_P = k_P t_s$, where T_P = time produced in actual seconds, k_P = the slope, and t_s = the stimulus stated verbally—is plotted on the same graph as time estimates, the *y* axis now gives the objective seconds as produced by *S* and the *x* axis now gives the subjective seconds. Hence,

$$k_P = 1/k_E. \qquad [1]$$

Reproduction also depends on the same clock. One way of formulating the events during reproduction is assuming that first *S* estimates the presented interval and then produces the estimated interval. If this describes adequately the events in reproduction, then based on the previously

[1] This research was supported by U.S. Public Health Service Research Center Grant 5-P01-GM-15430-05. The authors appreciate the technical assistance of K. Van Horn and E. Dubroff.

[3] A linear function was chosen since time judgments at the stimulus range of the present study (3-40 sec.) have been shown by numerous investigators to follow a linear trend. This is also true for judgments obtained during anesthetic inhalation (Adam, Rosner, Hosick, & Clark, 1971). Intercepts are usually very small (Adam et al., 1971; Carlson & Feinberg, 1968) and are negligible for the purpose of the analysis.

stated relations between estimation and production, the following should be true:

$$T_R = k_R t_r, \qquad [2]$$

where T_R = the reproduced interval, t_r = the presented stimulus, and k_R = the slope of the function. Since first *S* is assumed to estimate the stimulus, this estimate is

$$T_E = k_E t_r. \qquad [3]$$

This estimate, T_E, in turn, is the stimulus for production; thus,

$$T_P = k_P T_E. \qquad [4]$$

Since the final value of reproduction is equal to the production of the estimated interval, it follows from Equations 2–4 that

$$T_R = T_P = k_P k_E t_r. \qquad [5]$$

It follows from Equations 2 and 5 that

$$k_R = k_P \cdot k_E. \qquad [6]$$

Since k_P has already been defined as $k_P = 1/k_E$ for the case where *S* uses the same clock rate in estimation and production, then

$$k_R = 1. \qquad [7]$$

In other words, the function of reproduction against time should always have a slope of 1.0 (i.e., 45°).

The relations delineated above have been shown to closely approximate the actual results obtained from normals and schizophrenics (Carlson & Feinberg, 1968). In a more recent paper, Carlson and Feinberg (1970) have shown that production and estimation may involve different "clock rates" when not obtained from the same *S*. Also, the slopes of production and estimation may vary with experience even when obtained from the same *S*. However, it was demonstrated again that if all 3 measures are obtained from the same individual the relations outlined above are maintained.

The purpose of this study was to use anesthetic drugs in order to observe whether the relations among the 3 methods still hold under conditions where it is known that at least one of these methods gives an altered slope. Adam, Rosner, Hosick, and Clark (1971) have shown that some general anesthetics increase the slope of production, that is, slow down the supposed clock.[4] The present experiment employed low concentrations of fluroxene —a general anesthetic. Time judgments were obtained before and during drug inhalation.

Method

Subjects. The *S*s were 6 young paid male volunteers participating in a study of the neurophysiological effects of fluroxene in conscious man.[5] After giving informed consent to participate, each *S* underwent a complete physical examination, blood count, urine analysis, chest X ray, electrocardiogram, and determinations of blood urea nitrogen, and serum glutamic oxaloacetic transaminase. Only *S*s within the normal range on each of these tests were accepted for study.

The *S* avoided all solids, liquids, and drugs for 12 hr. prior to the study. During the study, respiratory rate and end-tidal carbon dioxide were monitored. Blood pressure, heart rate, and rectal temperature were recorded throughout the study.[6] The anesthetic was delivered through a nonrebreathing circuit vented to the out-of-doors. A mouthpiece was used rather than a mask for easier control of drug concentrations. Dose was adjusted individually to allow testing. The *S* was tested when equilibrium was reached (end-tidal concentration within .1–.2% of the inspired concentration).

Material and procedure. Reproduction was tested by having *S* listen to a tone for a specified number of seconds. The *E* then started a second tone and *S* had to stop the tone by pressing a microswitch when he felt that the second tone equaled the first one in duration. For production, *S* activated a tone by pressing a microswitch which he released when he felt the duration of the tone was equal to an interval stated verbally by *E*. In estimation, *S* heard a tone activated by *E*. He then had to state its duration in seconds.

Reproduction was tested for 3-, 10-, 20-, and 40-sec. intervals, estimation for 3-, 20-, and 40-sec.

[4] This effect cannot be attributed to the slowdown which occurs with practice (Carlson & Feinberg, 1970). The removal of the anesthetic brought about a decreased slope, whereas the effect of practice on production alone would be to continuously increase the slope.

[5] D. L. Clark, A. D. Castro, and N. Adam. Neurophysiological effects of fluroxene. Manuscript in preparation.

[6] No correlation was found between these variables and time judgments in another study with other general anesthetics (Adam et al., 1971). Hence this aspect was not assessed in the present study.

intervals, and production for 6-, 20-, and 40-sec. intervals. Each S was tested with all 3 methods. The order of methods was counterbalanced over Ss. Stimuli for each method were presented randomly, with the constraint that not more than 2 identical stimuli were given consecutively.

Control measures were obtained first, with the anesthesia system hooked to S and delivering zero concentration. Testing during drug inhalation was done when equilibrium was achieved. The only time S gave a verbal response was during estimation. Usually it was possible to understand his answers despite the mouthpiece. If not, a throat microphone was used. If this was not effective, S was asked to signal his answer with his fingers.

When testing was completed, the mouthpiece was removed and S was taken to the hospital recovery room until ready for discharge.

Results

Time judgments were plotted separately for each individual for the 3 methods. The best-fitting linear functions for individual Ss for control and anesthetic conditions are shown in Figure 1. Table 1 gives the arctan of the slope of each function, the expected arctan slope of production according to the relation Slope Production = 1/Slope Estimation, and the expected arctan slope of reproduction according to the relation Slope Reproduction = Slope Estimation × Slope Production (see Equations 1 and 6). Intercepts were very small, with $M = .21$ and $SD = .77$. Since the anesthetic did not affect the intercept significantly (see also Adam et al., 1971), the intercepts are not shown in the table.

As seen, 4 Ss (RS, RO, KC, and RM) showed the expected relations among the 3 methods in both control and drug conditions. The deviations of the actual arctan slope of production from the expected values were, respectively, 2°10′, 2°10′, 4°20′, and 3°20′ for control, and 0°50′, 2°20′, 1°, and 1°10′ for the drug condition. The deviations of the arctan slope of reproduction from the expected values for these 4 Ss were 1°30′, 0°30′, 0°40′, and 0°10′ for control, and 0°20′, 3°50′, 3°20′, and 2°20′ for the drug condition. All of these values represent deviations of less than 10% from the expected values. There was no tendency for the actual values to be either consistently larger or smaller than the expected values.

Although the anesthetic did not alter the relations among the results from the 3 methods in these 4 Ss, it did affect the slopes of estimation and production. The arctan slope of production was increased in all 4 Ss, ranging from an increase of 1°30′ for RS to 13°50′ for KC. This confirms the results obtained by Adam et al. (1971) for the production method with several other inhalation anesthetics. The slope of estimation was decreased accordingly, ranging from a decrease of 3°20′ for RM to a decrease of 17°15′ for KC.

The 2 remaining Ss, however, deviated in some respects from the expected trends. For both TB and AS, all 3 control response curves had slopes smaller than 1.0 (arctan smaller than 45°) (see Figure 1). This is in contrast to the expected curves, where reproduction should subtend 45° and production and estimation should be symmetrical around the reproduction curve. This implies that both these Ss did not follow the relation shown in Equation 1. Table 1 gives the expected and obtained values for k_P.

Note that if $k_P = 1/k_E$, then the other relation derived from the model is $k_R = k_P \cdot k_E = 1$ (Equations 6 and 7). However, if $k_P \neq 1/k_E$ but if reproduction still follows the suggested sequence of estimation and production, then the relation $k_R = k_P \cdot k_E$ still holds, only it is not equal to 1 (Equation 6). The control results of TB and AS seem to fit this latter relation. The deviation of the obtained from the expected arctan k_R was 0°55′ for TB and 2°50′ for AS, a deviation of less than 10%.

The anesthetic affected the results in the predicted direction for production and estimation. The slope of production increased and that of estimation decreased. The only S to be tested at 2 different anesthetic concentrations was AS. As predicted, as concentration increased from 1.01% end-tidal to 1.21% end-tidal, the arctan slope of production increased from 49° to 63°. Accordingly, that of estimation decreased from 36°45′ to 31°25′, indicating the dose-

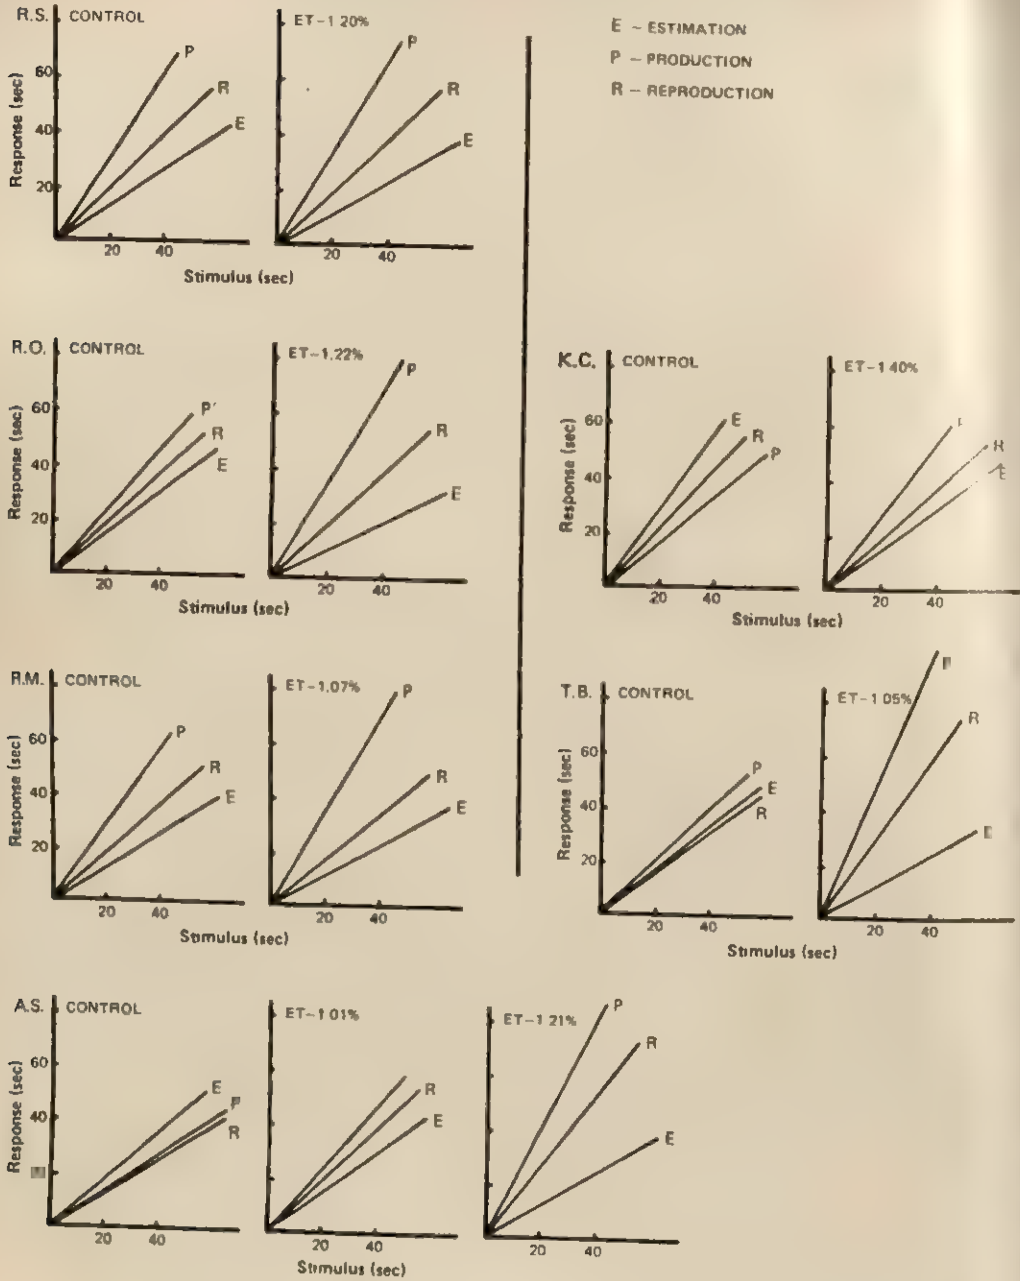

FIGURE 1. Best-fitting linear functions for estimation, production, and reproduction before and during fluroxene inhalation. (Data presented for individual *Ss*. The corresponding arctan slopes are given as obtained values in Table 1.)

related effect of the drug. The relation $k_R = k_P \cdot k_E$ was held also during the anesthetic condition for both *Ss*. The deviation of obtained from expected values was 1°20′ for TB and 3°10′ and 2°30′ for AS for the lower and higher drug concentration, respectively. Note that for AS at end-tidal concentration of 1.01% arctan k_R came very close to the expected 45° (obtained value = 43°50′). However, this

has no significance since further increase of concentration again removed k_R from 45° (see Table 1).

The order in which *S* had to perform the 3 methods had no effect on the results. Table 1 gives the order. Note that each *S* was tested in a different order. However, any order effect would be mainly due to the order of estimation and production in relation to one another. Note that the 2 exceptional *S*s, TB and AS, performed estimation and production in a different order.

DISCUSSION

Control results showed that the model first suggested by Carlson and Feinberg (1968) and delineated mathematically in the introduction, describes adequately the time behavior of 4 *S*s but only partially the results from the other 2 *S*s (TB and AS). For the first 4 *S*s all predicted relations were found. The obtained slope of production was reasonably close tlo the expected 1/Slope Estimation and the sope of reproduction was reasonably, close to the product of the slopes of estimation and production. This is in line with the findings of Carlson and Feinberg (1968, 1970) for the case when each *S* gave time judgments on all 3 methods. This gives support to the theoretical notion of a single "clock" underlying estimation and production and explaining reproduction as involving estimation of a presented interval followed by production of the estimated interval. The fact that in these 4 *S*s the anesthetic altered the slopes of production and estimation but without changing the expected relations among the 3 methods validated the results obtained under normal conditions.

Two *S*s, however, gave somewhat different results. In both cases, all 3 psychophysical methods had a slope smaller than 1.0. This implies that the slope of production did not conform to the predicted 1/Slope Estimation. This may mean one of two things. First, for some reason these 2 exceptional *S*s may have used a different clock rate for production

than for estimation. This, in turn, resulted in a slope for production that is not the inverse of that for estimation. Another possibility is that the same clock was used for both methods but some unidentified response or processing variables affected the final result. Such variables could, of course, affect either estimation or production or both. It is reasonable to consider estimation as a process involving "starting the clock" and obtaining a reading when the stimulus is over; production then may be conceptualized as a process in which S produces his own imaginary stimulus which he estimates every so often and compares the result with the required interval. He stops when the 2 match. If so, then obviously different response variables may affect the 2 processes. The present results do not give any clue as to why only 2 out of 6 *Ss* were affected in this way.

Since for these 2 *Ss* k_P did not equal $1/k_E$, it follows from Equation 6 that $k_R = k_P \cdot k_E$ but need not equal 1.0. This relation was found to describe adequately the results from the 2 exceptional *Ss*, thus supporting the notion that reproduction depends on estimation with later production of the estimated interval. The anesthetic increased the slope of production and decreased that of estimation, as it did with the other 4 *Ss*.

No correlation was found between the serial order of response and the magnitude of a time judgment. Also, the order of presentation of methods did not seem to have a noticeable effect. It is particularly important that the order of estimation and production was different for the exceptional *Ss*.

Another approach to the mechanism underlying time perception suggests that time judgment depends on memory content (Frankenhaeuser, 1959). Thus, the obtained linear functions describing time judgments of periods longer than the immediate present reflect the decay of memory traces. According to such a concept, the anesthetic altered the slopes of estimation and production because the memory content deteriorates faster under the anesthetic. However, Frankenhaeuser has not presented any specific model for predicting the relationships among the 3 psychophysical methods, nor is it clear from her work how reproduction is carried out. If she adhered to the reproduction process as presented in the present article, her model would predict the same anesthetic effects on reproduction as the clock model. How[illegible] there is an alternative way to conceptuali[illegible] reproduction which fits her framework. [illegible]m the point of view of memory theory, [illegible]luction may be thought of as reflectin[illegible]gnition processes; that is, the second [illegible]is is found matching to the first stimul[illegible] when it is recognized as being similar to the first stimulus already stored in mem[illegible] This latter possibility fits well the data [illegible]4 of our *Ss*. As part of another study, [illegible] were also tested for performance on a [illegible]gnition task of 6-word lists during fluroxene inhalation. The effects were negligible for all *Ss*. Thus, the fact that the slope of reproduction did not change in the anesthetic condition in 4 *Ss* can be accounted for by the negligible effects of fluroxene on recognition at the studied concentrations. However, 2 of our *Ss* did show altered reproduction slopes in the anesthetic condition. These changes were predictable on the basis of the relations among the 3 psychophysical methods provided by the clock model. These results cannot be explained on the basis of impaired recognition performance since the latter was hardly affected. Some anesthetics do have a marked effect on recognition even at very low concentrations (Adam, 1973). It should be interesting to observe behavior on time judgments during inhalation of these anesthetics.

MULTIDIMENSIONAL ANALYSIS OF CHOICE REACTION TIME JUDGMENTS ON PAIRS OF ENGLISH FRICATIVES

FREDERICK F. WEINER [1]
Department of Speech and Hearing Science, University of Maryland

SADANAND SINGH
Ohio University

Choice reaction time (CRT) judgments of *same–different* responses were measured for all possible pairs of nine English consonants by two groups of 10 *S*s each. A multidimensional analysis (IND SCAL) of the CRT values, for the first group of *S*s showed that the magnitude of *S*s' CRTs was governed by the distinctive feature differences between consonant pairs. A four-dimensional analysis revealed that the distinctive features, *voicing*, *sibilant*, *front/back* and *palatal* were those used by the group. Examination of the individual *S*s showed differing patterns of weighting these features. Analysis of the second group of 10 *S*s served to cross-validate the results obtained from the first group. Results showed no significant difference in the relationship between CRT and distinctive feature differences for the two groups. Comparison between these results and the 1969 results of Chananie and Tikofsky seems to suggest that CRT is a good measure of phoneme similarity when extraneous factors contributing to CRT are minimized.

Judgments of consonant similarity have been used to find a set of phonological features that may be distinctive within a listener's repertoire (Singh, Woods, & Becker, 1972). These judgments of similarity have been made on the basis of subjective evaluations using methods of magnitude estimation and psychological scaling (Singh et al., 1972) or by obtaining perceptual errors of direct judgments while listening to signals acoustically distorted by noise or filtering (Miller & Nicely, 1955; Singh, 1966, 1971).

The results of several investigations have indicated that choice reaction time (CRT) varies directly with the similarity of stimulus alternatives, (Crossman, 1955; Thurmond & Alluisi, 1963; Weiner, 1973). Reaction times are short when discriminating between items which are obviously dissimilar and increase when discriminating between similar stimuli.

Chananie and Tikofsky (1969) attempted to evaluate the similarity of consonants by relating CRT with the number of distinctive feature differences between consonants. They were unable to show that CRT was a measure of interphonemic similarity determined by distinctive feature differences.

[1] Requests for reprints should be sent to Frederick E. Weiner, Department of Speech and Hearing Science, University of Maryland, College Park, Maryland 20742.

The distinctive feature system used was that of Miller and Nicely (1955). Recently, investigators have demonstrated that this feature system is a relatively poor predictor of phonemic perception (Singh & Becker, 1972; Singh et al., 1972; Wickelgren, 1966). Others have varied the experimental conditions and found this system a good or better predictor of phoneme perception than other feature systems (Singh, 1970; Wang & Bilger, 1973).

Rather than beginning with an a priori feature system, such as Miller and Nicely's (1955), to evaluate similarity, the present investigation was designed to find, by means of multidimensional scaling technique, the feature system used by a group of *S*s and then to determine whether CRT relates to similarity in terms of the features retrieved.

Method

Subjects. Two groups of 10 undergraduate native American English speakers without history of hearing loss served as *S*s. The responses of the first group of *S*s served as an input to the multidimensional analysis for purposes of retrieving the group's perceptual feature system. The responses of the second group of *S*s were used to cross-validate the relation between CRT and consonantal similarity observed in the first group of *S*s.

Stimuli. The stimuli were pairs of consonant–vowels (CVs) composed of one of the following English fricatives: /f,v,θ,ð,s,z,ʃ,ʒ,h/ followed by the vowel /ɑ/. Half of the stimuli were constructed so

that both pairs of CVs for each item were identical. The remaining items were constructed so that the fricative of the second member of each pair was different from the fricative for the first member of that pair. Thus, 72 stimuli were recorded on channel 1 of a two-channel tape recorder. A pure tone was recorded on channel 2 at the initiation of the second member of each pair. All stimuli were presented so that the members of each pair were separated by 1 sec., with 5 sec. elapsing between stimuli.

Apparatus. The stimuli were presented by way of a Sony (TC 200) stereo tape recorder with a frequency response of 50–10,000 Hz. ± 3 db. and an overall frequency response of 50–14,000 Hz. The *S*s heard the stimuli through TDH-39 headphones. The output from channel 2 was connected to a pulse generator which in turn was connected to a (model DP 210) Hickock time interval meter. Each time a signal appeared on channel 2, a pulse was sent from the pulse generator to start the time interval meter. The *S*s were seated in front of a reaction time box having one button labeled "S" and the other labeled "D." The reaction time box was connected to the time interval meter so that depression of one of the two buttons stopped the meter. Choice reaction time, then, was measured from the initiation of the second CV to the eventual response of pushing one of the two buttons. Response times and button choice were recorded on a Hickock (PR 4900) printer connected to the time interval meter.

Subjects were instructed to respond by pressing the button marked "S" if the two phonemes they heard were identical or to press the button marked "D" if the two phonemes were not the same. They were told to respond as quickly as possible without committing errors. Each *S* was presented with 30

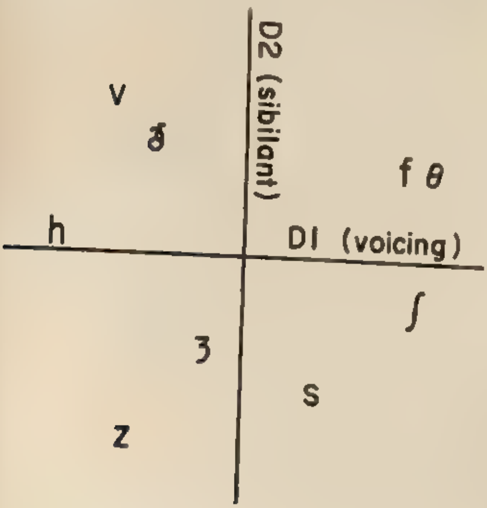

FIGURE 1. Plotting of Dimension 1 (D1) and D2 of the four-dimensional IND SCAL configurations showing *voicing* and *sibilant*.

practice items and was encouraged to respond below 500 msec. Most *S*s made their determinations before the termination of the second syllable. Thus, *S*s with unusually long CRTs were trained to make their decisions before completion of the second syllable for each stimulus. The *S*s then participated in the experiment, which consisted of four randomized presentations of each stimulus pair.

RESULTS AND DISCUSSION

The median of the four CRTs for each stimulus pair was taken to represent *S*'s score on that pair. Utilizing these scores, 10 symmetric matrices for each *S* in Group 1 were analyzed by Individual Scaling (IND SCAL) developed by Carroll and Chang (1970). This procedure is a multidimensional scaling program designed to determine the number of dimensions *S*s utilize in making psychological judgments. The output provides stimulus and *S* weightings on each of the dimensions of an *n*-dimensional space.

The choice of dimensionality was based on the criteria of uniqueness and interpretability of solution. A unique solution is one in which the stimuli and *S* points in a given dimensional space converge to the same solution irrespective of the random starting configuration. Interpretability is determined by the solution yielding the most definable phonetic features. In the present investigation a four-dimensional solution was considered unique where Dimension 1 (D1) was interpreted as *voicing*; Dimension 2 (D2) as *sibilant*; Dimension 3 (D3) as *front back*; and Dimension 4 (D4) as *palatal*.

Figure 1 is a plotting of D1 versus D2. From this representation it can be seen that the voiceless consonants of the set /f,θ,s,ʃ/ are separated from the voiced consonants /v,ð,z,ʒ,h/. Although /h/ is usually considered voiceless in English, perceptually it was positioned at the extreme end of the voicing dimension. The most probable explanation for the placement of /h/ is that /h/ is homorganic with /ɑ/, with which /h/ was combined. The phoneme /h/ is also the only consonant which is considered minus-consonantal (Chomsky & Halle, 1968), a feature regularly assigned to vowels. Thus, *S* judgment may have

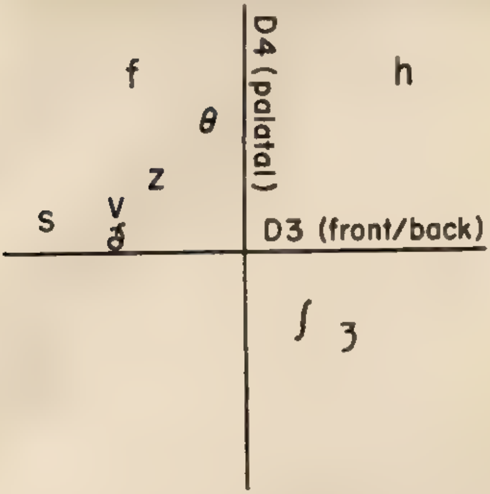

FIGURE 2. Plotting of Dimension 3 (D3) and D4 of the four-dimensional IND SCAL configurations showing *front/back* and *palatal*.

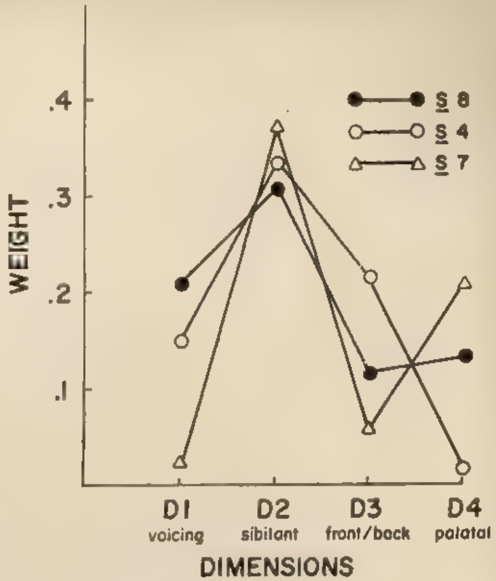

FIGURE 3. Plotting of individual *S* weightings as a function of distinctive features retrieved for *S*s 4, 7, and 8.

been grossly influenced by /ɑ/ each time /hɑ/ was compared with other CV sequences. Dimension 2 is clearly a *sibilant* dimension wherein the sibilants /s,z,ʃ,ʒ/ are separated from the nonsibilant fricatives /f,v,θ,ð,h/.

Figure 2 is a plotting of D3 versus D4. Dimension 3 can be labeled as a *front/back* dimension where the consonants /f,v,θ,ð,s,z/ produced anteriorly in the oral cavity are separated from the consonants /ʃ,ʒ,h/ which are produced posteriorly. Obviously, these *S*s were not using other distinctions of place of articulation on this dimension. For example, in Figure 2 the /θ/ is positioned closer to *back* than /s/. Hence, the extent of the psychological reality of articulatory features for these *S*s was limited only to a *front/back* distinction. On D4 the *palatal* consonants /ʃ,ʒ/ are separated from the nonpalatal consonants /f,v,θ,ð,s,z,h/. Thus more than one place dimension was utilized by these *S*s.

The four dimensional solution discussed above was found to account for 72% of the variance in *S* responses. Of this 72%, D1 (voicing) accounted for 24%; D2 (sibilant) 19%; D3 (front/back) 15%; and D4 (palatal) 14%. An examination of the individual *S* weights of these dimensions revealed three different trends. These three trends are reported in Figures 3, 4, and 5.

Figure 3 shows that *S*s 4, 7, and 8 weighted D2 the highest. Thus, incon-

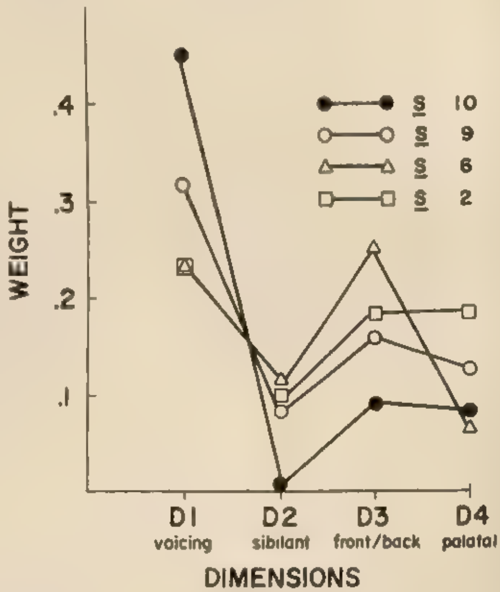

FIGURE 4. Plotting of individual *S* weightings as a function of distinctive features retrieved for *S*s 10, 9, 6, and 2.

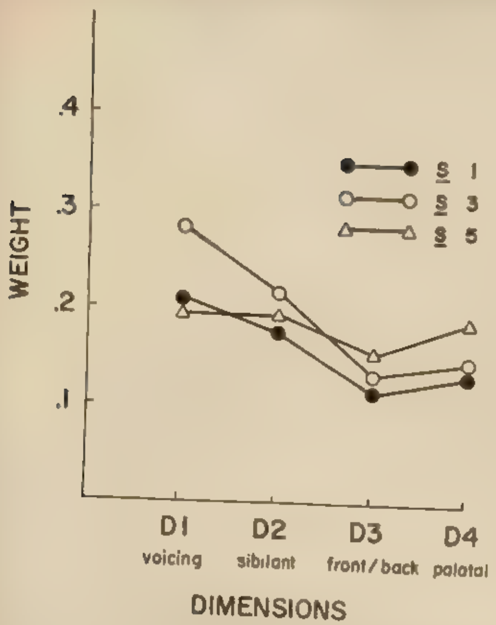

FIGURE 5. Plotting of individual *S* weightings as a function of distinctive features retrieved for *S*s 1, 3, and 5.

sistent with the overall trend, these *S*s were weighting *sibilant* inordinately high. In contrast, *S*s 2, 6, 9, and 10 in Figure 4 weighted *voicing* high and *sibilant* low. Again, in contrast with the overall trend, these four *S*s weight the *sibilant* dimension lowest. The weightings of the third group of *S*s are shown in Figure 5, where *S*s 1, 3, and 5 seem to confirm the overall trend of the general stimulus space.

In the past, various investigations have attempted to determine a feature system and the relative importance of the features for a group of *S*s (Miller & Nicely, 1955; Singh & Black, 1966; Wickelgren, 1966). Results of this study show that, while it is possible to determine a feature system for a group, it is difficult to draw conclusions about the relative weightings of features for that group. This difficulty arises from the evidence presented in Figures 3, 4, and 5 wherein it can be seen that group feature weights represent a mean of extreme individual weightings. Therefore, while it is interesting and possible to determine the feature system of a group, it is much more revealing to examine the way the individual *S*s weight these features. That is to say that examination of individual *S*s provides information regarding their perceptual strategy, which may be different from the strategy of the other *S*s.

Even though the weightings of the individual *S*s were different on each dimension, the general conclusion is that all *S*s utilized all four dimensions. On the basis of the four dimensions recovered in this study, it is assumed that CRT judgments can be used as a criterion for determining phonemic similarity. In a phonological system involving binary features, a pair of CV syllables, which is different by any one of the four features, is considered minimally distinct and thus should yield a larger CRT than a pair of CV syllables having a two-feature difference. This assumption was not validated by Chananie and Tikofsky (1969) who performed a similar study using the Miller and Nicely (1955) distinctive feature system. Figure 6 shows CRT as a function of "zero", one, two, three, and four feature differences. Zero difference represents the phoneme pairs /f–θ and

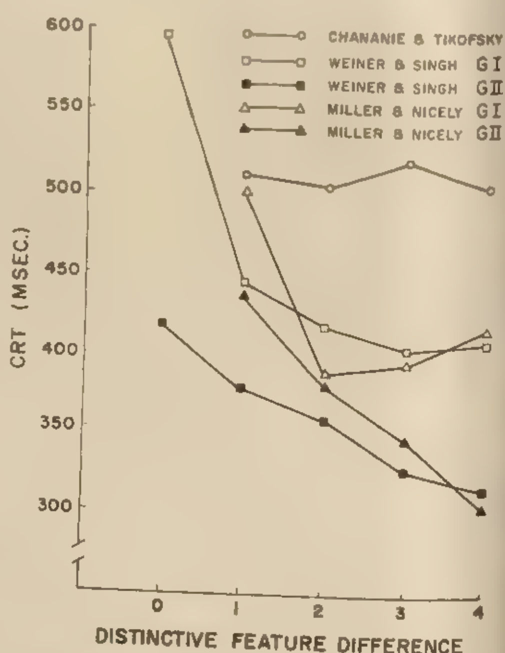

FIGURE 6. Choice reaction time as a function of distinctive features for data collected from groups one (GI) and two (GII) in the present study as compared with a previous study of Chananie and Tikofsky (1969).

/v–ð/ since these pairs remained indistinct on all of the four dimensions reported in this study. A one-feature difference represents a difference by any one of the four features. The two-, three-, and four-feature differences are combinations of any of the features.

The top curve in Figure 6, taken from Chananie and Tikofsky (1969), clearly shows a lack of relationship between CRT and distinctive feature differences. The curve labeled "Weiner & Singh GI" represents the mean CRTs for pairs of consonants representing zero, one, two, three, and four feature differences obtained for the first group of *S*s. A single-factor, repeated measures, analysis of variance was performed to test the difference between these mean CRT scores. The results showed that the mean differences were significant, F (4, 36) = 16.08, $p < .05$. A Tukey (*a*) (Winer, 1962) showed that CRT values for zero-feature differences were significantly greater than values associated with any other feature difference. In addition, the CRT value associated with one feature difference was significantly greater than differences of three and four features.

Since the above mentioned curve in Figure 6 was derived from the same data utilized to find the feature system, the slope was expected. It was therefore deemed necessary to cross-validate these results. The bottom curve is a plotting of the second group of *S*s. To determine whether these functions showed similar relationships, a comparison of slopes procedure (Dixon & Massey, 1969) was performed. The result was that the two beta coefficients were not different from each other, t (6) = .494, $p < .05$. Thus, the slopes were not significantly different from each other. There was a difference, however, in terms of the magnitude of the two curves. This is attributed to substituting photoelectric cells for the "push-type" response buttons used by the first group; a change made before realizing that a cross-validation would be necessary. However, for the purposes of this investigation, magnitude of CRT is not important. The purpose was to determine whether CRT was a function of distinctive feature differences.

A single-factor repeated measures analysis of variance was performed to test the difference between the mean values of CRT obtained for the second group. The results showed that the mean differences were significant, F (4, 36) = 11.17, $p < .05$. A Tukey (*a*) showed that CRT values for zero-feature differences were significantly greater than values associated with any other feature difference. Additionally, one-feature difference was significantly greater than a two-, three-, and four-feature difference; while differences of two, three, and four features were not different from each other.

Since a number of investigations have demonstrated that psychological judgment of the proximity of a phoneme pair is a function of the phonological difference between them, it is surprising that Chananie and Tikofsky (1969) did not find such a relationship. In an attempt to determine the reason for this discrepancy, we plotted the CRT values obtained from the two groups of *S*s in the present investigation as a function of the Miller and Nicely feature system as plotted by Chananie and Tikofsky. The curves labeled "Miller & Nicely GI" and "Miller & Nicely GII" in Figure 6 represent Miller and Nicely feature system plottings of the *S* data in the present investigation of groups one and two, respectively. Not only is it apparent from these results that the differences in features play a role in determining mean reaction times, but there is no significant difference between the slopes of Weiner & Singh GI and Miller & Nicely GI, t (5) = .524, $p < .05$, or Weiner & Singh GII and Miller & Nicely GII, t (5) = .621, $p < .05$. Thus it appears that either system of distinctive features explained the similarity of phonemes as evaluated by CRT. This finding is expected and should occur using any distinctive feature system since all feature systems draw on the same articulatory events.

The difference between the results of the present investigation and that of Chananie and Tikofsky (1969) may be attributed to their level of reaction time which was considerably higher than the reaction time obtained in the present study. Figure 6

suggests that the number of features distinguishing one phoneme from another becomes more important the lower the overall magnitude of reaction time. The magnitude was highest in the Chananie and Tikofsky study and number of features played no role. The magnitude was lower in Weiner & Singh GI and there was a slope. The magnitude was lowest in Weiner & Singh GII and the slope was steepest. In other words, it appears that when extraneous factors contributing to reaction time are minimized the differences in number of features begins to play a role.

INTERACTIONS AND RANGE EFFECTS IN EXPERIMENTS ON PAIRS OF STRESSES:

MILD HEAT AND LOW-FREQUENCY NOISE [1]

E. C. POULTON [2] AND R. S. EDWARDS

Medical Research Council, Applied Psychology Unit, Cambridge, England

Twelve men performed 3 tasks in 102-db.(C) low-frequency noise, at 38°/33° C. (100°/92° F.), and with the two stresses combined, as well as in a control condition. The three tasks were tracking with peripheral lights, the five-choice task, and visual vigilance, in that order. The low-frequency noise had a beneficial effect upon all three tasks. It interacted with the mild heat on the tracking, and on false detections in the vigilance task. The results are related to behavioral arousal. When compared with a previous experiment on mild heat and loss of a night's sleep, performance in the control conditions was found to be influenced by the stresses included in the within-subjects experimental designs. This raises doubts about the validity of the interactions.

A number of experiments examine the interactions of pairs of stresses (Grether, 1970; Poulton, 1970, chap. 25). In some experiments reliable interactions are reported. In other experiments the effects of a pair of stresses appear to add. The combination of heat and noise does not produce reliable interactions, except possibly in the 1946 experiment by Viteles and Smith (see Wilkinson, 1969b, p. 267). The present experiment investigates the combination again, using tasks which are found to reveal reliable interactions between other pairs of stresses.

The left side of Figure 1 shows the results of a hypothetical experiment on the interaction of two stresses A and B. The control condition 00 is represented at the bottom. Stress A alone at A0, and stress B alone at OB, both increase the number of errors. Errors are rather more frequent still at AB, where the two stresses are combined. The interaction is reliable if the combined effect of A and B, represented by the height $(x + y + z)$, is reliably different from the sum of the two separate effects, represented, respectively, by the heights z and $(y + z)$. This reduces to x being reliably different from z. Since x represents the effect of A in the presence of B, and z represents the effect of A alone, an equivalent statement of the interaction is that the effect of A in the presence of B is reliably different from the effect of A alone.

Where reliable interactions are reported in the literature, the combined effect upon performance is always smaller than the sum of the two separate effects (Grether, 1970; Poulton, 1970). The only apparent exception is in experiments with knowledge of results as one of the two stresses. The relationship in Wilkinson's (1961) experiment on loss of sleep paired with knowledge of results, is illustrated on the right of Figure 1. In the first illustration on the right, A stands for the stress of no sleep

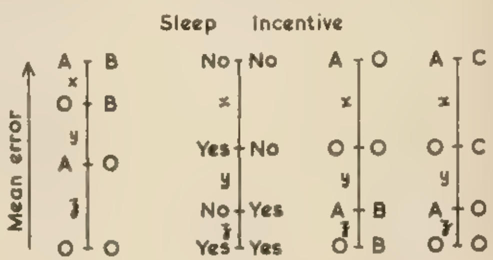

FIGURE 1. Interactions between two stresses.

[1] This work forms part of a program of research for the Royal Naval Personnel Research Committee. The experimental subjects were supplied by the British Royal Navy. The authors are grateful to A. Carpenter for building the noise equipment and for advice on its use. Muriel M. Woodhead kindly tested the hearing of three people with and without a thermistor in the external auditory meatus.

[2] Requests for reprints should be sent to E. C. Poulton, M.R.C. Applied Psychology Unit, 15 Chaucer Road, Cambridge CB2 2EF, England.

on the previous night, and B stands for the stress of immediate knowledge of results whenever the man makes an error, or does not respond for 1.5 sec. The loss of sleep increases errors, while the knowledge of results reduces errors. As usual the combined effect, represented here by $-y$, is smaller than the sum of the two separate effects, represented, respectively, by x and $(-y-z)$. This is equivalent to stating that zero is smaller than $(x-z)$, or that x is greater than z.

Wilkinson's (1961) alternative description of the interaction is illustrated on the extreme right of the figure. An O has been substituted for B, and a C for O. The C stands for loss of incentive, just as A stands for loss of sleep. Here the combined effect is represented by $(x+y+z)$. It is greater than the sum of the two separate effects, represented, respectively, by z and $(y+z)$, because x is greater than z.

Fortunately in most experiments on interactions between stresses, it is clear which conditions present the stresses. It is only with knowledge of results that there is any doubt. Probably this is because knowledge of results tends to be more effective when a person has been deprived of it, than it does when it has always been given (Brown, 1966). A within-subjects experimental design improves performance with knowledge of results, and depresses performance with no knowledge. Neither of the two changed levels of performance can be taken as the true baseline level of performance.

Range Effects

The observed heights of x and z may be distorted by a range effect. All experiments investigating the interactions between pairs of stresses use within-subjects designs. The same people perform in a control condition, under each stress singly, and under the combined stresses. Within-subjects designs can produce range effects which bias the results (Poulton, 1973). Performance in one condition is influenced by the other conditions included in the experimental design. A subsidiary aim of the present experiment is to look for possible range effects. Part of the experiment is designed to be identical with a previous experiment on mild heat and loss of sleep (Poulton, Edwards, & Colquhoun, in press). A reliable difference in the control condition which is common to the two experiments, would indicate the influence of range effects.

Low-Frequency Noise

Low-frequency or green noise is weighted heavily against the higher frequencies. It is used to reduce the chances of a permanent hearing loss, while maintaining a high overall sound-pressure level. Apparatus and speech sounds are not masked as effectively as they are by white noise, which has a flat spectrum. Low-frequency noise arouses the man, without isolating him from his auditory environment. Thus it may have a rather different effect upon performance from the conventional white noise. This is an additional point investigated here.

Method

Tracking with peripheral lights. Two of the three experimental tasks are described in detail in a previous paper (Poulton et al., in press). In the tracking task (Hockey, 1970a, 1970b) a target marker moves irregularly from side to side. In the present experiment the top track frequency is about 45 cycles per minute (cpm) instead of the 25 cpm used by Poulton et al. The man has to keep a response marker in line with a target marker, by raising and lowering a lever with his right hand. He is told that this is his main task. Time on target is noted for each 5-min. period.

The six peripheral lamps are arranged in a semicircle. Each lamp is surrounded by a lightproof case, except for a white circle of tape, 1.5 cm. in diameter, which lies in front of it. When the lamp is switched on, the white circle turns yellow. The brightness of the circle increases from 1 to 7 cd/m² (.3 to 2 equivalent ftc.). In the present experiment the man is provided with a chin rest. When he places his chin on the chin rest and looks at the central tracking display, the two nearest lamps lie 20° out from his line of sight, one on each side. Each lamp lights up on average once every 30 sec. The remaining four lamps, two on each side, lie, respectively, 50° and 80° out from the line of sight. Each lights up on average once every 2 min. The time interval between lamp signals varies irregularly from 6 to 24 sec. in steps of 3 sec. When a lamp lights up, the man has to extinguish it as quickly as possible by pressing the corresponding microswitch with a finger of his left hand. His response time is recorded. The combined task lasts 30 min.

The five-choice task. For this task (Leonard, 1959) five neon lamps are arranged in a pentagon of side 5 cm. They are mounted on an almost vertical panel. Five brass discs, each 3 cm. in diameter, are arranged in a corresponding pentagon with 9 cm. between centers. They are mounted flush in a horizontal panel which lies directly in front of the neon lamps. The man uses a stylus 18 cm. long to tap the disc corresponding to the neon lamp which is lit up. Tapping any disc extinguishes the lamp and lights up the next lamp in the series. The order of lamps in the series is irregular. The man has to work at the task without stopping for 30 min. The number of correct taps, and the number of times the wrong disc is tapped in error, are recorded automatically and noted for each 5-min. period. Gaps of 1.5 sec. or longer between responses are also recorded.

Wilkinson visual vigilance task. The task is a visual analogue of the Wilkinson (1969a) auditory vigilance task of the previous paper (Poulton et al., in press). A white circular window 1.5 cm. in diameter lies in the middle of a black panel 18 × 20 cm. The panel slopes backward at an angle of 45°. Immediately behind the window is a neon lamp The window has a brightness of 2 cd/m² (.5 ftL.) when the lamp is off. The window turns yellow and increases in brightness to 30 cd/m² (8 ftL.) when the lamp is on. The black panel has a brightness of .15 cd/m² (.04 ftL.). The neon lamp lights up for .4 sec. every 2 sec. A signal is a shorter flash of only .3 sec. There are five signals, scattered irregularly during each 7.5 min. The task lasts 30 min.

In the present experiment the man has three push buttons to indicate his degree of confidence, instead of the single push button of the previous experiment. When he detects a signal, he has to press one of the three buttons as quickly as possible. The three push buttons have diameters of 1.2 cm. They are mounted in a row 8 cm. below the circular window, with their centers separated by 4 cm. The blue push button on the right indicates certain signal. The green push button in the middle indicates probable signal. The yellow push button on the left indicates possible signal. A record is kept of each response button pressed. The response times of correct responses are also noted.

Experimental subjects and design. The 12 naval enlisted men have ages ranging from 18 to 28 yr., median age 21 yr. The experimental design is given in Table 1. There is a practice control condition before the start of the Latin square, as in the previous experiment (Poulton et al., in press). This enables the groups of naval enlisted men used in the two experiments to be compared directly, before they commence the conditions of the Latin square. The Latin square ensures that nobody works in noise on two successive days.

The hot and cool climates are similar to those of the previous paper (Poulton et al., in press). The hot climate has dry-bulb/wet-bulb temperatures of 38°/33° C. (100°/92° F.). This gives an Effective Temperature for men stripped to the waist of 34° C. (93° F.). The cool climate has temperatures of

TABLE 1

Experimental Design for Two-Week Period

Team[a]	Main practice (Wednesday)	Test 1 (Thursday)	Test 2 (Monday)	Test 3 (Tuesday)	Test 4 (Wednesday)
A	Control	Noise	Heat	Noise + Heat	Control
B	Control	Control	Noise + Heat	Heat	Noise
C	Control	Heat	Noise	Control	Noise + Heat
D	Control	Noise + Heat	Control	Noise	Heat

[a] In all cases, $n = 3$

20°/17° C. (68°/62° F.). This gives an Effective Temperature for men fully clothed of 19° C. (66° F.).

The low-frequency noise is presented from 2 loudspeakers, each 35 cm. in diameter. They are mounted respectively in the wall and ceiling of the hot room. The loudspeaker in the wall is at head height. It is on the man's right when he is tracking, and behind him when he rotates 90° to his left to perform the two remaining tasks. The ceiling loudspeaker is above his head, slightly to his left when he is tracking, slightly in front of him for the other 2 tasks.

The average intensity of the low-frequency noise is about 102 db. on the C scale of a Dawe 1400E sound-level meter. The intensity varies slightly, depending upon exactly where the man has his head. The noise is attenuated about 7.5 db. per octave by a lowpass filter. The noise had a rumbling quality. It is possible to converse by shouting at a distance of 1 m. In tracking with peripheral lights it is possible to hear the noises made by the pursuitmeter program, and to hear the clicks made by pressing the response switches for the lights. With the five-choice task it is possible to hear the difference between tapping a brass disc, and tapping the panel in which the discs are mounted.

The fans which circulate the air produce an average sound-pressure level of about 80 db. (C) in the quiet condition. Here the frequency spectrum is fairly flat up to 1 kHz. Above 1 kHz. the intensity is attenuated about 7.5 db. per octave.

Procedure. This follows the procedure of the previous experiment (Poulton et al., in press). Each man is always tested at the same time of day. One man of each team is tested in the morning, the other two men in the afternoon. The order of the three tasks is always the same: tracking with peripheral lights, five choice, and Wilkinson vigilance.

Thermistors are worn in both ears, to record the temperature of the external auditory meatus. Wearing a thermistor does not affect the threshold of hearing.

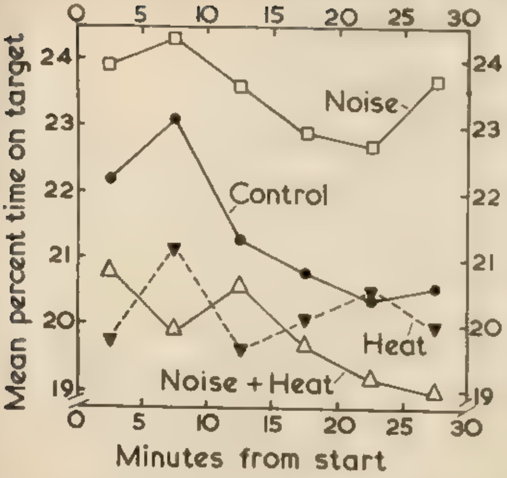

FIGURE 2. The average percent time on target for successive 5-min. periods when tracking with peripheral lights.

Statistical tests. Nonparametric tests (Siegel, 1956) are always used. All tests are two-tailed except where stated.

RESULTS

Heat noise interaction in tracking with peripheral lights. Figure 2 shows that in the control condition the average time on target is less during the last 5 min. of the tracking task than during the first 5 min. ($p < .05$). A similar result is reported in the previous paper (Poulton et al., in press), and by Hockey (1970a, 1970b).

Compared with the control condition, the noise alone produces an improvement which is reliable during the last 5 min. of the task ($p < .05$). The heat alone produces a decrement which is reliable during the first half of the task ($p < .05$). The directions of the changes with noise and heat follow those of previous experiments (Hockey, 1970a, 1970b; Poulton et al., in press).

The novel aspect of the results is the reliable interaction, between the heat and the noise, which is particularly marked during the last 5 min. of the task ($p < .02$). Here heat by itself produces only a small decrement of .5 in the average percent time on target. But when added to the noise, the heat changes an improvement of 3.0 to a decrement of 1.5. The reduced percent time on target produced by adding the heat to the noise is therefor[e] com-pared with only .5 for the heat itself. There are no reliable difference[s] on the lights task related to the noise, [or] to the heat.

Shift in control condition with [the] five-choice task. The five-choice task [was] used also in the previous experiment o[n th]e loss of a night's sleep paired with [the] heat (Poulton et al., in press). It is [perfo]rmed second in both experiments, s[witc]hed between tracking with peripher[al] lights and the vigilance task. The mai[n] differ-ence between the two experiment[s is] that the loss of sleep of the previous ex[per]iment is changed to low-frequency nois[e in] the present experiment. Table 2 sho[ws] that the change has a reliable effect upo[n m]ean percent errors in the control co[ndi]tion. During the last 5 min. of the task, t[he] con-trol mean is 3.2% in the present [ex]peri-ment with noise, compared with 1.[?]% in the previous experiment with loss of [s]leep ($p < .02$).

The bracketed entry at the top [o]f the table shows that the two groups o[f] men are well matched in the main c[o]ntrol practice on the day before the experiments start. Thus the difference between the two control conditions must be due to range effects produced by the balanced experimental design of Table 1 and the comparable design of the previous experi-ment. The particular stresses which are paired together affect the control condi-tion. Since the control condition provides the baseline against which the effects of

TABLE 2

MEAN PERCENT ERRORS ON THE FIVE-CHOICE TASK IN TWO EXPERIMENTS ON PAIRS OF STRESSES

Noise and heat		Loss of sleep and heat[a]	
[Practice control	2.1]	[Practice control	2.3]
Control	2.1[b]	Control	1.4[b,d]
Noise	1.4[c]	Loss of sleep	4.0
Heat	2.9	Heat	2.4
Noise + heat	2.2	Loss of sleep + heat	4.5

[a] Data from Poulton, Edwards, and Colquhoun (in press).
[b] Two control conditions different at .05 level with a one-tailed test.
[c] Noise different from all other conditions at the .05 level.
[d] Control different from all other conditions at the .05 level or better.

the stresses are measured, it means that the measured effect of a stress in an experiment on pairs of stresses depends upon the stress with which it is paired.

The left side of Table 2 shows that in the present experiment the low-frequency noise improves performance, while the mild heat if anything degrades performance. Whereas the right side of the table shows that in the previous experiment both the loss of a night's sleep and the heat degrade performance. Probably the difference between the two range effects is due to the beneficial effect of the low-frequency noise in the present experiment. The noise condition gives 1.4% errors, which corresponds to the 1.4% of the control condition of the previous experiment. Thus in the present experiment the noise condition appears to become the baseline condition, while the control condition becomes a noise-deprived condition.

Other measures of performance obtained with the five-choice task also indicate the beneficial effect of the low-frequency noise. During the first 5 min. there are reliably ($p < .05$) more correct responses in the noise than in the control condition. In addition, combining the noise with the heat reliably ($p < .02$) reduces the number of gaps of 1.5 sec. between responses, compared with the heat alone.

Heat noise interaction in visual vigilance. Figure 3 shows how true and false detections are related during the first and last 7.5-min. periods. For the full 30 min. there are more false detections in the heat than in the control condition ($p < .01$), as in the previous paper (Poulton et al., in press). The proportion of false detections is increased also in the noise, although the difference between the noise and the control condition is not reliable ($p > .05$). When the noise and heat are combined, the proportion of false detections is not far above the control level. The interaction is reliable ($p < .02$). Thus adding the heat to the noise largely eliminates the undesirable increase in false detections which both stresses produce on their own.

The noise gives the greatest proportion of true detections during the first 7.5 min.,

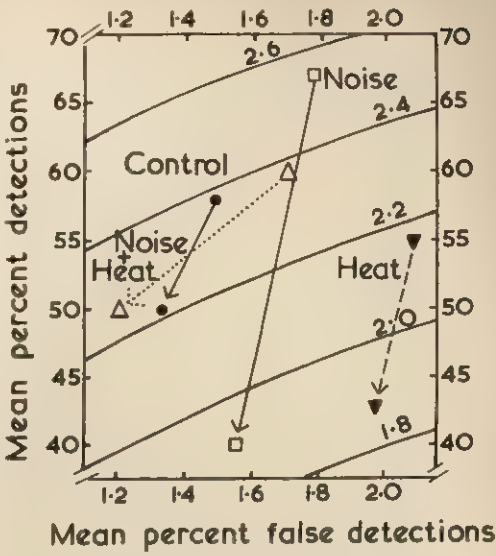

FIGURE 3. The average percent of detections in the visual vigilance task during the first and last 7.5-min. periods, plotted against the average percentage of false detections. (False detections are given as a percentage of the number of nonsignal light flashes. There are 2.2 percent of true signals. The arrows point from the value for the first 7.5 min. to the value for the last 7.5 min. The contours represent equal values of d', an index of the ability to detect signals.)

but changes reliably ($p < .01$) to give the smallest proportion during the last 7.5 min. For the full 30 min., there are no reliable differences in true detections between any of the four conditions. However the noise gives reliably more certain detections than the control condition ($p < .05$, one-tailed test), and reliably fewer moderately certain detections ($p < .01$). The man responds reliably more quickly when he is certain, than when he is uncertain ($p < .02$).

DISCUSSION

Interactions described in terms of arousal theory. Reliable interactions between the heat and the noise are illustrated in Figure 2 for the tracking, and in Figure 3 for false detections in the vigilance. In both cases, the combined effect of the two stresses is smaller than the sum of the two separate effects. In the past such interactions have usually been described in terms of the inverted-U relationship of arousal theory. The effects of the combined stresses will tend to cancel each other if one

stress increases arousal while the other stress reduces arousal. Cancellation can also occur if both stresses increase arousal, and the person thus becomes overaroused (Poulton, 1970, chap. 25).

Noise is generally taken to be an arouser. It produces physiological changes which are associated with arousal. On the five-choice task it reduces the effects of a night without sleep, which presumably lowers the level of arousal (Wilkinson, 1963).

The relationship between heat and arousal is less straightforward. Arousal probably increases while a person is being heated up (Poulton & Kerslake, 1965), and when he is uncomfortably hot (Colquhoun & Goldman, 1972; Wilkinson, Fox, Goldsmith, Hampton, & Lewis, 1964). Whereas a constant mild warmth probably reduces the level of arousal (Wilkinson et al., 1964). In the previous experiment on heat paired with loss of a night's sleep, the heat reduces the detrimental effect of the loss of sleep at the start of the auditory vigilance task (Poulton et al., in press). Thus here the heat must act as an arouser.

The results in Figure 3 for the visual vigilance task can also be described by taking the heat as an arouser. Both the heat and the noise increase arousal and produce more false detections. Adding the heat to the noise produces overarousal, and so cancels the increase in false detections which both stresses produce on their own.

The reliable interaction in Figure 2 for the time on target can also be described in terms of the overarousal which results from combining the two arousers heat and noise. However, the results in Figure 2 cannot all be described in terms of arousal. If the noise increases the time on target by increasing arousal, the heat which also increases arousal should not reduce the time on target as it does. Clearly some other factor in addition to arousal is required to account for the opposite effects of the heat and noise. A similar difficulty is reported in the previous paper where heat is paired with loss of sleep (Poulton et al., in press).

Alternative explanations of interactions. In order to discuss the interactions between stresses in terms of arousal theory, it has to be assumed that an observed interaction reflects a genuine interaction in the underlying process in the brain. However there are other possible causes of an observed interaction. First, the measure of performance may not be related linearly to the underlying brain process. Thus x and z on the left of Figure 1 can be reliably different, without an interaction in the underlying brain process. This possibility is difficult to disprove, because the underlying brain process cannot be observed directly.

The time-on-target measure of Figure 2 is notoriously nonlinear. Bahrick, Fitts, and Briggs (1957) show that on this measure the shape of the learning curve depends upon the size of the target. It would be foolish to claim that performance with the particular size of target used here is more likely to be related linearly to the underlying brain process than is performance with some other size of target. But the criticism of a possible nonlinear relationship to brain function applies to any measure of performance.

A second possible cause of a reliable interaction between two stresses is suggested by the results of Table 2. The relative sizes of x and z on the left of Figure 1 may be distorted by a range effect introduced by a within-subjects experimental design. The present experiment provides no clear evidence on this point, because the range effects appear in the five-choice task, while the reliable interactions appear in the two remaining tasks. But the implications are worth considering.

Many range effects involve a central tendency (Poulton, 1973). Usually, the range is reduced. If the reduction is symmetrical, it need not affect the calculation of the interaction very much. This is because the interaction on the left of Figure 1 is represented by $(x - z)$. If the scale contracts symmetrically about its center, the value of $(x - z)$ may not change much.

But if the range effect has a bias in a single direction, it may, for example, reduce the size of x without appreciably changing the size of z. If so, the difference $(x - z)$ will be smaller than it should be. When the value of $(x - z)$ is negative, as in experiments where the combined effect of two stresses is smaller than the sum of the two separate effects, the range effect will then increase the chances of obtaining a reliable interaction. Both the reliable interactions reported here, and all those reported in the literature, may possibly be produced or exaggerated by an artifact of this kind.

When the value of $(x - z)$ is positive, as in experiments where the combined effect is larger than the sum of the two separate effects, a range effect which reduces the size of $(x - z)$ will reduce the chances of obtaining a reliable interaction. Since no reliable interactions in-

lving potentiation have yet been reported, an artifact of this kind may well be operating in experiments where potentiation is to be expected. Clearly, in order to investigate the interactions between stresses unbiased by range effects, it is necessary to use a separate-groups design. This has not yet been done.

Beneficial effects of low-frequency noise. Table 2 shows that on the five-choice task the low-frequency or green noise reliably reduces the mean percent errors. The noise also reliably increases the rate of responding during the first 5 min. These are entirely new effects of noise on the five-choice task. Presumably the low-frequency noise increases arousal, without having any of the detrimental effects of the noise used in previous experiments.

There are 10 previous experiments where the five-choice task is performed in noise. In all but two of the experiments the noise is white with an approximately flat spectrum. In 7 of the 10 experiments, noise reliably increases errors (Broadbent, 1953, 1957; Colquhoun & Edwards[3]; Hartley, 1973, in press-a, in press-b, Experiment 1; Wilkinson, 1963, Experiment 1). In the remaining three experiments the effect of noise upon errors is not reliable (Corcoran, 1962; Hartley, in press-b, Experiment 2; Wilkinson, 1963, Experiment 2). In none of the 10 experiments is there a reliable reduction in errors in noise, as there is here.

In only one of the 10 experiments does noise have a reliable effect upon the rate of responding. Here the rate of responding is reduced (Colquhoun & Edwards, see Footnote 3). In none of the experiments is the rate of responding reliably increased in noise, as it is at the start of the present task.

The quite different results in the present experiment must be due partly to the spectrum of the noise. There is a 7.5 db. per octave attenuation, which greatly reduces the intensity of the high frequencies. It largely prevents the masking of taps, clicks, and speech, which is produced by the unattenuated high frequencies of white noise. Stevens (1972) suggests that the masking may be responsible for the deterioration in noise, when it occurs.

Broadbent's (1957) experiment partially supports this view. He takes machinery noise having roughly equal energy per octave. He filters it at 2,000 Hz. to give either predominantly high-frequency or low-frequency noise. Both kinds of noise increase errors on the five-choice task, but the low-frequency noise has the reliably smaller effect. Presumably a noise with still greater filtering of the high frequencies, might turn the small increase in errors into the reliable decrease shown in Table 2.

However, the spectrum of the noise cannot alone account for the results in Table 2, because Hartley (1973) reports a reliable increase in errors using noise with a similar spectrum, but at a sound-pressure level of 100 db.(A), or 118 db.(C). Thus both the spectrum and the intensity of the noise are important. To obtain a reduction in errors, the low-frequency noise must not be too loud.

The other beneficial effects of the low-frequency noise are similar to previously reported effects of noise with a flatter spectrum. The improvement in the tracking illustrated in Figure 2 corresponds to the improvement in noise reported by Hockey (1970a, 1970b) toward the end of the tracking task. The effect of the low-frequency noise in increasing confidence in the visual vigilance task, occurs also in visual vigilance with the white noise used by Broadbent and Gregory (1963, 1965).

Most probably, both low-frequency noise at 102 db. (C) and white noise at 100 db. (A) improve performance by increasing the level of arousal. Where the low-frequency noise improves performance while the white noise degrades performance, it may be due to the masking of important auditory cues by the more intense high frequencies of the white noise, as Stevens (1972) suggests.

STORAGE CODING TRADE-OFF IN SHORT-TERM STORE[1]

FRANCIS S. BELLEZZA[2] AND RICHARD J. WALKER[3]

Ohio University

Information rehearsed in short-term store (STS) can be primarily new information, if only temporary storage is required; or it can be a mixture of old and new information, if transfer to long-term store is to be optimized. Because STS is of limited capacity, a storage coding trade-off should take place in the use of STS capacity as the memory task changes. Using a single-trial free-recall learning task it was found that *S*s using a storage strategy recalled more words in immediate recall, but fewer words in final free recall, than did *S*s using a coding strategy. Also, *S*s using a storage strategy recalled fewer new words in final free recall than did *S*s using a coding strategy. The results were interpreted as supporting the concept of a storage–coding trade-off in STS.

In dual-storage memory models such as those of Atkinson and Shiffrin (1968) and Waugh and Norman (1965), the process of rehearsal serves to maintain new information in short-term store (STS), and at the same time transfers some of this information with each rehearsal into long-term store (LTS). Recent evidence indicates that rehearsal may not be a unitary process that simultaneously maintains information in STS and transfers it to LTS. Under some conditions, rehearsal may maintain information in STS without transfer to LTS. To support this view, Jacoby and Bartz (1972) have shown that increasing the number of rehearsals in STS does not necessarily lead to more information being transferred to LTS. Although rehearsal in STS may take place without transfer to LTS, the opposite does not seem to be true. Atkinson and Shiffrin (1971) cite evidence which shows that transfer of new information to LTS cannot take place without rehearsal.

The storage and transfer functions of rehearsal are interdependent because both are control processes in STS and both use STS capacity (Atkinson & Shiffrin, 1968). Shiffrin and Atkinson (1969) discuss how rehearsal, under the control of *S*, can be used primarily for maintenance of new information in STS or for transfer of information from STS to LTS. The *S* uses a storage strategy if he fills STS to capacity with new information and rehearses it. He is able to maintain maximum new information in STS, but the rate of transfer to LTS is reduced. The *S* can increase rate of transfer to LTS by using a coding strategy that consists of adding appropriately chosen old information retrieved from LTS to new information in STS and rehearsing the entire ensemble. This description of transfer from STS to LTS implies that the amount of new information being stored in STS must decrease if *S* uses a coding strategy rather than a temporary-storage strategy. Because of the limited capacity of STS (Miller, 1956), *S* must trade off storage space for encoding space, or vice versa, depending on the strategy he wishes to use.

There is some evidence from recall experiments which shows that *S*s may use a strategy involving more encoding into LTS if recall is always delayed rather than immediate. Bartz (1969) presented *S*s with 9-digit lists in a serial-learning task where every third list was identical. All *S*s improved in performance on the identical lists. However, those *S*s in the delayed-recall condition attained a higher performance level than those in the immediate-recall condition. In a multitrial free-recall experi-

[1] This research was supported in part by Grant OURC-437 to the first author from the Ohio University Research Committee.

[3] Now at the University of London, London, England.

ment, Bellezza and Dixon[4] alternately presented a list of words and a list of numbers. The *S*s in the immediate-recall condition recalled the items from each list immediately after each list was presented. The *S*s in the delayed-recall condition recalled the other list after each list was presented. After 10 trials, the performance of the delayed-recall group was better on both lists than that of the immediate-recall group. Although it may be that *S*s in the delayed-recall conditions in these 2 experiments were using STS capacity to optimize coding into LTS, there is no way to determine if the amount of new information in STS decreased correspondingly.

The present experiment used a gaming situation in which all *S*s received 1 point for each item immediately recalled. However, *S*s in the coding condition were informed before the words were presented that they would receive 10 additional points for all words that they could recall in a final free recall. The *S*s in the storage condition were not informed of these additional points until shortly before final free recall was requested. It was predicted that *S*s in the coding condition would do more poorly in immediate recall, but would do better in final free recall.

Method

Subjects. The *S*s were 48 volunteers, drawn from a pool of introductory psychology students at Ohio University, who received course credit for their participation.

Procedure. The *S*s were run individually, using a Lafayette IBM memory drum, and were informed that they were in a memory game in which they were to try to win as many points as they could. All *S*s were told that they would be presented 7 lists of numbers and would receive 1 point for each number that they could free recall immediately after each list was presented, as long as they did not pause for more than 2 sec. between responses. A pause of more than 2 sec. was used to indicate that *S* had emptied STS (Murdock & Okada, 1970). Each *S* was then presented 7 lists of 10 2-digit numbers, with both digits different and no zeros used. All 10 numbers on each list were presented at once in a row for 15 sec. The *S*s recalled orally, and *E* checked items off a score sheet as they were recalled. As soon as *S* stopped recalling, the next list was presented. After the lists of numbers were presented, the 24 *S*s in the coding condition were informed that they would be presented 7 lists of words and would again receive 1 point for each word immediately recalled. In addition, these *S*s were told that there would be a final free recall in which they would receive 10 additional points for each correctly recalled word from the 7 previous lists. The other 24 *S*s in the storage condition were not informed of the final free recall. Each *S* was then presented 7 lists of 10 1-syllable words randomly drawn from Thorndike and Lorge (1944) and having a frequency of occurrence of 10–40 per million. The immediate-recall procedure for words was the same as the procedure used for numbers. Each number and word was used only once with each *S*. Eight different randomizations of the lists of numbers and words were devised, and 6 *S*s were run on each form. After all 7 lists of words were presented, all *S*s were presented with a 3-digit number and were asked to count backward by 7s as fast as they could for 1 min. This was to eliminate any items in STS. The *S*s were then requested to try to recall as many of the words in the 7 lists as possible, and *S*s in the storage condition were then informed of the 10 additional points for each word correctly recalled. Recall was oral, and *S*s were given 1 min. and 50 sec. for final free recall.

Analysis. The results of the experiment were evaluated using a $2 \times 8 \times 7$ analysis of variance, with the specific factors being strategy condition, randomization form, and list position. Strategy condition and randomization form were between-*S*s factors. The analysis was done on 3 different dependent variables: the number of 2-digit numbers per list immediately recalled, the number of words per list immediately recalled, and the number of words per list recalled in final free recall.

Results

The analysis of variance of the number of 2-digit numbers recalled showed only the significant main effect of list position, F (6, 192) = 4.02, $p < .001$, $MS_e = 1.15$. Figure 1 shows the number of numbers immediately recalled from each list. There seems to be a slight interlist primacy effect, and a trend analysis (Kirk, 1968) showed the linear component to be significant, F (1, 192) = 6.24, $p < .025$, $MS_e = 1.15$. Because there were no significant effects involving strategy condition, it can be concluded that *S*s were performing at the same level in immediate recall before different STS strategies were induced.

The analysis of variance on the number of words immediately recalled per list

[4] F. S. Bellezza and R. W. Dixon. Storage versus coding functions of short-term store. Paper presented at the meeting of the Midwestern Psychological Association, Cleveland, May 1972.

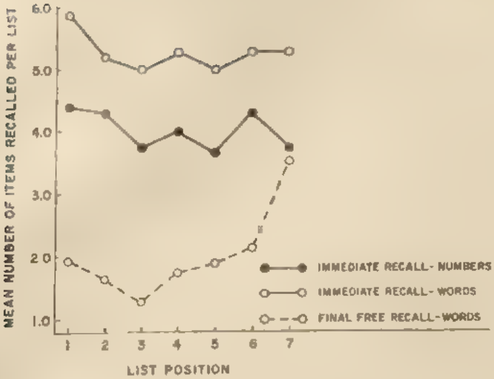

FIGURE 1. Number of items recalled from each 10-item list.

showed a significant main effect of strategy condition, F (1, 32) = 62.51, $p < .001$, $MS_e = 2.56$. The *S*s in the storage condition recalled a mean of 6.00 words/list and *S*s in the coding condition recalled 4.64 words/list. These results are shown in Figure 2. There was also a significant effect of list position, F (6, 192) = 3.92, $p < .001$, $MS_e = 1.17$, as shown in Figure 1. As in the immediate recall of numbers, there appears to be an interlist primacy effect. A trend analysis showed the linear component to be marginally significant, F (1, 192) = 3.67, $p < .10$, $MS_e = 1.17$. The one other significant source of variation was the Strategy Condition × Randomization Form interaction, F (7, 32) = 2.39, $p < .05$, $MS_e = 2.56$. Inspection of the strategy condition means in each randomization form showed that *S*s in the storage condition performed better than did *S*s in the coding condition on all forms except the fourth, where the means were the same. There is no obvious explanation for this except individual differences among *S*s.

When the data from the final free recall were analyzed, the main effect of strategy condition was again significant, F (1, 32) = 46.01, $p < .001$, $MS_e = 1.91$. As shown in Figure 2, *S*s in the storage condition recalled 1.48 words/list, whereas *S*s in the coding condition recalled 2.48 words/list. There was a significant main effect due to list position, F (6, 192) = 13.08, $p < .001$, $MS_e = 1.89$. As shown in Figure 1, not only is there a slight interlist primacy effect, but there is also a pronounced interlist recency effect, even though *S*s engaged in a difficult 60-sec. interpolated task before final recall began. No other sources of variation were significant in this analysis.

To determine to what degree the same words were given in immediate and in final free recall, all the words on the lists were placed into 1 of 4 categories: those given in both immediate and final free recall; those given in immediate recall but not in final free recall; those not given in immediate recall but given in final free recall; and those not recalled at all. The mean numbers of words in each of these 4 categories recalled by each S in each strategy condition are given in Table 1. In order to determine if the strategy conditions differed in all 4 categories of recall, a 2 × 8 × 4 analysis of variance was performed, with the specific factors being strategy condition, randomization form, and recall category. Strategy condition and randomization form were between-*S*s factors. The dependent variable was the total number of words recalled by each S in each category. The Strategy Condition × Recall Category interaction was significant, F (3, 32) = 28.21, $p < .001$, $MS_e = 29.03$. Tests of simple main effects (Kirk, 1968) showed that the

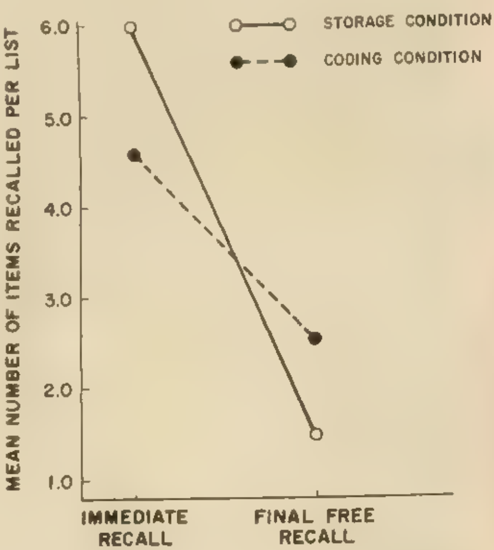

FIGURE 2. Number of words recalled per list in the storage and coding conditions.

TABLE 1

Mean Number of Words Recalled in Each Category in Final Free Recall

Condition	Category			
	IF	I$\overline{F}$	$\overline{I}$F	$\overline{IF}$
Coding	11.75	20.71	5.63	31.91
Storage	9.00	33.00	1.38	26.62
Difference	1.75*	−12.29**	4.25**	5.29**

Note. Abbreviations: IF = words given in both immediate and final free recall; I$\overline{F}$ = words given in immediate but not in final free recall; $\overline{I}$F = words given in final but not in immediate free recall; and $\overline{IF}$ = words not recalled at all.

* $p < .05$.
** $p < .001$.

means of the strategy conditions were significantly different in each recall category.

Discussion

The results support the concept of a storage–coding trade-off in STS. The trade-off is necessary because STS is of limited capacity. If *S* desires to transfer new information into LTS, he must load stored information into STS so that the new information can be appropriately placed in LTS (Shiffrin & Atkinson, 1969). This reduces the amount of new information that can be stored in STS. Because of the gaming situation used in the present experiment, *S*s in the storage condition loaded STS with as much new information as possible and stopped rehearsing it only after immediate recall. As shown in Figure 2, the storage group recalled significantly more words in immediate recall, but significantly fewer words in final free recall, than did the coding group. This indicates that STS capacity was being used in different ways by each group. It can be seen from Table 1 that the storage group recalled 1.38 words in final free recall that were not recalled in immediate recall. In the coding group, this number was 5.63. With a coding strategy, *S* would be likely to stop rehearsing an item when he thought it was coded into LTS, so that other words could be coded. This means that these coded words would not be available in the immediate-recall condition, which required almost uninterrupted responding. With the greater amount of time given for search and retrieval in final free recall, these words could be recalled. The *S*s in the storage condition were likely not to stop rehearsing any word transferred to LTS because this word would not be available for immediate recall. The results shown in [illegible] predicted from the notion tha[illegible] strategy necessarily consists of ad[illegible] appropriately chosen old information retri[illegible]d from LTS to new information in STS and re[illegible]ersing the entire ensemble. Other interpreta[illegible]ns of the data are possible. For example, a[illegible]ing strategy that involved nothing more th[illegible]lectively rehearsing a fewer number of ite[illegible]ould lead to the same results.

The better immediate recall perform[illegible] in the early lists of numbers and of word[illegible] in Figure 1 is probably not the result of [illegible] Bartz (1969) found an overall increase [illegible] the number of digits recalled as a function [illegible] position, although there was an initial de[illegible] in his first 3 lists. Melton (1963) also fou[illegible] a practice effect in a serial recall task. An al[illegible]nate explanation is that first-list performa[illegible] in immediate recall has a larger LTS co[illegible]ponent than does performance on later list[illegible] On the first list, *S* may be able to retrieve in[illegible]formation quickly from LTS, since information from only one list is stored there, and the problems of search and decision are easier and therefore faster (Shiffrin, 1970). The interlist primacy effect which seems to have occurred in final free recall could be the result of the earliest lists having more temporally distinct associated cues and hence being more accessible in LTS (Shiffrin, 1970). However, the effect could also be the result of the better immediate recall of the early lists, since the recall of an item has the same effect as an additional presentation trial (Tulving, 1967). The mechanism of memory search developed by Shiffrin can account for the interlist recency effect found in the final free recall, because information from the more recent lists is more accessible in LTS.

The results of the present experiment indicate that the concept of a storage–coding trade-off in STS could be a useful one in short-term memory experiments

EFFECT OF TEST STIMULUS RANGE ON STIMULUS GENERALIZATION IN HUMAN SUBJECTS[1]

GARY HANSEN, ARTHUR TOMIE, AND DAVID R. THOMAS[2]

University of Colorado

DORIS H. THOMAS

Colorado Women's College

In Experiment I, *S*s were exposed to a 55° line angle training stimulus and then tested for generalization (recognition) with lines of 40°, 55°, and 70° (Group 1); 40°, 47.5°, 55°, 62.5°, and 70° (Group 2); or 25°, 40°, 55°, 70°, and 85° (Group 3). Groups 1 and 2 yielded similar decrements to 40° and 70° lines, indicating no units effects; however, Group 3 responded more to these 2 stimuli, indicating a reliable range effect.

In Experiment II, the training stimulus was a 530-nm. light, and the test values were 515, 530, and 545 nm. (Group 1); 515, 522.5, 530, 537.5, and 545 nm. (Group 2); or 500, 515, 530, 545, and 560 nm. (Group 3). Group 3 responded more to 515 and 545 nm. than did Groups 1 and 2, which did not differ, again indicating a range effect and no units effect. Prior evidence of a units effect was probably due to a confounding of number of units with range of test stimuli.

The amount of stimulus generalization decrement in human *S*s has been shown to be influenced by a number of factors in addition to the physical distance between training and test stimuli. Mednick and Freedman (1960) have hypothesized that one such factor is the number of stimulus units that separate the test stimulus from the training stimulus. Their "units hypothesis" generates 2 primary predictions. (*a*) The amount of generalization decrement between a training stimulus and a given test stimulus along the same dimension is a positive function of the number of intervening test stimuli. (*b*) The generalization decrement obtained for a given number of units away from the training stimulus will be the same for units of different size. Note that Prediction *b* assumes that the number of units is the sole determinant of generalization decrement, whereas Prediction *a* assumes that it is a determinant, but not necessarily the onl

Thomas and Hiss (1963) reported a study designed to test these predictions using wavelength generalization. Three groups of human *S*s viewed a training stimulus of 530 nm. followed by a 5-stimulus generalization test in which the training stimulus occupied the physical midpoint of the test range. The groups varied in the sizes of the test unit, i.e., the physical distance between adjacent stimuli, which were 5, 10, or 20 nm., respectively.

The results reported by Thomas and Hiss (1963) supported the first of the Mednick and Freedman (1960) predictions. Responses to common test values (i.e., those experienced by 2 different groups) decreased as the number of test stimuli between them and the training stimulus increased. This study, however, failed to support the second prediction. A comparison of generalization gradients plotted in terms of number of units revealed a significant effect of unit size. Thomas and Hiss concluded, therefore, that both the number of units and the physical distance between stimuli influenced generalization slope.

The apparent finding of a units effect in the Thomas and Hiss (1963) study is

[1] This research was supported by National Institutes of Health Research Grant HD-03486 and Training Grant MH-10427 under the direction of the third author. Experiment I was performed by the first and second authors. Experiment II was performed by the third and fourth authors while on leave at the University of Iowa. The authors wish to acknowledge the assistance of James L. Thomas in the analysis of the data of Experiment II.

subject to an alternative interpretation, however. Because the number of test stimuli was held constant (at 5) across groups, unit size was confounded with the range covered by the test series. An increase in unit size produced a proportional increase in the series range. This increase in range could have had an effect on generalization decrement independent of the change in unit size. It is also possible that the units effect is dependent on an interaction between unit size and test range.

A recent experiment by Tomie (1972) suggests that the range of test stimuli used by Thomas and Hiss (1963) may have indeed been a significant factor. Two groups in the Tomie study were exposed to a training stimulus of 505 nm. and were then tested for generalization to values of both longer and shorter wavelengths than the standard. For one group, only a single test value of shorter wavelength (500 nm.) was used; for the other group, the test stimuli included 500, 495, 490, and 485 nm. Thus, for both groups, 500 nm. was one unit removed from the training value but, for one group, there were additional stimuli still farther removed. This group showed significantly more responding to the 500-nm. stimulus, indicating that increasing the range of generalization test stimuli flattens the gradient.

Two investigations of the units hypothesis have been conducted using pigeons and wavelength generalization tests. Friedman (1963) employed a selection of test values similar to that used by Thomas and Hiss (1963), in that he varied unit size while holding the number of test stimuli constant. This produced a unit size by stimulus range confounding, as noted above. Despite this confounding, Friedman found no support for either prediction based on Mednick and Freedman's (1960) units hypothesis. While no reliable differences were found in responding to common test values, the group tested over the widest range *did* respond at the highest level in all 4 relevant comparisons.

An experiment by Marsh (1967) is somewhat difficult to interpret because of variations in level of responding to the training stimulus among the different groups. Marsh used varying numbers of test stimuli, all placed to one side of the training value. He reported, in agreement with Thomas and Hiss (1963), that generalization decrement varied with both the physical size and the number of units separating the training and test stimuli. Although Marsh's experiment was designed in a way which permitted the investigation of a range effect, he found none.

The purpose of the present study was to separate the potential influences of range and size of stimulus unit on generalization decrement in an experiment with human *S*s. Three test conditions were employed involving (*a*) small units–small range, (*b*) large units–large range, and (*c*) large units–small range. The latter condition was achieved by the use of a reduced number of different test stimuli. This produced a group difference in the total number of stimulus presentations, but subsequent analysis indicated that this difference did not affect the slope of the obtained gradient. In order to enhance the generality of the present investigation, both line angle and wavelength test dimensions were employed in 2 separate experiments.

Experiment I

Method

Subjects. The *S*s were 30 male and 30 female undergraduate students enrolled in introductory psychology courses at the University of Colorado.

Apparatus. The apparatus contained a 4.5-cm.-diam. circular aperture in a 122 × 76 cm. black panel. The aperture was covered with translucent plastic. Line angles were produced by backlighting (with a 7.5-w. lamp) a .3-cm.-wide black plastic strip mounted immediately behind and bisecting the aperture cover. Thus, the stimuli were black lines at various angles viewed against a homogeneous white field. The line angles used in this experiment varied from 25° to 85° (counterclockwise from horizontal) in 7.5° steps. Angle adjustment and stimulus backlighting were performed manually by *E*, who was seated behind the panel. The *S*s were seated with their faces approximately 60 cm. from the panel, with the circular aperture approximately at eye level.

Procedure. The *S*s were randomly assigned to 3 groups with the restriction that each group contain 10 males and 10 females. Instructions were the same for all *S*s and included a general explanation of the experimental task. The *S*s were instructed

to study the sample stimulus carefully and to respond on each trial by judging the test stimulus as *same* or *different* in relation to the sample. The instructions emphasized that *S* should respond on each trial and that responses should occur during the stimulus presentation.

All *Ss* received the same sample stimulus (a black line 55° counterclockwise from horizontal) for 15 sec. The generalization test consisted of 9 blocks of trials with the appropriate test series randomized within each block. During the generalization test, each stimulus presentation was 5 sec. in duration, with an intertrial interval of approximately 5 sec. The *E* supplied no feedback to *S* during the generalization test.

Group 1 received stimulus lines of 40°, 55°, and 70° during each test block. Group 2 received 40°, 47.5°, 55°, 62.5°, and 70° lines; and Group 3 received 25°, 40°, 55°, 70°, and 85° lines. The selection of these stimulus values allows an evaluation of the units effect with range held constant (Groups 1 and 2) and an evaluation of the effect of range with the unit size held constant (Groups 1 and 3).

Results and Discussion

Initially a Group × Stimuli (40°, 55°, and 70°) × Sex analysis of variance was performed. Because the variable of sex of *S* neither yielded a significant main effect nor entered into any significant interaction all subsequent comparisons were pool across sex.

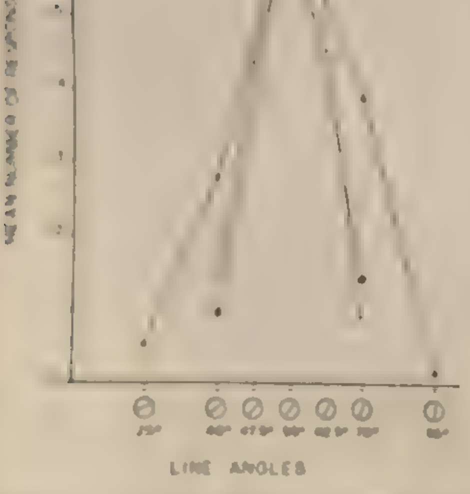

FIGURE 1. Mean generalization gradients for the 3 groups of *Ss* in Experiment I.

The mean numbers of *same* responses f the 3 groups are shown in Figure 1. The data of primary interest are the number of *same* responses to the common stimuli 40°, 55°, and 70°. All gradients peaked essentially the same level. Mean resp to 55° were 6.3, 6.6, and 6.8, for Group 1, 2, and 3, respectively, ($F < 1$).

Same responses to 40° and 70° pr the primary measure for comparing effects of range and unit size on stimu generalization. The gradients of Gro 1 and 2 provide a direct test of the fi prediction generated by the units hypo esis. If generalization decrement var positively with the number of units inte vening between training and test value Group 2 should show fewer *same* responses to 40° and 70° than Group 1. The mean total *same* responses to 40° and 7 these 2 groups were 2.40 and 2.4 tively ($F < 1$). Inspection of Fig shows the gradients produced by th 2 groups to be nearly identical.

The second prediction generated by the units hypothesis is that the generalization decrement shown for a given number of units away from the training stimulus will be the same for units of different size. If this prediction were correct, the level of responding to 40° and 70° for Group 1 should equal that to 47.5° and 62.5° for Group 2. This is clearly not the case. Mean total responses to these respective sets of stimuli were 2.45 and 8.40, which differ significantly, $F(1, 38) = 56.11$, $p < .01$. Another comparison relevant to this prediction involves Stimuli 25° and 85° for Group 3 vs. 40° and 70° for Group 2. Here the mean total responses, .25 and 1.15, respectively, again differ significantly, $F(1, 38) = 5.11$, $p < .05$.

Group 3 shows a substantial level of responding to 40° and 70°, with a mean of [illegible]

$= 10.18$, $p < .01$. Separate Newman-Keuls comparisons between Group 3 and Groups 1 and 2 were also significant ($p < .01$). As is shown in Figure 1, the effect of series range is not dependent on [illegible] to the [illegible] end values. The mean total responses to 25° and 85° were only .25.

It should be noted that the generalization test for Group 1 contained 27 stimulus presentations, compared to 45 for Groups 2 and 3. This procedural difference can be shown to be inconsequential in 2 ways. First the gradients of Groups 1 and 2 were comparable, despite the difference in length of the test. Second, the data for Groups 2 and 3 were reanalyzed so as to include only the first 5 test series (25 stimulus presentations). The gradients were then computed, based on the percentage of opportunities on which a response actually occurred. All of the group comparisons reported for data for the entire test were also observed in this reanalysis, at the same levels of confidence.

This experiment, then, offers no support for the units hypothesis and suggests that the data presented by Thomas and Hiss (1963) also failed to support it. It should be noted that our Groups 2 and 3 varied in the same [illegible] in their study. The gradients show the same direction of differences in responses to the common test values. The inclusion of our Group 1, however, suggests that such differences are the result of test series [illegible] in testing.

EXPERIMENT II

Because the results of Experiment I and of the Tomie (1972) study suggest the [illegible] able, and [illegible] procedure [illegible] work revealed that when the monochromatic lights were matched for brightness (which Thomas and Hiss did not do), a [illegible] was required than the 5 nm. they used. Another change was the use of verbal *same-different* responses instead of the finger-lift response used by Thomas and Hiss. Pilot work in our laboratory has shown the verbal and motor responses to be functionally equivalent. We have also determined that a much shorter exposure to the training stimulus then the 60 sec. used by Thomas and Hiss produces comparable data.

Method

Subjects. The *Ss* were 30 male and 30 female undergraduate students enrolled in introductory [illegible] courses at the University of Iowa.

Apparatus. The apparatus contained a 2.22-cm diam circular aperture in a 76.20-cm. wide by 61.40 cm high black panel. The aperture was covered with translucent plastic. The light source, a Bausch and Lomb Model 33 86 02 monochromator equipped with a tungsten light source, was mounted 22.86 cm behind and at the same height as the circular aperture. A pair of circular Kodak Type M carbon neutral density optical wedges was mounted on the monochromator between the light source and the diffraction grating. All stimuli were equated for brightness by adjusting the settings of the variable [illegible] prior to the initiation of the experiment. Adjustment of both the monochromator and the wedge was done manually by *E* during the intertrial intervals. The *Ss* were seated with their faces approximately 60 cm. from the panel, with the circular aperture approximately at eye level.

Procedure. The *Ss* were randomly assigned to 3 groups with the restriction that each group con[illegible] of the [illegible] to study the sample stimulus carefully and to [illegible] test stimulus in relation to the sample. The [illegible] trial and that responses should occur during the stimulus presentation.

All *Ss* received the same sample stimulus, a 530-nm. light, for 15 sec. The generalization test consisted of 9 blocks of trials, with the appropriate test series randomized within each block. During the generalization test, each stimulus presentation was 5 sec. in duration, with an intertrial interval of [illegible] to *S* during the generalization test.

Stimuli received were of 515, 530, and 545 nm. for Group 1, 515, 522.5, 530, 537.5, and 545 nm

for Group 2; and 500, 515, 530, 545, and 560 nm. for Group 3. The selection of these stimulus values allowed an evaluation of the units effect with range held constant (Groups 1 and 2) and an evaluation of the effect of range with unit size held constant (Groups 1 and 3).

Results and Discussion

Because the rationale and design of Experiment 2 parallel Experiment I, the presentation of results will also be parallel, and can therefore be somewhat condensed. Again, an initial Group × Stimuli (515, 530, and 545 nm.) × Sex analysis of variance was performed. Because the variable of sex of *S* neither yielded a significant main effect nor entered into any significant interaction, all subsequent comparisons were pooled across sex. The generalization gradients of the 3 groups are presented in Figure 2. The 3 groups responsed quite comparably to the 530-nm. training stimulus value, with 8.1, 7.1, and 7.5 responses for Groups 1, 2, and 3, respectively ($F < 1$). The units hypothesis generates the prediction that Group 2 should show fewer *same* responses to 515 and 545 nm. than Group 1. The mean total *same* responses to these 2 values were 2.75 and 3.45 for Groups 1 and 2, respectively. This difference is insignificant ($F < 1$) and in the opposite direction from that predicted. A second prediction generated by the units hypothesis is that Group 1 should respond as much to 515 and 545 nm. as Group 2 does to 522.5 and 537.5 nm. Mean responses to these respective sets of stimuli were 2.75 and 7.40, which differ significantly, $F(1, 38) = 32.79$, $p <$ .01. According to the same principle, Group 3 should respond as much to 500 and 560 nm. as Group 2 does for 515 and 545 nm. However, the mean total responses, .25 and 3.45, respectively, again differ, $F(1, 38) = 21.53$, $p < .01$.

FIGURE 2. Mean generalization gradients for the 3 groups of *S*s in Experiment II.

Group 3 showed a substantial level of responding to 515 and 545 nm., with a mean of 5.70 total responses to these 2 stimuli. Analysis of variance including all 3 groups showed a significant difference in summed responses to 515 and 545 nm., $F(2, 57) = 4.85$, $p < .025$. Separate Newman–Keuls comparisons between Group 3 and Groups 1 and 2 were also significant ($p < .05$). As is shown in Figure 2, the effect of range of test stimuli is not dependent on any substantial responding to the added end values. Indeed, responses to these values almost never occur.

Finally, a reanalysis of the data including only the first 5 test series of Groups 2 and 3 yielded all of the same group differences and similarities reported above for gradients obtained over the entire course of testing. Thus, in all major respects, the results obtained with wavelength stimuli in Experiment II parallel those obtained in Experiment I with line angles.

General Discussion

Several interpretations may be offered for the effect of the range of test stimulus values on the slope of stimulus generalization gradients. Capehart, Tempone, and Hebert (1969) have proposed that Adaptation level (AL), rather than the absolute value of the training stimulus, serves as the reference value in stimulus generalization studies. This view assumes that the training stimulus becomes the AL value and, in subsequent generalization

testing manipulations which affect the AL value affect generalization accordingly. Such manipulations include the use of a test series asymmetrically spaced around the training value, the over representation of certain test values during testing, etc. In the present experiment, the range of test stimuli in a symmetrical distribution around the training stimulus would presumably not affect the mean AL, but it would affect AL variance and thus *S*'s degree of certainty about whether a particular test stimulus was at the AL value at that time. If *S* had a set to "respond when in doubt," then increasing the variance of AL could result in a flattened gradient.

An alternative interpretation involves an application of Parducci's (1965) range-frequency hypothesis, originally developed to predict performance in magnitude estimation tasks. If *S*s placed the line angle stimuli (for example) in 3 categories (sharper than the training stimulus, same as the training stimulus, or flatter than the training stimulus), then broadening the range of test stimuli might extend the boundaries of the *same* category, with a consequent flattening of the line angle gradient. The present study does not permit a rejection of either of these interpretations, and there may be others which are equally tenable.

With the proposed reinterpretation of the Thomas and Hiss (1963) study, it appears that support for Mednick and Freedman's (1960) units hypothesis is meager at best. None of the studies explicitly designed to test the hypothesis have provided confirmatory evidence. Furthermore, the evidence cited in the original Mednick and Freedman article was entirely based on a comparison of experiments performed in different laboratories, such that innummerable procedural differences might have accounted for the results obtained.

Evidence for a range effect is somewhat more substantial, having been found reliably in a wavelength generalization study by Tomie (1972) and in the present line angle and wavelength experiments. In neither of the wavelength generalization studies with pigeons by Marsh (1967) and Friedman (1963) was reliable evidence found for a range effect, although in the latter case, there was some supportive evidence, which failed to achieve statistical significance. The variables that determine the presence or magnitude of a range effect in stimulus generalization have yet to be determined. Capehart et al. (1969) considered and rejected the possibility that infrahuman *S*s may not be subject to contextual effects in generalization testing. We agree with their judgment that, in principle, such effects should not be limited to humans. Giurintano (1972) has demonstrated in a study with pigeons that when training has been very brief, generalization testing with a series of stimuli with all values to one side of the training stimulus may result in a shift of maximal responding to a more centrally located stimulus. Perhaps the amount of training administered to *S*s will similarly prove to be a crucial variable in the investigation of the range effect in stimulus generalization, and what now appears to be a species difference will turn out to be only a procedural one.

SOURNESS OF ACID MIXTURES [1]

HOWARD R. MOSKOWITZ [2]

Pioneering Research Laboratory, U.S. Army Natick Laboratories, Natick, Massachusetts

The sourness of 5 acids (citric, hydrochloric, phytic, succinic, and gluconolactone) was assessed at 4 concentrations of each acid and in 16 mixtures with citric acid by the method of magnitude estimation. Power functions fit to the sourness of unmixed acids were either added directly to predict mixture sourness, or both acids in the mixture were first converted to equivalent levels of citric acid and then exponentiated according to the appropriate power function. Summation of sourness functions accounted best for mixtures of citric acid with gluconolactone. Summation of acid equivalents was better for mixtures with phytic acid. Both models predicted mixtures with succinic and hydrochloric acids equally well. Mixtures with hydrochloric acid were synergistic. The results are discussed in terms of possible mechanisms underlying taste mixtures.

For the past 50 years, sensory additivity of taste and smell has concerned investigators, who have attempted to derive relations between the perceived intensity of mixture components tasted or smelled in in the unmixed (pure) state and the intensity of the mixture. Three major classes of models have been proposed, two from studies of taste and one from studies of smell. The present article concerns these models as they apply to the sourness of acid mixtures.

Model 1, the summation of concentrations, derives from the earliest studies of taste mixtures and can be best seen in historical perspective in the extensive sweetness studies of Cameron (1947). Cameron noted that the sweetness of mixtures containing 2 or more sugars could be predicted if each sugar component were first compared to a reference sweet substance. In the unmixed state, each component was compared to glucose and the "glucose equivalent" determined experimentally. The sum of the glucose equivalents of the 2 (sometimes 3) components approximated the glucose equivalent of t mixture.

Cameron's (1947) additivity model wa limited to equal-sweetness matches, since, at that time, no appropriate measures were developed for the direct assessment of sensory intensity that would, simultaneously permit subjective magnitudes to be added, subtracted, or multiplied by a constant With the development of magnitude estimation, *S*s have been given a tool to repor sensory intensities along a ratio scale. In this procedure, *S*s assign numbers to taste intensity (S), and these numbers are regressed against concentration (C) (Moskowitz, 1970). The results for acids, evaluated in the unmixed state, suggest that the simple power function $S = kC^n$ provides a reasonable description of the growth of sourness with concentration (Moskowitz, 1971). For 2 acids in a mixture, 2 separate power functions may be obtained:

$$\begin{aligned} \text{Acid A:}\quad S_a &= k_a C_a{}^m \\ \text{Acid B:}\quad S_b &= k_b C_b{}^n. \end{aligned} \qquad [1]$$

The exponents m and n need not be equal, and for organic acids they typically lie between .5 and 1.0, so that sourness is a decelerating function of concentration. The intercepts k_a and k_b may also vary, and reflect the sourness estimate at 1.0 gm. molecular weight (M) of each acid.

Cameron's (1947) additivity model may be expanded to account for power functions

[1] The author wishes to thank Harry L. Jacobs for numerous helpful discussions about the models of additivity and for suggestions about relating psychophysical measurement to electrophysiological studies.

of sensory intensity. Equation 1 can be solved for equivalents of 1 acid (e.g., Acid A)

$$S_a = S_b \text{ implies } k_aC_a^m = k_bC_b^n, \quad [2]$$

$$C_a = (k_bC_b^n/k_a)^{-m}. \quad [3]$$

Equation 3 presents the concentration of Acid A that is as sour as the corresponding concentration of Acid B. In a mixture of the 2 acids ($C_a + C_b$) the sourness can be predicted by Equation 4:

$$S_{ab} = k_a[C_a + (k_bC_b^n/k_a)^{-m}]^m. \quad [4]$$

Model 2, the summation of perceived sournesses, suggests that the gustatory system treats the 2 acid concentrations as separate inputs, processes them separately, and adds the outputs ("sensory judgments") together. Equation 5 presents Model 2:

$$S_{ab} = k_aC_a^m + k_bC_b^n. \quad [5]$$

Model 2 is simpler than Model 1, since it does not require any cross terms in the mixture equation. It also suggests a substantially different process by which the gustatory system adds together information from a compound source.

The third model, the vector addition of sourness judgments, is derived from an approach to odor mixtures reported by Berglund, Berglund, Lindvall, and Svensson (1972). They proposed that binary mixtures of odors, e.g., dimethyl disulfide + pyridine, hydrogen sulfide + pyridine, etc., may add together together in intensity as if they behaved like vectors separated by a constant angle Q. Their additivity equation is shown in Equation 6:

$$S_{ab} = [S_a^2 + S_b^2 + 2S_aS_b(\cos Q)]^{.5}. \quad [6]$$

When the 2 odors (or here, acids) are qualitatively identical, then the angle separating them, Q, becomes 0, and its cosine becomes 1.0. Note that the vector additivity is expressed in terms of subjectively perceived intensity. A slight modification is needed to represent Equation 6 as the sum of power functions.

A previous study with sweeteners and their mixtures failed to distinguish between Models 1 and 2, viz., taste summation of concentrations vs. summation of subjective intensities (Moskowitz, 1973). In that study, glucose was mixed with fructose, saccharin, or cyclamate, and *S* was asked to estimate perceived sweetness. The 2 models were shown to differ maximally when 2 conditions prevailed: (*a*) the exponents *m* and *n* differed widely from 1.0, and (*b*) as little "noise" as possible was present in the mixture estimates. The 2 models become increasingly similar as the exponents approach 1.0 (at which point they become identical).

The present study concerns acid mixtures and the 3 models of summation. Previous studies with the sourness of organic acids (Beebe-Center, 1949; Moskowitz, 1971) suggested that the rated sournesses of tartaric acid, citric acid, and a number of other compounds grow according to a simple power function of concentration: $S = kC^n$. The exponent *n* is usually lower than 1.0, lying around .7 for citric acid and perhaps slightly higher for tartaric acid. When the measure of concentration is defined in terms of pH ($-\log$ H+ ions in solution, a measure of hydrogen ion concentration), the exponent *n* becomes -1.7, suggesting that apparent sourness grows as an accelerating function.

Method

In 4 experiments, citric acid was evaluated both in unmixed solutions and when mixed with another acid (either hydrochloric, acetic, phytic or gluconolactone). Four concentrations of citric acid and 4 of the second acid were evaluated in each experiment, as well as the 16 mixtures of the 2 acids. Table 1 lists the concentrations used. The stimuli were prepared in 250-ml. quantities with distilled water (Hydro Service Supply, Inc.). At the time of preparation, the stimuli remained for 24 hr under refrigeration (4°C), following which they were frozen until use 2 wk. later. The solutions were thawed, remixed thoroughly, and served to *Ss* at room temperature (21°C ± 1).

Each stimulus was presented to *S* in small (½ oz.) paper cups containing 15-20 ml. of the solution. The stimuli in each set were presented in random order of concentration, compound, and mixture, and within any session, each *S* sampled all 24 stimuli (8 unmixed stimuli and 16 mixtures). The entire session required about 30 min., with *S* taking approximately 1 min. to sample the stimulus, record the sourness estimate, and then rinse with 50-100

Citric	.92	.15	2.15	.95	.11	1.73

Note. Concentrations (molarity) were .05, .025, .0125, and .00625 for hydrochloric, succinic, citric, and phytic acids; and .80, .40, .20, and .10 for gluconolactone.

[a] $n = 8$.
[b] $n = 7$.
[c] $n = 6$.
[d] $n = 7$.

ml. of water provided for that purpose. The rinse water was room-temperature tap water.

All *S*s were military enlisted men (aged 18–24 yr.) who had had previous experience in judging the apparent sweetness of sugars by magnitude estimation. None were aware of the purpose of the study, and each had been previously trained on the use of magnitude estimation according to the procedure outlined by Moskowitz (1970). A pool of 10 *S*s participated, but smaller groups of individuals participated in any one session. The experiments consisted of one test in the morning and a replication of that test in the afternoon. The same *S*s participated in each session.

Analysis. The median magnitude estimate was computed for the 24 judgments for each set of stimuli. The median was selected as the preferred measure of central tendency because it is not as drastically affected by an erratic judgment as is the geometric mean. For each experiment, power functions in their linearized form ($\log S = n \operatorname{Log} C + \log k$) were computed by a least squares procedure, both for the median judgments of citric acid and for the median judgments of the second acid (in unmixed form). The goodness of fit was assessed by (*a*) the Pearson r^2, (*b*) the standard error of the regression, and (*c*) the standard error of the exponent.

The 2 theoretical models of sourness summation were used in conjunction with the simple power functions to predict the sourness of the 16 mixtures in each experiment. Each model uses both the exponent n and intercept k, according to Equations 4 and 5, respectively, and for every pair of acid concentrations, the 2 models predict different expected sourness values. In addition, estimates were made of the cosine of the angle separating the 2 "sourness vectors" for the vector model of additivity (Equation 6). Finally, in order to assess which model fits most appropriately the theoretical mixture sourness from Equations 4 and 5, theoretical mixture sourness (S_t) was related to the empirical estimate of mixture sourness (S_e) by the following equations:

$$\log (S_e) = n \log (S_t) + k_1, \qquad [7]$$

and

$$\log (S_e) = 1.0 \log (S_t) + k_2. \qquad [8]$$

Equation 7 states that the relation between predicted and obtained sourness is a power function. If the exponent n is 1.0, (Equation 8), then both predicted and obtained sourness differ only by a single value, k_2 (i.e., by a constant ratio). If the exponent n is higher than 1.0, then the mixture sourness grows more rapidly than the theoretically predicted sourness. As the sourness level increases, the mixture sourness will eventually be substantially higher than that predicted from the models. The opposite occurs if the exponent is lower than 1.0. Finally, if a single index number is desired to represent, on the average, how different the predicted and the empirical sourness values are, then Equation 8 is useful. The exponent is set arbitrarily to 1.0, and the least squares solution for k_2 provides that index number. If k_2 is positive, then the empirical sourness is stronger than that predicted from the additivity models; whereas if k_2 is negative, then the empirical sourness is weaker than that predicted. The former corresponds to "synergism," whereas the latter corresponds to "suppression."

RESULTS

Figure 1 shows the 4 pairs of sourness functions obtained from the median magnitude estimates of sourness, and Table 1 lists their respective parameters and the goodness-of-fit statistics. The acids are not described by the same power functions, but differ both in the exponent n and in the intercept k. The exponent of phytic acid, for example, is higher than that of citric acid judged in the same session. This means that equal percentage changes in concentration for the 2 acids produce a greater increment in the judged sourness of phytic acid than that of citric acid. Citric acid, in turn, is governed by a higher exponent than hydrochloric (a factor of almost 2.5:1), so that hydrochloric acid grows more slowly in sourness than citric acid for commensurate increments in molar concentration.

In the evaluation of simple, unmixed acids, the appropriate experimental procedure may be to determine sourness functions for both acids judged in the same session. In this way, the same *S* judges the 2 acids, using the same modulus, and

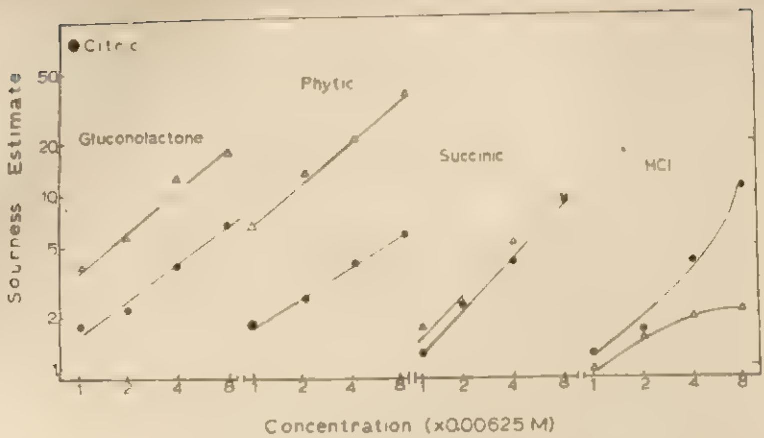

FIGURE 1. Sourness functions for 4 experiments. (In each experiment, citric acid and 1 other acid were each evaluated at 4 concentrations. The coordinates of the figure are log log, and straight lines represent power functions whose exponents are given by the slope of the line. The concentrations are in terms of molarity, and the median magnitude estimate is plotted against concentration.)

brings to bear in the experiment the same biases toward the operation of judgment. Were 2 acids to be evaluated in separate sessions by different *S*s, one *S* might use a larger range of numbers than another. The limited number range adopted by some *S*s can decrease the power function exponent considerably and has been called the "regression effect" in psychophysical judgment (Stevens & Greenbaum, 1966). If the regression bias is multiplicative or belongs to a class of transformations known as power transformations, then the relative exponents, determined under these conditions, would yield the same ratio, even though each exponent might be reduced or increased considerably. Here, the different *S*s may have influenced the variability of the exponent for citric acid from a low of .62 to a high of 1.01. This range of values lies within the range of exponents previously reported for various organic acids (Moskowitz, 1968, 1971).

In the evaluation of unmixed acid solutions, a single representative value for relative sourness is often desirable, if only

TABLE 2

PARAMETERS OF MIXTURE FUNCTIONS

Parameter	Mixture			
	Citric + gluconolactone	Citric + succinic	Citric + phytic	Citric + hydrochloric
Model 1: summation of concentrations				
n	.94(.17)[a]	1.04(.14)	1.09(.09)	1.18(.16)
k_1	.15	− .09	− .24	− .03
SE estimate	.14	.12	.10	.16
r^2	.68	.79	.90	.79
k_2	.10	− .06	− .11	.08
Model 2: summation of sournesses				
n	1.01(.14)	1.05(.15)	1.19(.11)	1.15(.16)
k_1	.02	− .11	− .48	− .01
SE estimate	.14	.12	.11	.15
r^2	.69	.79	.89	.79
k_2	.02	− .07	− .20	.09

Note. (*a*) log (Sourness$_{\text{empirical}}$) = n log (Sourness$_{\text{predicted}}$) + k_1. (*b*) log (Sourness$_{\text{empirical}}$) = 1.0 log (Sourness$_{\text{predicted}}$) + k_2.
[a] Numbers in parentheses refer to the standard error of estimate of n.

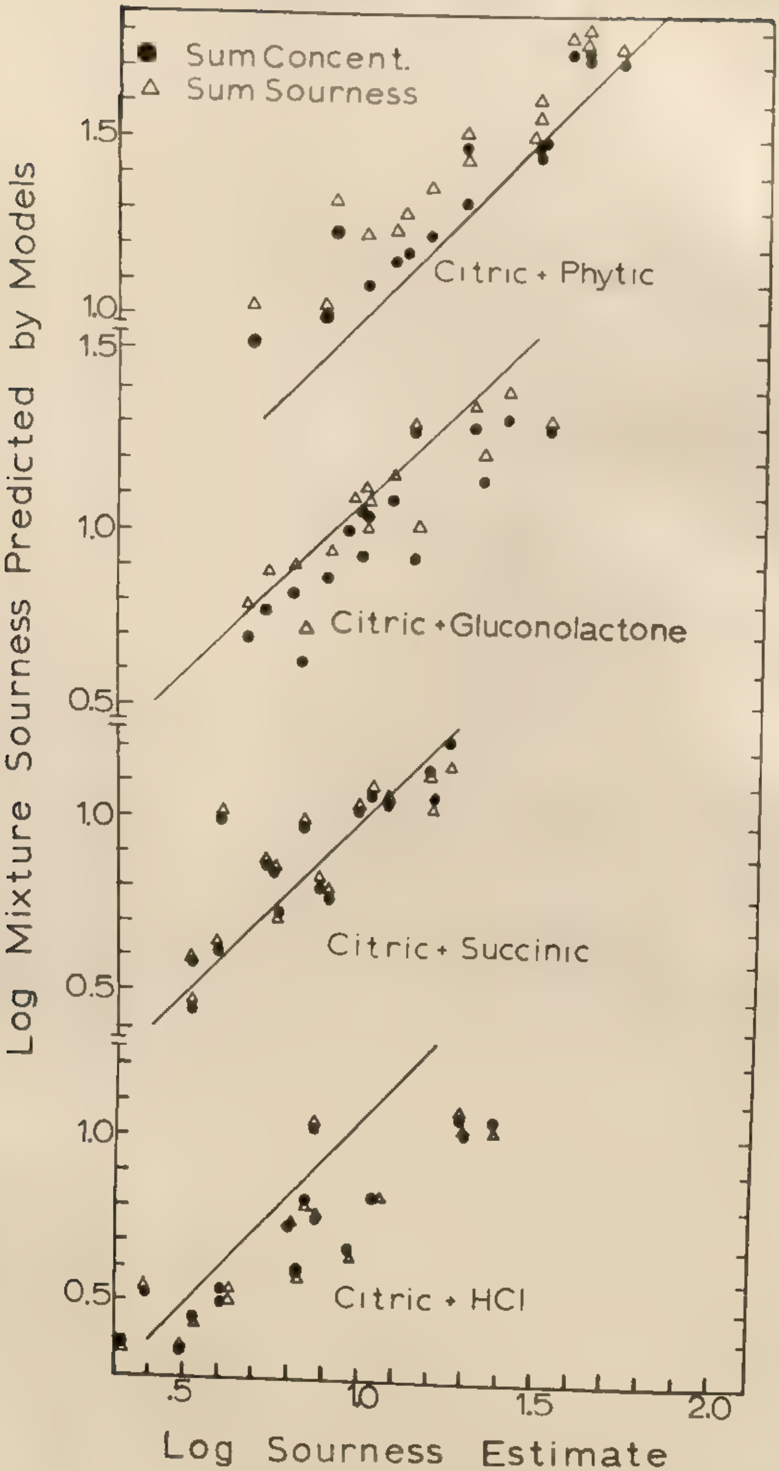

FIGURE 2. The relation between obtained (median) estimates of sourness for mixtures of 2 acids at varying concentrations, and the predicted sourness based upon 2 models of additivity. (The coordinates are log–log, so that

to serve as an index number for purposes of comparing different chemicals. The relative sourness for 2 acids may be immediately obtained by comparing 2 magnitude estimates of different acids (usually at 1 common concentration, e.g., 1.0 M). The ratio of estimates (corresponding to the difference in logarithmic values) corresponds to the desired ratio of sensory magnitudes. In contrast, the traditional (although misleading and ambiguous) definition of relative sourness has been the ratio of concentrations of 2 acids that produce an impression of the same sourness level. This latter ratio might better be called *taste potency* rather than relative taste intensity.

When exponents differ for acids, the relative sournesses tend to vary with concentration. In order to achieve a single index for the relative value, the 2 sourness functions must be forced to conform to a single power function with fixed slope (any slope or exponent suffices). The least squares estimate of the intercepts then serves as a useful value for sourness and can be used across the entire continuum of concentrations. In Table 1, the exponent has been set arbitrarily at .7 for each acid (independent of the actual least squares exponent) and the value k' corresponds to the intercept (at 1.0 M) for the .7 exponent. In all cases, the value for citric acid is 1.73 (in logarithmic units). Numbers lower than 1.73 represent lower sourness, so that .73 means that the second acid is 1.0 log unit lower in sourness (equal to 10% as sour as citric acid at equal concentrations). Gluconolactone has a sourness of 1.34, so that relative to citric acid, its sourness is $-.39$ (i.e., $1.34 - 1.73$). That value corresponds to approximately 40% relative sourness ($10^{-.39} = 40\%$). Phytic acid is the most sour and gluconolactone the least sour acid.

Acid mixtures. Table 2 presents the summary statistics for the analysis of acid mixtures, and Figure 2 presents the relation between the logarithms of the sourness estimates (empirically obtained judgments) of mixtures and the values for mixture sourness predicted by the summation models. The models were evaluated both by the summation of concentrations (expressed in equivalents of citric acid) and by the summation of sournesses (i.e., addition of power functions). In many instances, the mixture sourness exceeded the predicted sourness, and as a result, the vector model of additivity required a cosine greater than 1.0, an impossible case. Vector additivity could not account for synergistic effects, and was eliminated as a predictor model, based upon the relatively large number of synergistic mixtures.

The computations for mixture sourness in Table 2 and Figure 2 result from the composition of individual sourness functions (i.e., by adding together psychophysical power functions) rather than from the empirical sourness estimates themselves. As a result, the models are capable of accounting for mixtures of concentrations that are not directly tested in the experiment, since a function is used to transform concentration to sourness. In addition, however, those discrepancies between predicted and obtained sourness of mixtures may, in part, be traced to the choice of sourness functions for the unmixed acids. The increase in generality by appeal to a simple parsimonious function will be offset when that function provides only a modest fit to the sourness estimates of unmixed acids.

In Figure 2, the coordinates are logarithmic, and the best fitting functions in Table 2 refer to those coordinates. The straight line tilted 45° represents the line of congruity. When the predictions exactly

deviations from the 45° line—ideal congruence between predicted and obtained values—correspond to percentage deviations, not absolute deviations. Mixtures that are plotted above the 45° line represent pairs of acids whose predicted sourness is greater than the empirically judged sourness. Those mixtures show *suppression* or partial additivity. Mixtures plotted below the 45° line represent stimulus pairs whose predicted sourness is less than the empirical sourness. Those mixtures show *synergism*.)

equal the empirical sourness estimates, then all points fall along the line. Points *below* the line correspond to synergism, so that the obtained sourness estimates exceed the predicted values. Points *above* the line correspond to suppression, so that the obtained sourness estimates are less than the predicted values. Deviations from straight lines are logarithmic distances, corresponding to ratios in linear coordinates. The conversion to logarithms allows a constant percentage discrepancy to appear as a constant difference. In linear coordinates, that constancy would be difficult to ascertain by visual inspection alone. In addition, small deviations at the low end of the sourness scale are as important for the appropriateness of the models as are the larger deviations that would be expected at the higher end of the sourness scale. The small deviations would be masked substantially in linear coordinates.

A number of phenomena emerge from Figure 2. First, for the mixtures of citric acid with either gluconolactone or succinic acid, the mixture sourness grows as rapidly as that predicted from the mixture equations. The parallel functions do not appear for mixtures of citric with phytic and hydrochloric acids. Instead, when the sourness estimate is the dependent variable, the slope relating the 2 mixture sournesses exceeds 1.0, so that the 2 values depart increasingly from each other with increasing sourness. Second, departures from congruence, even when of a constant percentage nature (i.e., mixtures of citric acid with succinic acid and gluconolactone, respectively) can be either synergism (with gluconolactone) or slight suppression (with succinic acid). It is also interesting to note that phytic acid (which shows most suppression in mixtures) is the strongest of the acids in terms of the sourness it produces, whereas gluconolactone is the weakest. It is possible that relative sourness is implicated in synergism vs. suppression. Third, the 2 models produce highly correlated predictions that differ principally by a constant percentage. That percentage, rather than any other goodness-of-fit statistic, is the critical parameter by which the 2 models can be differentiated and evaluated. The percentage by which one model exceeds the other (Figure 2) is not constant, however, but varies systematically according to the component power functions that are used to generate the 2 mixture equations. For mixtures of citric and succinic acids, the models produce virtually the same predictions, whereas for mixtures with gluconolactone, the models predict moderately different sourness levels.

Discussion

The models of additivity suggested previously to account for the sweetness of sweetener mixtures (Cameron, 1947; Moskowitz, 1973) appear to be useful for predicting mixture sourness of acids as well. The present results bear upon 2 areas of taste psychology: (*a*) the analyzability of taste impressions and its correlation with taste intensity of mixtures, and (*b*) potential sensory mechanisms subserving taste impressions and their elucidation from studies of taste mixtures.

Analyzability. None of the *S*s in the present experiment appeared to be aware that they were sampling both simple stimuli and mixtures. Rather, the tastes were reported to be uniformly sour. Each *S* was questioned at the completion of the series of experiments, but none reported any other taste but sourness. Similar failure to perceive a taste as a mixture when both components possess the same quality was reported previously when fructose was added to glucose (Moskowitz, 1973). In that study, as in this, no stimuli contained bitter or other side tastes that might have interfered with sweetness or sourness, respectively. It may well turn out that like-tasting compounds add together according to a simple arithmetic manner, with synergism or suppression simply phemomena that reveal a failure to account in an adequate way for the law of summation.

In contrast to simple additivity of like-tasting compounds, mixtures with different tastes suppress each other. A study by Beebe-Center, Atkinson, Rogers, and O'Connell (1959) investigated the saltiness and sweetness of compound tastes containing NaCl and sucrose. The saltiness and sweetness were reduced by a total of 40% (in gusts, their unit of taste intensity), to 60% of the starting value. In a second study (Moskowitz, 1972), mixtures of sweet substances (glucose and fructose, 2

simple sugars) with NaCl (salty), citric acid (sour) or quinine sulfate (bitter) also showed suppresion, so that the total magnitude estimate given to the mixture (i.e., the sum of the magnitude estimates given to the 2 components) was less than the arithmetic sum of the estimates given to the unmixed components.

It is possible that the laws governing taste mixtures parallel *Ss*' ability to analyze the mixture into its components. Those mixtures in which analyzability is high (e.g., sweet + salty mixtures) may exhibit substantial suppression. Intermediate mixtures in which the components are qualitatively similar and merge slightly (e.g., some odor mixtures) show more additivity and less suppression. Finally, mixtures of like-tasting compounds may show total additivity, or at least a high degree thereof. It is also intriguing to note that an entire continuum of mixture phenomena is possible, ranging from synergism to complete (100%) additivity, through partial additivity, and down to suppression. Taste mixtures in general occupy 2 separate regions. Like-tasting compounds occupy the upper region, whereas different-tasting compounds occupy the lower region of suppression.

Underlying sensory mechanisms and taste mixtures. A study by Halpern (1959) compared the neural response at the medulla (nucleus fasisculus solitarius) to responses of the chorda tympani (peripheral taste nerve). At the chorda tympani homogeneous mixtures of inorganic salts produced an additive intensity response, so that the neural response to the mixture could be well approximated by summing the responses to the components. Heterogeneous mixtures of sucrose and citric or acetic acids also produced additive neural response (Halpern, 1967). In contrast, the central neural response at the medulla did not show a parallel summation. Instead, the magnitude was smaller than the expected sum, but greater than either response to the components separately. It would be instructive to compare central vs. peripheral neural responses to both homogeneous and heterogeneous mixtures and to then determine parallels between human psychophysical judgments of mixtures and neural responses.

A SEMANTIC INTERPRETATION OF ENCODING SPECIFICITY[1]

LYNNE M. REDER,[2] JOHN R. ANDERSON, AND ROBERT A. BJORK

University of Michigan

Two experiments are presented to clarify possible interpretations of the Encoding Specificity Principle of Tulving and Thomson. This principle states that a cue must have been studied with a word in order for the cue to be effective at testing. In the experiments reported here, recall and recognition of words were impaired by a change in the accompanying cues only if the to-be-remembered (TBR) words were of high frequency; low-frequency words did not support the Encoding Specificity Principle. The data suggest that both recall and recognition of a TBR word depend upon recognition of a specific interpretation of the word originally encoded, rather than its physical representation.

The considerable recent research on context effects in memory (e.g., Bobrow, 1970; Light & Carter-Sobell, 1970; Thomson, 1972; Thomson & Tulving, 1970; Tulving & Thomson, 1971; Winograd & Conn, 1971) has demonstrated that the ability to recall or recognize a word can be severely impaired by changes from study to test of the context in which the word is presented. Light and Carter-Sobell, for example, paired homographs with one adjective at the time of study (e.g., soda *cracker*) and later tested recognition of the homographs when paired with the same adjective or with an adjective that primed a different sense of the homograph (e.g., safe *cracker*). Recognition was significantly better when the same adjective was paired with the target word even though *S* knew that only the noun was to be judged for familiarity; thus, a word's context can greatly affect whether *S*s can access information stored with that word. This result is significant, since many models of memory (e.g., Anderson & Bower, 1972; Kintsch, 1970) assume that accessing a word's trace is an automatic process in tests of recognition memory.

Tulving and Thomson (1971) and Thomson (1972) have also found that recognition memory for to-be-remembered (TBR) words is impaired by changes in the cue word that is paired with a TBR word. Also, they found that adding or subtracting the cue word at the time of test impaired the recognition of TBR words. In contrast to the Light and Carter-Sobell (1970) procedure, however, Tulving and Thomson did not use transparent homographs, and they did not make a deliberate attempt to prime different meanings of the words. Thomson and Tulving (1970) also have found that cued recall of TBR words is lowered when the cue employed at the retrieval test is different from the encoding cue given at input, and that result holds even when the retrieval cue is a strong normative associate of the TBR word. Strongly associated, extralist cues (*strong cues*) enhance recall when no cues are presented with the TBR words at input (Bahrick, 1969; Thomson & Tulving, 1970), but are inferior probes compared to weak cues that were paired with TBR words at the time of input. It is possible in the Thomson and Tulving cued-recall situation that the *S* implicitly generates the TBR word to the strongly associated cue, but does not recognize the TBR word as being from the list. This interpretation is supported by the fact that *S*s can generate the TBR item in a free-association task to a strong cue, yet fail on a later

test to recognize that word as a TBR word (Tulving & Thomson, 1973).

Tulving and Thomson (1973) argue that only their Encoding Specificity Principle is consistent with these results. In defining this principle, they state that: "In its broadest form the principle asserts that only that can be retrieved that has been stored, and that how it can be retrieved depends on how it was stored [p. 359]." They assert that TBR words are stored as higher order episodic units and only elements of the *episodic* as opposed to *semantic* (see Tulving, 1972) higher order unit can access the TBR item. However, Light and Carter-Sobell (1970) reject the notion that their results could be due simply to "the effect of breaking up an encoded adjective-noun unit at recognition [p. 8]." They point out that words were recognized less frequently when a new adjective changed the sense of the noun than when the original adjective was simply deleted, and that recognition was better when the original adjective (e.g., soda *cracker*) was replaced by one that did not drastically alter the semantic interpretation of the target word (graham *cracker*) than when the new adjective did alter the semantic interpretation of the target word in a substantial way (safe *cracker*). Thus, Light and Carter-Sobell interpret their results as evidence that recognition of a word in a verbal learning experiment may involve recognition of the appropriate meaning of the word.

Work by Winograd and Conn (1971) supports the Light and Carter-Sobell (1970) interpretation. Words known to have multiple meanings were presented to *Ss* with no explicit context, that is, no encoding cue. Prior to the main experiment, the relative frequencies of the various interpretations of each word were determined. Recognition for these words was then tested by presenting a word in 1 of 3 ways: (*a*) In a sentence that used a frequent meaning or interpretation of the word; (*b*) in a sentence that used an infrequent meaning of the word; or (*c*) by itself, that is, with no context or meaning imposed by *E*. Homographs tested in a context that utilized their high-frequency meanings and those tested without an imposed context were recognized about equally well, and both were recognized far more often than the homographs forced into an uncommon encoding or meaning. Winograd and Conn concluded that words with multiple meanings are encoded with respect to a specific meaning even though no cue is presented at input and that, in the absence of an experimentally provided context, the most frequent meaning of a word tends to be the one encoded.

It might appear that the Light and Carter-Sobell (1970) and the Winograd and Conn (1971) analyses do not extend to the Tulving and Thomson data because Tulving and Thomson did not use explicit homographs. However, many words in the language that are not explicit homographs still have multiple senses or interpretations. For instance, *water* does not have 2 obviously different meanings, but the sense of *water* when presented with *lake* is somewhat different than the sense of *water* when presented with *drink*. In fact, *Webster's Seventh New Collegiate Dictionary* (1965) lists 8 main senses of the noun *water* and 16 subsenses and 19 sub-subsenses Included are senses unfamiliar to most people and some obscure senses—e g., "a capital stock not representing assets of the issuing company and not backed by earning power [p. 1006]"—that are unrelated to any of the normal senses of the word. It is also certainly the case that there are still other interpretations of the word that are not in the dictionary but are known to some *Ss*. Thus, many words not considered homographs allow multiple semantic interpretations, and a plausible explanation of the Tulving and Thomson data posits that a change in cue words can tap a different sense of the TBR word.

The experiments reported here were designed to test this semantic interpretation of encoding specificity. The basic idea is that words with few senses should be less vulnerable to changes in context in the

Tulving and Thomson paradigm than should words with many senses.

Although the idea behind this research is relatively straightforward, obtaining an adequate, objective measure of the number of senses associated with words is a nontrivial methodological problem. One cannot simply ask *S*s to report how many senses they have for particular words; it is not easy for *S*s to retrieve all the senses they have for a word (MacKay & Bever, 1967), nor is it easy to convince them that subtle distinctions like those associated with *water* are to be regarded as different senses. If it were easy to retrieve all the senses of a word, *S*s would not suffer the difficulties they do in experiments like those of Light and Carter-Sobell (1970).

For other reasons, number of dictionary meanings is also an inadequate measure. Many senses listed in a dictionary are not instantiated in most people's lexicon, while other colloquial and idiosyncratic senses are not in the dictionary. It is also difficult in practice to be consistent in terms of the cutoff point one uses to decide that a dictionary distinction is in fact substantial enough to denote separate senses of a word.

Based on these and other considerations, word frequency was chosen as the index of number of word senses. Words of very low frequency (less than 9/1,000,000 in Kučera & Francis, 1967) were contrasted with words of moderate to high frequency (more than 50/1,000,000). Generally, low-frequency words (e.g., hippopotamus, aspirin) tend to have only one sense. This phenomenon is probably attributable to there being little opportunity for multiple senses to differentiate and be maintained. It may also reflect the fact that words with one unique sense are appropriate to only a few situations and as a result have low frequency of occurrence. Therefore, word frequency is a fairly sensitive correlate of number of senses instantiated in the typical *S*. Schnorr and Atkinson (1970) found a strong positive correlation between word frequency and number of dictionary meanings, as did we for the words used in the experiments reported here, $r = .61$; $t\ (118) = 8.3$, $p < .001$.[3] Both word frequency and number of dictionary meanings are undoubtedly imperfect reflectors of number of senses, but frequency seems to provide a somewhat more satisfactory and objective basis on which to partition words into those having few or many senses. Later in this report frequency and number of dictionary meanings are compared in terms of their ability to predict memory performance.

Experiment I

Method

Design and procedure. Four lists of 30 TBR words, 15 high frequency and 15 low frequency, were presented by slide projector at a 3.5-sec. rate to *S*s for study and subsequent recall. Each TBR word was initially paired with a weakly associated cue; the TBR word was shown in uppercase letters directly below the cue word, which was shown in lowercase letters. After presentation of 30 pairs, 10 of the TBR words were tested in each of the 3 following conditions: (*a*) The *S* saw the original weakly associated input cue and was asked to recall the TBR word that appeared with it; (*b*) *S* saw a new cue strongly associated with a TBR word and was asked to use it to help him think of a TBR word from the last list; or (*c*) *S* received no cue for the word and was simply asked to try to recall the item from memory. Within each list, the 2 levels of word frequency were crossed with the 3 types of output conditions. There were 5 words in each Frequency × Output combination. Three different sets of recall sheets were used for each list so that, across *S*s, all words appeared in all output conditions. Each set consisted of 2 recall sheets, one for cued recall and one for the recall of words for which no probe or cue was given. The sheet for cued recall was presented before the free-recall sheet for half of the *S*s and after the free-recall for the other *S*s. The *S*s had as much time as they wanted for both uncued and cued recall. When uncued recall preceded cued recall, *S*s were asked to recall all the TBR words; when uncued recall followed cued recall, *S*s were told that they only needed to recall those words from the list that they had not recalled on the cued-recall sheet, but that they need not worry about duplications.

The word presentation order within a list and the order of the cue words on the cued-recall

[3] We had a group of *S*s rate all the words in our experiments for number of different meanings they could think of for each word. The *S*s were only able to generate a mean of 1.93 meanings per word whereas Webster's dictionary has 8.83 meanings. The number of generated meanings correlates .64 with frequency and .67 with number of dictionary meanings.

sheets were randomly determined but were held constant across *S*s. Half of the 20 cues were asterisked to indicate that they were new cue words. The various recall sheets and the order of list presentation were counterbalanced over *S*s. Two priming lists, which were not scored, preceded the 4 lists of interest. The priming lists, composed of medium-frequency words, were tested at recall with their original input cues. The purpose of the priming lists was to induce *S*s to encode the TBR word with respect to the original cue presented; *S*s were not informed that the priming lists were practice lists. Forty-eight paid *S*s at the University of Michigan were tested in groups of 1–7.

Materials. All TBR words were nouns judged to be high in both meaningfulness and imagery. Items were selected from norms of frequency of words in print (Kučera & Francis, 1967); the high-frequency words came from the upper third of the rank ordering in frequency, and the low-frequency words came from the bottom third; words in the priming lists were taken from the middle range. (The high-frequency words all had A or AA Thorndike & Lorge, 1944, ratings, and the low-frequency words averaged 6.7/1,000,000 in the Thorndike and Lorge count.) Those nouns selected that were included in Paivio, Yuille, and Madigan's (1968) rating of meaningfulness and imagery of nouns received scores that confirmed the subjective criterion for high imagery and concreteness: They all were above 6 on the two 7-point scales. Thomson and Tulving (1970) constructed their lists of TBR words by selecting response words from free-association norms in which each TBR word occurred twice in the norms: once as a high-frequency response to a *strong cue* stimulus word and once as a low-frequency response to a different *weak cue* stimulus word. Association norms could not be used to select the cues for this experiment due to the difficulty of finding norms that contain low-frequency nouns as responses to other words, particularly as strong associates.

Because of these inherent difficulties, strong and weak cues were generated according to intuitive criteria. That is, the strong cues seemed likely to elicit the TBR words frequently, the weak cues infrequently. The fact that the cues were constructed in an informal manner does not seem a serious problem in methodology. The basic requirement is simply that the strong cues for low-frequency words are not more effective than strong cues for high-frequency words. This requirement is important because the predicted results (namely, that recall of low-frequency words with their new, strong cues will be superior to recall of high-frequency words with their new, strong cues) might otherwise be an artifact of prior strength. Five colleagues, naive with respect to the study, gave free associations to each of the strong cues used in the experiment. High-frequency TBR words were generated as free associates to the strong cues 24% of the time; low-frequency TBR words were generated only 12% of the time.

TABLE 1

Proportions of High- and Low-Frequency To-Be-Remembered Words Recalled on Tests of Cued and Free Recall

Word frequency	Cued recall		Free recall
	Strong extralist cue	Weak within-lists cue	
Cued recall before free recall			
High	.31	.69	.04
Low	.64	.72	.05
Cued recall after free recall			
High	.36	.63	.12
Low	.59	.69	.14

The other cue-construction requirement used by Thomson and Tulving (1970) is that the strong and weak cues for a given TBR word should not be associatively related. This requirement was impossible to maintain with low-frequency words. For 2 words to be both associatively related to a third word and yet not be associatively related themselves tends to require that the third word have more than one interpretation, and low-frequency words often do not. The only requirement in the current experiment was that no 2 cues to a given word be synonyms.

Results and Discussion

In Table 1, recall probabilities are shown as a function of type of test, order of tests, and TBR word frequency. The statistical analyses reported in this section were carried out on arc sine transformations of the proportions in Table 1.

Cued recall. Since performance on tests of cued recall was not sensitive to testing order, F (1, 46) = 1.2, the other statistical analyses of the cued-recall data were carried out on the pooled data. The result of greatest interest in this experiment, that is, the frequency by cue (strong vs. weak) interaction, was highly significant, F (1, 46) = 18.3, $p < .001$, with performance in the high-frequency strong-cue condition much worse than performance in the other conditions. For high-frequency words, strong extralist associates were much less effective as recall cues than were weak intralist associates, F (1, 46) = 77.44, $p < .001$. In the case of low-frequency words, there is a smaller but still signifi-

cant advantage in the same direction, $F(1, 46) = 7.56$, $p < .01$. The latter result is not too surprising since low-frequency words are sometimes polysemous, and in such cases a change of cue would have adverse effects.

In order to rule out the possibility that the foregoing results might be attributable, in part, to item selection (cf. Clark, 1973), the data were also analyzed by collapsing over *S*s and treating words as the random effect. The Critical Frequency × Cue interaction was still highly significant, $F(1, 118) = 13.51$, $p < .001$. Even with both significant *F*s, however, the results may still be colored by *S*–item selection. Clark prescribes the use of a *min F′* statistic, $(F_1F_2)/(F_1 + F_2)$, a conservative test, the significance of which guarantees generalizability of a result over *S*s and items. The *min F′* statistic is significant for both the Frequency × Cue interaction, $F'(1, 149) = 7.77$, $p < .01$, and for the effect of weak vs. strong cues for high-frequency words, $F'(1, 135) = 37.91$, $p < .001$. On the basis of this more conservative test, however, the effect of weak vs. strong cues was not significant for low-frequency words, $F'(1, 142) = 3.45$.

Free recall. The results of the free-recall test in Experiment I are relatively straightforward. Overall, *S*s were a great deal less likely to free recall the 10 TBR words not tested on the cued-recall sheets than they were to recall TBR words in response to either type of cue. In contrast to the cued-recall performance, there was a distinct effect of test order, $F(1, 46) = 41.9$, $p < .001$. The test of cued recall appears to have provided substantial interference with subsequent free recall of TBR words not tested during the cued recall, whereas cued recall was independent of whether there was or was not a prior free recall.

Experiment II

Our interpretation of the context effects on cued recall in Experiment I involves a generation–recognition model for recall (see Anderson & Bower, 1972; Bahrick, 1969; Kintsch, 1970). However, the model we have in mind, unlike the prior generation–recognition models, assumes that *S* does not recognize the words per se, but rather, semantic interpretations of these words. The *S* implicitly generates words and attempts to recognize their senses. If he recognizes the senses as being from the TBR list, then he recalls the corresponding word. The difficulty caused by a change in context is attributable to the recognition phase of recall; *S* can generate the TBR word to the strong cue but he cannot recognize it because he assigns a different interpretation to it than he assigned when the word was paired with the weak cue. In Experiment II, *S*s were instructed to generate free associations to strong cues, and then to recognize if any of the associates were TBR words. If the difficulty of recalling high-frequency words to new, strong cues results from difficulties in generation, then new, strong cues should have a greater propensity to elicit their low-frequency TBR words than would the corresponding new, strong cues to their high-frequency TBR words. However, we expected this not to be the case. Rather, we expected that high-frequency TBR words, when generated to the cues, would not be recognized as well as low-frequency TBR words.

Method

Subjects. Thirty undergraduates at the University of Michigan participated as paid *S*s. The *S*s were tested in groups of approximately 5.

Materials and apparatus. Four of the 6 lists used in Experiment I were used in Experiment II—the same 2 priming lists and 2 of the 4 critical lists. Each list consisted of 30 TBR words, again the priming lists being all medium-frequency words, while the critical lists were half high-frequency words and half low-frequency words. All words in each list were paired with a weak cue. Each list was presented by means of a Kodak Carousel slide projector.

Procedure and design. The 2 priming lists preceded the 2 critical lists. The procedure followed and the reason for including the priming lists in the design were the same as in Experiment I.

After presentation of the first of the 2 critical lists, there was the following sequence of events.

1. The *S*s were first given a sheet of paper with 30 strong extralist cues listed in a column on the left-hand side of the sheet. They were asked to generate exactly 4 free associates to each strong cue. It was pointed out to *S*s that their

free associates to a given cue might contain a TBR word from the preceding list. They were asked to circle any such words they generated.

2. After the free-association and recognition tasks, *Ss* were given a 4-alternative forced-choice (4-AFC) recognition test consisting of 30 sets of 4 words, each set containing 1 of the 30 TBR words presented in the first critical list. The 3 distractor words in each set were drawn from words generated by several individuals asked to free associate to word pairs consisting of a TBR word and its strong cue. The distractors were selected to have about the same frequency as the TBR word.

3. Finally, in order to motivate *Ss* to attend to the weak within-list cues presented in the second critical list, there was a test of cued recall involving the weak within-list cues used in the first critical list.

The presentation of the second critical list was followed by the same sequence of events, except that when *Ss* free associated, they were asked to think of as many meanings as possible for each word generated. That is, *Ss* were asked to generate 4 words to the cue, but then to try to examine each of these words for meanings not related to the cue that elicited them. This instructional manipulation was motivated by the idea that it might reduce the inhibiting effect of the semantic context induced by the strong cue on the recognition of TBR words generated by *Ss*.

Results

The data from Experiment II are presented in Table 2. The effect of instructions, i.e., to think of multiple senses of the generated words during the free-association task, was insignificant with respect to all 3 dependent variables so the data are pooled over the 2 critical lists.

As expected, the probability of generating a high-frequency word to the new, strong cue was not lower than that for a low-frequency word; if anything the reverse was true: High-frequency TBR words were generated with probability .59 to their respective cues, and low-frequency TBR words were generated with probability .55 to their strong cues. The probability that a low-frequency TBR word was recognized (.84), however, given that it was generated during the free-association task, was more than twice the probability that a high-frequency word was recognized (.38) given it was generated. The probability of recognizing low-frequency TBR words in the 4-AFC

TABLE 2

Recognition and Cued Recall Probabilities as a Function of Test Type and Word Frequency

Word frequency	Type of test: Generation-recognition	4-AFC recognition	Cued recall
High	.38 (.59)	.72	.61
Low	.84 (.55)	.85	.71

Note. The values in parentheses are the probabilities that a to-be-remembered word was generated in the free-association task. Abbreviation: 4-AFC = 4-alternative forced-choice recognition test.

recognition test (.85) was also higher than the recognition of high-frequency words (.72), although the difference was much smaller.

The recognition proportions for individual *Ss* were converted via the arc sine transformation and the transformed scores were subjected to an analysis of variance with the independent variables being word frequency and method of test. The Frequency × Test Type interaction was highly significant, $F\ (1, 29) = 30.34$, $p < .001$, as was the difference between recognition of *S*-generated high- and low-frequency TBR words, $F\ (1, 29) = 117.56$, $p < .001$, and the difference between the recognition of high- and low-frequency TBR words on the 4-AFC test was also significant, $F\ (1, 29) = 9.39$, $p < .01$. Again, in consideration of possible selection artifacts, *min F′*s were computed for the Frequency × Type of Recognition Test interaction, $F'\ (1, 73) = 16.25$, $p < .001$, the difference between recognition of high- and low-frequency generated TBR words, $F'\ (1, 87) = 41.93$, $p < .001$, and the difference between frequency levels in the 4-AFC, $F'\ (1, 50) = 7.02$, $p < .025$.

The fact that the discrepancy between the recognition of high- and low-frequency TBR words is less on the 4-AFC test than it is for the recognition of *S*-generated TBR words is probably attributable to differential effectiveness of the context induced by the test. The meanings of *S*-generated TBR words are clearly determined by the strong cue from which they are generated. However, in the 4-AFC test, *Ss* seemed better able to judge

a word without regard to the other alternatives. Since the strong cue was not actually present on the 4-AFC test, it was, presumably, easier to think of the word with a meaning different from that imposed by the strong cue and more like that imposed by the original cue. Tulving and Thomson (1973) also found improved recognition of TBR words when the alternatives in the 4-AFC test were not generated by the S[4] to the strong extralist cue.

Recall to the original cues yielded results very similar to the corresponding conditions in Experiment I: The cued recall probability for high-frequency words was .61 and the corresponding probability for low-frequency words was .71.

General Discussion

The present results necessitate some refinement and clarification of Tulving and Thomson's (1973) Encoding Specificity Principle. It seems plausible, at least for retention intervals on the order of those in the present paradigm, that what is recognized in a recognition test is a particular sense of a word rather than phonemic or orthographic information. A cue may generate the same word presented earlier, but if the semantic interpretation imposed by the cue in this generation process is different from the meaning originally encoded, the word is unlikely to be recognized or recalled. It may be that if the word is tested after a brief retention interval, then phonemic cues will improve recognition. However, in experiments such as these in which Ss must use long-term memory at testing, the information retrieved would probably be a sense of the word, not its spelling pattern or phonemic characteristics per se. Past studies have shown that long-term memory confusions are semantic in nature rather than acoustic as they are in short-term memory (e.g., Craik, 1968). Furthermore, since the relation between a TBR word and its cue is a semantic one, it is even more likely in cuing experiments than in other experiments that an S would tend to the meaning of the TBR word.

Tulving and Thomson (1973) assert that the generation–recognition models for recall (Anderson & Bower, 1972; Bahrick, 1969; Kintsch, 1968, 1970) are incompatible with the findings that support their Encoding Specificity Principle. They argue that generating a word does not guarantee that it will be recognized (which is the requirement for recall) even though the "event information," as they call it, is *available*. Previous descriptions of the generation–recognition model (e.g., Anderson & Bower, 1972) stipulated that if the TBR item was encoded as occurring in the list, only implicit generation of the appropriate spelling pattern (or phonemic cues) was required for recall. Tulving and Thomson showed that this was not the case. However, if the generation–recognition models are modified by the assumption that word senses are the basis of recognition, then these models become compatible with their principle. Words, per se, are not generated to a cue, but rather senses of a word are generated. The generated meaning must match a meaning encoded during the experimental task before recall can occur.

Effect of Strong versus Weak Cues

We proposed that many words have multiple senses and frequency of the word in print is a good index of how many senses words have for a particular S. Some senses of a word will unavoidably be used and encountered more often than others. A strong cue, as manifested by its high propensity to elicit the TBR words, probably selects a salient sense of the TBR word. On the other hand, weak associations tend to be bizzarre and thus tap less likely interpretations of the TBR words. When S sees a strong cue and generates the TBR word, the sense or interpretation which comes to mind is totally different from the obscure one studied, and S frequently cannot think of all the possible meanings related to a word generated and thus does not "notice" the studied sense. Therefore, it would seem that the more obscure or removed the old interpretation, the less likely that it will be noticed, and consequently, the less likely the word would be recognized.

Tulving and Thomson noted that their theory could not account for the finding that weak input cues paired with strong output

[4] The difference between recognition of words generated by S and recognition of words that were generated by a yoked S was in the same direction as our results although the difference was smaller. The smaller difference may be due to the fact that in their experiment the strong cue words were presented along with the distractors.

cues produced higher recall than strong input cues and weak output cues, as they expected no difference (Thomson & Tulving, 1970). If one assumes, however, that recall requires both generation and recognition, then one should expect better recall when the output cues are strongly associated rather than weakly associated because, in the task of recall, the candidates must be thought of before they can be recognized as words from the list. There is simply a much higher probability of *generating* the TBR word with the strong cue, regardless of the 2 cues' relative effects on recognition. Therefore, one would have to predict that weak input cues with strong recall cues give better performance than the converse.

Given the generation–recognition distinction and the assumption that it is senses that are recognized, the predictions for recognition are the opposite of those made for recall: A TBR word presented with a strong cue and later tested with a weak cue should be better recognized than a word originally presented with a weak cue and later tested with a strong cue. This prediction follows because the TBR word in the presence of a strong associate is not likely to suggest the obscure alternate sense of the word studied during its presentation with a weak cue. On the other hand, if the TBR word were originally presented with a strong cue, a frequent interpretation of the word would be studied. Because this sense is so salient, *S* would be likely to revive that same sense even when the word is presented in the context of a new, weak associate. This prediction was also confirmed in Tulving and Thomson's (1971) data, but no explanation was offered for that outcome.

Thomson (1972) also did not explain a result from one of his recognition experiments in which context was deleted. He found that presenting only 1 of 2 words originally presented as a pair had a less deleterious effect when the original pair had a strong associative relation than when it had a weak one. Also, the most harmful effect on recognition performance occurred on tests of single words initially presented on the right side of weakly associated input pairs. One possible explanation is that strongly related pairs tend to be encoded with the common sense of each word, so if either of the words is presented separately, the original sense is very likely to be noticed. On the other hand, when 2 words are only weakly related, at least 1 of the 2 words must be encoded in terms of a less frequently used sense of the word. It seems reasonable that the first word encountered when reading the pair imposes its dominant sense on the second word (unless, for some reason, a more obvious interpretation employs a common sense of the second and an obscure sense of the first). Thus, it seems plausible that a word on the right in a weakly associated pair would be likely to have an infrequent and unusual meaning encoded, which, in turn, would produce poor subsequent recognition of the word.

Effects of Word Frequency

As stated earlier, we think that word frequency is a better index of the average number of senses of a given word than is number of dictionary meanings. Although the 2 indices are strongly correlated for the words in this experiment ($r = .61$), the frequency measure correlated better with the obtained results. Using the data of Experiment I, a difference score was computed for each TBR word by taking the number of correct recalls to the original weak cue and subtracting the number of correct recalls to the new, strong cue. This difference score correlated .37 with frequency and .17 with number of dictionary meanings. The correlation between number of dictionary meanings and the difference score when frequency was partialed out was $-.06$ and frequency correlated .33 with the difference score when the number of dictionary meanings was partialed out. The first partial correlation is negative and not significant, $t\ (117) = .65$, $p < .60$. The second is significant, $t\ (117) = 3.78$, $p < .001$.

Rubenstein, Garfield, and Millikan (1970) provide incidental support for the notion that high-frequency words are basically quite similar to homographs and that frequency may be a better indicator of number of senses in a person's lexicon than dictionary entries. They administered a task that showed that decisions concerning whether letter strings are words had shorter latencies for homographs than nonhomographs. Their explanation was that homographs have more lexical entries and hence the probability of matching the stimulus with an entry is greater in any period of time, thus making reaction times shorter for homographs. Rubenstein et al. also found a highly significant effect for frequency of the word, high-frequency words being faster than lower frequency words; in fact, in a reanalysis of their data, Clark (1973)

found that the homography effect per se was insignificant, but that the strong frequency effect remained. Neither Rubenstein et al. nor Clark considered the notion that frequency might be a very sensitive measure of the number of meanings for a given word in a particular *S*.

RECALL AND RECOGNITION OF PICTURES BY CHILDREN AS A FUNCTION OF ORGANIZATION AND DISTRACTOR SIMILARITY[1]

JEAN M. MANDLER[2]
University of California, San Diego

NANCY L. STEIN
Washington University

Verbal description, recall, and recognition of complex meaningful pictures by children were studied, varying amount of organization in the stimuli and similarity of distractors. Across *S*s (sex, ethnic group, and grade level), verbal measures were poor predictors of recognition accuracy. Across stimuli, amount recalled and recognition accuracy were both related to amount of organization. Recognition was also a function of the type of transformations on the target that were used as distractors. For all transformations there was a close match between ability to recognize a transformation and judgment of dissimilarity of the transformation to the target. The TORSCA multidimensional scaling technique was applied to the similarity judgments to obtain a representation of a memory space for the targets and their transformations. The structure of this space was highly consistent across *S*s and indicated that transformations on meaningful pictures can be related to each other in stable ways. Location of transformations within the space was related to type of picture and amount of organization in the picture.

Investigators exploring the visual storage systems of both adults and children (Brown & Scott, 1971; Shepard, 1967; Standing, Conezio, & Haber, 1970) have shown that once *S*s are exposed to pictorial material, their ability to recognize previously seen pictures is extremely good. Standing et al. presented 2,560 pictures and found a hit rate for old pictures of .95 or better. Haber (1970) suggested that picture recognition may be essentially unlimited, and has contrasted it with recognition for verbal materials. "Unlimited" is perhaps too strong a term, however, since several variables are known to affect accuracy of picture recognition.

1. Similarity of distractors to target: Recognition of pictures of single objects is directly related to similarity of the distractors, when the latter are scaled along a single "similarity" dimension (Bahrick, Clark, & Bahrick, 1967). When more complex pictures have been studied, however, few experiments have systematically manipulated this variable. Most studies have used a random selection of distractors, chosen from the same modality as the target items (e.g., photographs) but with content uncontrolled. One study which used similar distractors (Dallett, Wilcox, & D'Andrea, 1968) found somewhat lower recognition rates, ranging .69–.85, but no attempt was made to define or scale degree of similarity. Brown and Campione (1972), working with children, studied a single dimension of similarity by using distractors that varied from the targets only in the type of action a central character performed. Immediate recognition averaged around 95%. Thus, for adults, recognition accuracy is affected by similarity of distractors, but there are not enough data to know whether this is as true for children. In addition, little is known about the dimensions along which children scale similarity of remembered pictures to distractor items.

2. Organization of the stimulus materials: Organization of a picture is defined here

[1] This research was supported in part by a grant from the San Diego Unified School District to the authors, and in part by U.S. Public Health Service Grant MH-15828 to the Center for Human Information Processing, University of California, San Diego. Responsibility for authorship is equally shared. We would like to thank George Mandler and participants in a research seminar at University of California, San Diego, for many creative suggestions during the course of this research.

by the relations among its various parts and is equated with the concept of meaning (see Garner, 1962, p. 141). Adults recognize pictures of faces better than inkblots (Goldstein & Chance, 1971), and children recognize meaningful pictures better than abstract or nonsense pictures (Nelson, 1971). However, little is known about the effects of higher levels of organization on recognition, namely, the relationships within a picture among parts that are themselves meaningful, such as are usually found in complex pictures.

It seems likely that judgments of similarity will vary with the amount of organization (i.e., number of meaningful relations among objects) in a picture. There is little information on this problem, yet it seems reasonable to assume that the more information that is organized into a single chunk (or picture) the less likely it is to be confused with another chunk containing an equal amount of different information. Thus, if complex pictures do contain a very large amount of both visual and semantic information, it is probably the case that the pictorial distractors used in experiments such as that of Standing et al. (1970) were grossly dissimilar from the target items. This brings us to the third variable known to affect accuracy of picture recognition.

3. Verbal or semantic information: Several studies have assumed that using pictorial distractors that have the same verbal label as the target pictures will increase distractor similarity and therefore decrease recognition. In 2 studies with children this was not the case; accuracy increased under this condition (Rosinski, 1970).[3] A decrease in recognition accuracy has been reported with adults, however (Bahrick & Boucher, 1968). Further, verbal labels attached to a geometric form have been shown to produce systematic changes in recognition accuracy along a continuum of physical similarity (Daniel, 1972). Clearly, one of the primary problems facing the investigator who is interested in recognition of meaningful pictorial materials by children or adults is the relation of purely visual dimensions, such as size or shape, to the semantic dimensions of pictures. For example, we do not know whether changes in orientation, deletions, or substitutions, affect recognition of meaningful collections of objects in picture form in the same way as they do for geometric shapes.

The present experiment investigated several of these aspects of picture recognition in children. The degree of organization of complex pictures was va[illegible]s well as the similarity of distracto[illegible] Distractors were constructed by [illegible]ing transformations on the original pictures. Two recognition tests were used, one measuring recognition accuracy and th[illegible]r requiring judgments of similarity of t[illegible]ious transformations to the remem[illegible] pictures. Multidimensional scaling techniques were used to construct dimensions of similarity of the various transforma[illegible] to the originals. In addition, verbal description and verbal recall of the pictures were studied.

One further problem was investigated in this experiment. It has frequently been suggested in the literature that black children may have more difficulty in handling pictorial material than white children (Farnham-Diggory, 1970; Pettigrew, 1964; Tyler, 1956). In spite of its widespread currency the hypothesis has never been adequately tested. Most of the studies used to support the hypothesis have contrasted performance on visual and verbal tasks in IQ test batteries. Such test batteries are not well-suited for measuring perceptual functioning, since each subtest usually involves a number of cognitive factors (e.g., Cohen, 1959). The present experiment provided an opportunity to test the hypothesis more directly, since 2 aspects of recognition of pictorial materials were studied, using measures relatively uncontaminated by verbal requirements. For this reason, as well as to insure generality of results, children from black, Chicano, and white (Anglo) ethnic groups were used as *S*s.

Method

Subjects

Because extensive verbal and recognition data were collected, a large number of *S*s was used, each working with only 2 target pictures, rather than a

[3] The second study is an unpublished report by L. R. Brooks written in 1971.

FIGURE 1. Organized and unorganized versions of 2 pictures.

smaller number of *S*s, each viewing many pictures. The *S*s were 168 children from the San Diego Unified School District, divided into groups by sex, ethnic group (black, Chicano, and white), and grade level (Grades 1 and 2). Chronological age in the first grade ranged 6.2–7.1 yr. ($M = 6.75$) and in the second grade, 7.2–8.3 yr. ($M = 7.8$). Almost the entire first and second grade English-speaking classes of one school, located in an upper-lower socioeconomic status area, were used as *S*s. The area was composed of a fairly even mix of the 3 ethnic groups. United States Census Tract data indicated a comparable socioeconomic status for the 3 groups in terms of employment. Median family income in the area was $7,075, with Chicanos having slightly higher income ($7,415) than whites, and blacks slightly lower incomes ($6,680). Median amount of schooling for adults in the area was 11.9 yr. Black adults were above the median (12.3) and Chicano adults slightly below (10.6 yr.). There were not enough black children to complete the sample, and slightly less than half of the second-grade black sample was drawn from another school from a somewhat higher socioeconomic status area, with a higher median family income of $10,150, but the same median schooling for adults of 12.4 yr.

Stimuli

Two sets of 21.6 × 27.9 cm. black-and-white line drawings were used; each set contained one "organized" and one "unorganized" picture. Within a set, the organized and unorganized pictures contained the same objects. In the organized version, a naturalistic scene was created, using familiar relationships among objects. In the unorganized version, the same objects were placed in an unrelated array. Because of some overlapping of objects in the organized pictures, there was more empty space at the edge of the pictures than in the unorganized versions. In the latter pictures there was more space between the objects. It was hoped that this difference would emphasize differences in processing of relationships among objects in the 2 types of picture, but it should be noted that the relationship of this variable to pictorial organization in general has not yet been systematically explored. The 4 pictures are shown in Figure 1.

The pictures were constructed during pilot testing. Easily recognizable objects with a considerable amount of detail were drawn by 2 amateur artists. Final selection was made on the basis that the various objects could fit into a "realistic" scene and that in the pilot group children from the same ages and ethnic groups used in the study could appropriately label all objects and details. A rough attempt was made to equate number of objects in the 2 sets of pictures. However, it is recognized that the pictures vary in a number of ways, such as saliency and location of items, likely focus of attention, etc.

The following 5 transformations were used for each of the pictures:

1. Reversal: A left-right mirror image of the original.

2. Deletion: Three items were deleted from the original, ranging in size from a small detail to a small object. In the bus pictures (see Figure 1), the girl's purse, the chimney on one house, and one of the books were deleted. In the lady pictures, the pendulum of the clock, one of the flowers on the table, and the pair of shoes were deleted.

3. Size change: One item was made larger or smaller. In the bus pictures, the bus was made

50% smaller. In the lady pictures, the vase with flowers was made 50% larger.

4. Rearrangement: The location of one item was changed. In the organized bus picture, the jacket on the hanger was moved from the right to the left of the table; in the unorganized version, the positions of the jacket and the dog were exchanged. In the organized lady picture, the shoes were moved from under the table to the right of the table; in the unorganized version, the positions of the shoes and the car were exchanged.

5. Substitution: One object was replaced by a conceptually similar object. In the bus pictures, the bowl of fruit was replaced by a basket of fruit. In the lady pictures, a different type of clock was used.

Design

The 168 *Ss* were divided into the 3 ethnic groups of 56 *Ss* each. The ethnic groups were further subdivided into equal numbers of boys and girls in the first and second grades. Within each of these 12 groups, each child worked with 2 pictures, an organized picture from one set and an unorganized picture from the other. Order of presentation (organized first or unorganized first; bus first or lady first) was counterbalanced across groups. Presentation order was not a significant variable in any of the analyses and will not be discussed further.

For each of the pictures shown to a child, the following 4 tasks were given in a constant order:

1. Verbal description of the picture while viewing the stimulus.
2. Verbal recall of the picture.
3. *Same–different* recognition test, in which *Ss* were presented with the 5 transformations and the original in a random sequential order. The *Ss* were required to respond to each presentation by saying whether the instance was exactly the *same* as the original or whether it was *different*. If the child responded *different* he was asked to tell how it was different.
4. The paired-comparison recognition test consisted of a 2-alternative forced-choice procedure in which each transformation and the original were paired with all other transformations to make 15 pairs of pictures. The *S* was asked to pick one picture from each pair which looked most like the original picture he had seen and described.

Procedure

Raven's Coloured Progressive Matrices were administered individually by testers of each *S*'s own ethnic group before the experimental procedures began. For this test and the experimental sessions, Chicano *Ss* were given the choice of speaking in English or Spanish. All of them chose to use English, and no language difficulties were observed. Following administration of the Coloured Progressive Matrices, each *S* was tested individually in 2 experimental sessions 1 wk. apart. In each session one target picture was used. At the beginning of the first testing session *S* was told that [illegible] voice would be recorded and that he would be [illegible] to listen to his voice. Then he was told he [illegible] going to see some pictures and that *E* wanted to [illegible] how children looked at pictures and remember [illegible] them. The *Ss* were assured that the testing proce[illegible] had nothing to do with grades or school work [illegible] When *E* felt that some rapport had been gained [illegible] *S* was reasonably relaxed, the experimental p[illegible] dure began.

Description. The *S* was given a practic[illegible] ure which was rich in detail and similar to th[illegible] ermental pictures. The *S* was asked to tell [illegible]y thing he saw in the picture, no matter how [illegible] all the detail, and to leave nothing out. He was [illegible]ed to point to each object or detail as he mentio[illegible] it. If *S* had any difficulty with the describin[illegible] nd pointing procedure, *E* demonstrated what w[illegible] required. The practice picture was kept in fr[illegible] of *S* until he described most of the details i[illegible] he picture.

After this preexperimental procedure, *S* was given the first experimental picture and the de[illegible]ription and pointing instructions were repeated. Presentation time was 3 min. If *S* responded incompletely or stopped too soon, *E* prompted him by asking if he saw anything else. At the end of 3 min., *E* flipped the picture over and talked to *S* for 20 sec.

Recall. The *S* was next asked to recall as many objects and details from the picture as he could remember. When he stopped the first time, *E* prompted him once. If he could not respond, the recall task was ended; otherwise, it continued until he stopped the second time.

Same-Different *task*. Approximately 30 sec after the recall task, *S* was presented with 6 pictures in sequence, 5 of which were transformations of the original picture, and 1 of which was a copy of the original. The *S* was told that he would see 6 pictures, some of which were exactly the same as the picture he had just described and recalled, and some of which were different. If a picture was exactly the same, *S* was to say *same*. If different, *S* was to say *different* and tell exactly how it was different. A different sequential order of pictures was used for each child in a Latin square design.

Paired-comparison task. After a short break of approximately 30 sec., *S* was told he was now going to see pictures 2 at a time. Each time a pair was presented he was to choose the picture which looked most like the original picture he had described and recalled and which was still lying face down on the table. He was told further that if neither picture looked exactly like the original picture he was to choose the one which looked most like the original. The *S* was then presented all combinations of target and transformations, 2 at a time. Presentation sequence was randomly chosen for each *S*.

The second session was identical to the first, except that the practice picture was not presented.

Results

Analysis of variance on the Coloured Progressive Matrices showed that Grade 2

TABLE 1

VERBAL DESCRIPTION AND VERBAL RECALL MEASURES

Variable	Description			Recall

scored higher than Grade 1, F (1, 156) = 19.25, $p < .001$, and males scored higher than females, F (1, 156) = 22.60, $p < .001$. There were no main effects due to ethnic group, but there was a Grade Level × Ethnic Group interaction, F (2, 156) = 8.27, $p < .01$. Newman–Keuls tests showed that black children in the first grade scored lower than the other groups, which did not differ from each other.

Verbal Description and Recall

Verbal description and recall measures are summarized in Table 1. The first column shows the main description score, consisting of the total number of items mentioned (either whole objects or details). Inferential statements (e.g., the girl *is happy*) and relational statements (e.g., the bowl *is on* the table) as well as repetitions were scored separately and not counted in the main description score. These measures are shown in Columns 2 and 3, respectively. Similar analyses were carried out for verbal recall, shown in Columns 4–6. Two other recall measures were computed: the percentage of items in each *S*'s description that also appeared in his recall, and the percentage of items in recall that had not been mentioned in that *S*'s description. These measures are shown in the last 2 columns. Analyses of variance (3 Subject Variables × 2 Stimulus Variables) were carried out on the various verbal measures. Significance levels for the analyses are also shown in Table 1.

Subject variables. (*a*) Grade—there were no main effects on any verbal measure due to grade level. (*b*) Sex—males had higher description and recall scores than females. Interactions with grade level on number of items in description ($p < .05$) and in recall ($p < .01$) showed that this effect was due primarily to the second-grade boys, who described and recalled significantly more than the other groups. (*c*) Ethnic Group—whites both described and recalled more than blacks, who in turn described and recalled more than Chicanos.

Stimulus variables. (*a*) Organization—degree of organization of the pictures did not affect amount of description but did affect amount of recall. Organized pictures produced a greater number of items recalled than unorganized pictures. (*b*) Picture set: The bus pictures produced more items in description than the lady pictures, but there was no significant difference in amount of recall of the 2 kinds of picture.

Number of inferential and relational statements was small in comparison with number of items mentioned, perhaps because of the type of instructions given, and the pointing method of description used. The 2 types of statements were combined into a single measure for purposes of analysis. In general, scores on this measure paralleled the total description and recall scores, males making more inferential and relational comments than females, and Chicanos making fewer than blacks and whites, who did not differ from each other.

Repetition of items occurred fairly frequently in both description and recall. There were no instructions that *S*s should not repeat themselves, but these data may be contrasted with the lack of repetitions, also without instructions, found in adult recall of verbal material (Borges, 1972). There were no significant differences in amount of repetition in description and recall as a function of stimulus variable, and the only *S* variable affecting repetition was ethnic group. Blacks repeated items more than whites, and Chicanos had very low scores on this measure.

There are several ways in which recall might be expressed in relation to description. Column 7 of Table 1 shows the percentage of items described that were also recalled. The mean for the total sample on this measure was 54%, a score high in comparison with immediate recall of well-organized lists of words (Mandler, Pearlstone, & Koopmans, 1969). However, recall can also be represented as a percentage of total number of items described by the *S* pool. It can be argued that the total number of items in a picture is better represented by the "total possible" set of items, rather than the subset actually mentioned by *S*. Such an assumption is bolstered by the finding that an average of 13% of an *S*'s recall score consisted of items not mentioned in his description of the picture. An inventory of all objects and details mentioned by any *S* (excluding different labels for the same items) was constructed for each picture, resulting in a total of 129 items in the lady pictures and 152 items in the bus pictures. Recall, expressed as a percent of this inventory, drops to a mean of 14% correct. Neither of the above procedures seems an entirely satisfactory method of estimating amount of recall; at best the 2 estimates provide upper and lower limits on amount of verbal recall of complex pictures.

Finally, it should be noted that there was a high *S* correlation between number of items mentioned in description and in recall, $r = .73$, $p < .01$. Both verbal measures had a low correlation with Coloured Progressive Matrices, $r = .10$, *ns*, and .16, $p < .05$, respectively.

Same–Different *Recognition Test*

Table 2 shows the proportion of correct recognition of the original picture, each of the transformations, and the total proportion correct. A rough correction for possible response bias in saying same or different was calculated by multiplying overall rate of saying *same* or *different* by actual occurrence of same or different pictures. This method resulted in an estimate of chance probability of a hit on the transformations of .48, and chance probability of a hit on the original of .07. It can be seen from Table 2 that recognition of the substitution transformation was essentially at chance, with size and rearrangement resulting in somewhat higher scores. Recognition was best for deletion, reversal, and the original picture. Overall, probability of correct recognition was .70.

Analyses of variance (3 Subject Variables × 2 Stimulus Variables) were carried out on a total recognition score, consisting of the total number of correct recognitions, and separately on the number correct on each transformation. Significance levels for differences among the various groups are also shown in Table 2.

Subject variables. (*a*) Grade—Grade 2 had a significantly higher total recognition score than Grade 1. This difference was primarily due to Grade 2 having higher scores on the reversal and deletion transformations. Thus, Grade 2 showed superior recognition even though there were no differences between the grades on verbal description or recall. (*b*) Sex—there were no significant differences between total

TABLE 2

Proportion Correct on Original Pictures and Five Transformations in *Same–Different* Recognition Test

Transformations	Original	Substitution	Size	Rearrangement	Deletion	Reversal	Total
Total (N = 336)	.89	.49	.58	.59	.77	.91	.70

*** Group values differ significantly, $p < .001$.

correct or on any transformation between males and females. Again, this result may be constrasted with the results on the verbal measures, in which males showed higher description and recall scores. (*c*) Ethnic group—there were no significant differences in total number correct. This result may also be contrasted with the differences found among ethnic groups on description and recall. The only significant difference in recognition occurred on the reversal transformation, on which blacks were slightly less accurate. A Grade × Ethnic Group interaction on this transformation ($p < .01$) indicated that the difference in recognition occured only in the first grade. Lower scores on the Progressive Matrices were also found for the first-grade black sample. Although this test is usually used as a nonverbal IQ test, it has a strong spatial component.

For all 3 S variables, verbal description and recall measures were poor predictors of accuracy of recognition. An S correlation between number of items described and total correct recognition resulted in $r = .21$, $p < .01$, and between number of items recalled and total correct recognition, $r = .25$, $p < .01$. The correlation between Coloured Progressive Matrices and total correct recognition was .16, $p < .05$.

Stimulus variables. (*a*) Organization—total correct recognition was significantly higher for organized pictures. The main transformations involved in this difference were rearrangement and size. These 2 transformations are most directly relevant to the degree of organization of a picture as it has been defined here, namely, as the number of meaningful relationships among the items in the picture. Both the rearrangement and size transformations involve a change in relationships among objects, and these changes were better recognized in the more organized pictures.

The other major difference occurred on the deletion transformation. Deletion of detail was better recognized in the unorganized pictures. Since there were no meaningful relationships among the objects in the unorganized pictures, it is possible that more attention was paid to details of the objects represented. In the organized pictures, on the other hand, more processing of relationships among objects took place. This does not appear to be a question of how Ss spent a limited processing time, since presentation of each picture lasted 3 min., but rather a question of what aspects of the organized and unorganized pictures tended to be coded for storage. When a deletion transformation was recog-

nized as different, on the average only 1 of the 3 deleted items was mentioned; in almost all cases this was the book in the bus pictures and the shoes in the lady pictures. In both cases these items were the largest of the 3 deletions. Apparently the 2 small deletions of detail were rarely noticed, although more often in the unorganized pictures.

(*b*) Picture set—The lady pictures were recognized significantly more often than the bus pictures. It will be recalled that the lady pictures contained less information, in the sense that they produced less verbal description and had a smaller total inventory of items. Although it has been assumed that high information pictures are easy to recognize because distractors tend to be very different, when distractors consist of small changes on the target pictures it is possible that recognition is hindered by a greater amount of information. Amount of information would have to be systematically varied to test this hypothesis.

There were significant interactions between the set and organization variables on the substitution, rearrangement, and size transformations. These differences appeared to reflect uncontrolled differences in saliency of various objects in the different pictures, perhaps in part as a function of their location in the picture as well as degree of organization in the picture as a whole. Since parametric variation in transformations of objects was not carried out in this experiment, no assessment of relative importance of, for example, size changes vs. substitutions, in recognition of meaningful pictures in general can be made at this time. It is likely, in fact, that accuracy of recognition of any given transformation can be systematically varied by manipulating the saliency of the object which is transformed and the extent of the transformation (e.g., amount of size change, number of rearrangements, etc.).

Concerning the relationship between verbal recall and recognition as a function of stimulus variables, only degree of organization affected both measures. More was recalled about the organized pictures, and they were better recognized. These differences in memory were not, however, related to number of words used to describe these types of picture.

Paired-Comparison Test

The *same-different* test showed which transformations were most difficult to recognize, i.e., which were more similar to or confusable with the original picture. The question then becomes whether it is possible to scale distances along a dissimilarity dimension(s) to aid our understanding of the structure of what is stored in memory. If it is assumed that memory for pictures can be represented as a multidimensional Euclidean space, and that the judged degree of similarity of any transformation to the original or to other transformations is inversely related to distances within that space, then the paired-comparison test can be used to estimate where in that space each transformation of the original picture is located.[4]

The mean percent times that the original and each transformation was chosen in comparison with every other was computed separately for the various groups and converted to d' scores (a measure of discriminability). Thus, matrices of d' scores were formed from the 15 paired comparisons of each original picture and its 5 transformations. These matrices give an estimate of the distance each transformation is from each other and from the original in the hypothetical memory space. To the extent that the original can be considered as an anchor point in the space (since each paired comparison was made on the basis of similarity to the original), the distances from the original to the transformations can also be considered a measure of distortion of the original by the particular transformation made.

Independent matrices, each based on 168 observations, were constructed for the 2 sets of original pictures, for the organized and unorganized versions of the pictures,

[4] An example of a similar type of analysis used to explore the structure of semantic, rather than pictorial, space can be found in Henley (1969), and for discriminability of letterlike forms in Harrington and Brown (1972).

and for Grades 1 and 2. Matrices for the 3 ethnic groups were based on 112 observations each. The breakdown by sex was not included because of the lack of differences found on the *same–different* test. Each of the matrices was analyzed separately by the TORSCA multidimensional scaling program (Young & Torgerson, 1967).

The Kruskal stress index for each analysis (giving an estimate of goodness of fit of the various points in a given number of dimensions) for 1- and 2-dimensional solutions, as well as percentage of variance accounted for by the dimensions are shown in Table 3. In all cases except the Chicano group, the 2-dimensional solution gave close to perfect fit (stress varying .01%–.6%), and even in the Chicano group the fit was excellent (1.6%). For the 1-dimensional solutions, stress varied .01%–10.4%. Since only 6 items were being compared, the excellent fit in 2 dimensions might have occurred by chance, although the high degree of similarity among solutions obtained from independent groups of *S*s and between different pictures makes such a possibility unlikely. Based on Klahr's (1969) analyses, the probability of obtaining by chance stress indices as low as those in the 1-dimensional solutions is less than .05 in each case.

The 1-dimensional solutions were highly similar to the first dimension of the 2-dimensional solutions, presumably because in both cases one dimension accounted for most of the variance. Although the 1-dimensional solutions were adequate descriptions of the data, the 2-dimensional solutions are presented here because they give a clearer picture of the data, and because work in progress with adults suggests that 2-dimensional solutions will be necessary. Figure 2 shows the solutions obtained from the various subgroups. For each breakdown the groups being compared are shown in the same space, although they were derived independently. Inspection of Figure 2 shows that in all cases original is located at one end of the main dimension, and that reversal is located at the greatest distance from the original, with deletion the next farthest from the original. The other 3 transformations are located in between, show the most overlap, and the most movement from analysis to analysis. No attempt was made to conceptualize the second dimension since it accounted for relatively little of the variance, although in all cases deletion was at one end of the dimension and rearrangement at the other.

TABLE 3

PERCENT STRESS AND PERCENTAGE OF VARIANCE ACCOUNTED FOR BY EACH DIMENSION IN ONE- AND TWO-DIMENSIONAL SOLUTIONS

Variable	Solution: Two-dimensional: Stress	Two-dimensional: Variance: First dimension	Two-dimensional: Variance: Second dimension	One-dimensional: Stress	One-dimensional: Variance
Set					
Lady	.01	79.8	20.2	.01	100.0

Chicano	1.61	89.5	8.2	6.67	92.2

Panel 1 shows the comparison between the 2 types of original picture. There should be a close correspondence between these 2 TORSCA analyses if we wish to conclude that the pictorial memory space thus constructed is general and not idiosyncratic to a particular picture. Looking at Panel 1 we can see that original, reversal, and deletion occupy roughly the same spaces. The greatest change from one picture to the other occurs on size and rearrangement, followed by substitution. Comparing the movement of these 3 transformations (toward or away from the original as a different picture is used) with the proportion of correct recognition for these transformations in the *same–different* test, shown in Table 2, we can see that in each case in which a transformation was

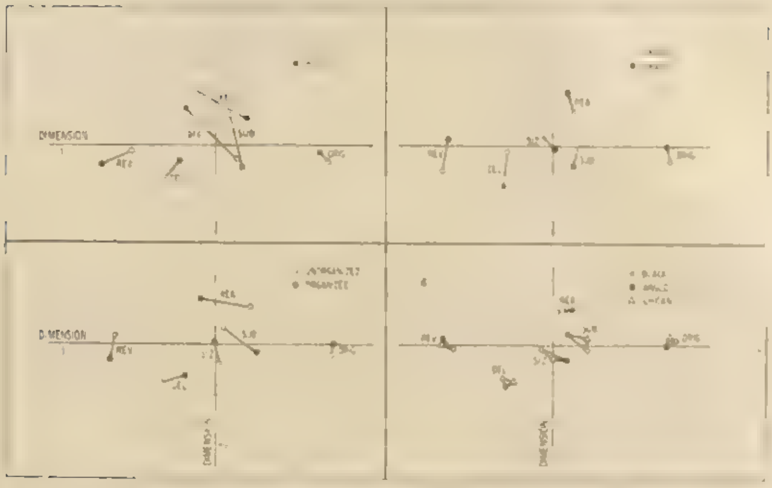

FIGURE 2. Two-dimensional TORSCA multidimensional scaling analyses derived from independent groups of Ss and different types of stimuli. (Panel 1 compares the 2 types of picture, Panel 2 compares organized vs. unorganized versions of the pictures, Panel 3 compares 2 grade levels, and Panel 4 compares 3 ethnic groups. Stress indices are given in Table 3. Abbreviations: REA = rearrangement, SIZ = size, SUB = substitution, REV = reversal, DEL = deletion, and ORIG = original.)

recognized less well it is closer to the original in the TORSCA analyses. As mentioned above, these 3 transformations seem to have different effects on recognition depending upon the saliency and location of the particular item transformed in a given picture.

Turning to the effects of organization, Panel 2 indicates that the rearrangement transformation was most affected by differences in degree of organization. Rearrangement was less frequently recognized in the unorganized pictures in the *same–different* test, and in the paired-comparison test this transformation was judged to be closer to the original in the unorganized pictures. Thus, there is good agreement between the 2 tests on the greater importance of relationships among objects in organized pictures.

Comparisons between Grades 1 and 2 are shown in Panel 3. They are very similar to each other on the first dimension. The first graders in fact show essentially a 1-dimensional solution, while the second graders' scores have begun to move into the second dimension. Although current work with adults indicates that the second dimension accounts for a still greater part of the variance, more work [illegible] led to conclude that there is a d[illegible]ntal difference in complexity of pictori[illegible]emory space.

Panel 4 shows comparisons among the 3 ethnic groups. The chief conclusion is that the pictorial memory space is highly similar for the 3 groups. This result confirms the lack of difference among ethnic groups on the *same–different* test.

Overall, there was excellent agreement between the 2 types of recognition test. The advantage of the paired-comparison test is that it gives a more detailed picture of differences between the original and the transformations. In addition it eliminates response biases such as the tendency to say *same* or *different* to most pictures, a factor which might well vary among Ss of different ages. Although a left- or right-choice bias could exist in the paired-comparison test, analyses of the number of times Ss chose the left or right picture indicated that no such bias was operating.

Because the 2 recognition tests were given in a constant order, it is possible that performance on the *same–different* test influenced choices on the paired-comparison test. For example, if an S correctly recog-

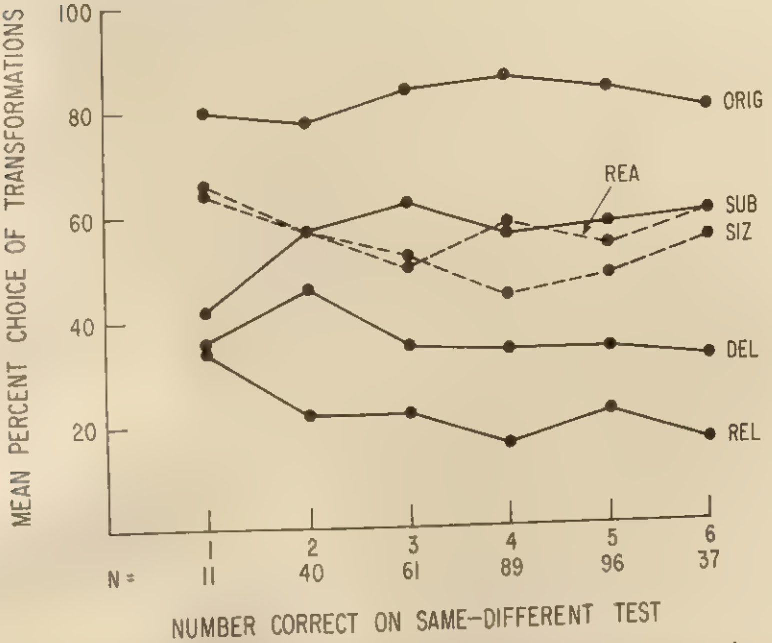

FIGURE 3. Percent choice of each transformation in the paired-comparison test plotted as a function of number of correct responses on the *same–different* test. (Number of *Ss* involved in each point is shown below the abscissa.)

nized a transformation as different, he might be less likely to choose it in the paired-comparison test. To check on this possibility, percent choice of each transformation in the paired-comparison test was plotted as a function of the number of correct responses on the *same–different* test. Two *Ss* who made 6 out of 6 errors on the *same–different* test were excluded from this analysis. The remaining *Ss*, grouped according to number correct, are shown in Figure 3. It can be seen that performance on the paired-comparison test did not differ as a function of accuracy on the *same–different* test, indicating at least some degree of independence of the 2 tasks.

Discussion

The present data offer little support for a conception of unlimited pictorial recognition. In spite of long presentation times, overall recognition rate was fairly low (70%) and varied from chance responding to 91% correct depending upon the nature of the distractor. The distractors used in this experiment consisted of transformations on the original pictures and thus were similar to the target pictures. Conflicting results have been reported when similar distractors have been used, some studies finding lower recognition rates, some not. The question then becomes how to define and scale similarity of complex pictures which contain many visual and semantic dimensions.

The multidimensional scaling method used in this experiment appears to be a useful technique for scaling the similarity of distractors to the picture stored in memory, and in addition to discover which aspects of pictures are most likely to be retained. Not only were transformations on the target pictures stably located in a memory space, but changes within that space were related to type of picture and the degree of organization within pictures. For example, the judged similarity of a given distractor differed as a function of amount of organization in the stimulus materials.

There was a very close correspondence between the 2 types of recognition tests, even though they asked for different judgments. In the *same–different* test, *S* was asked whether he had seen a picture before, and in the paired-comparison test he was required to make a similarity judgment. Although it has been assumed here that similarity of distractor to

target is a major factor in recognition accuracy, it should be pointed out that this assumption needs further testing. In the first place, similarity judgments may differ when they are made in the presence of the target items than when they are made about remembered targets. Second, it could be the case that reversal of a picture, for example, is easy to recognize as different yet be judged most similar to the original on the grounds that all the relationships among the objects are the same. The fact that recognition and similarity judgments were highly correlated for children does not necessarily mean that the same relationships will hold for adults. This problem is currently being investigated.

Although the present data do not allow an assessment of the relative importance of various transformations in recognition of pictures in general, the results for 2 of the transformations should be mentioned. Two transformations were consistently recognized across pictures and also judged as most dissimilar, namely, reversal and deletion of detail. Although experiments with adult *S*s have typically found only slight loss in recognition accuracy when reversals were used (Dallett et al., 1968; Standing et al., 1970), the .91 rate of recognition of reversals in this experiment seems surprising in light of a number of studies showing that children have difficulty in discriminating among reversals of pictorial geometric forms (e.g., Rudel & Teuber, 1963) Ease in recognizing reversals in more complex pictures may be a function of the total number of items whose location is changed. In the present experiment, reversal involved a greater number of locational changes than any other transformation. On the other hand, recognition of reversals may be a function of the meaningfulness of the material used. Current work is being done to evaluate these possibilities.

The other transformation most consistently recognized as different was deletion of detail. This result is consistent with experiments reported by Vurpillot (1972), showing that children of age 7 are better at detecting differences in detail in meaningful pictures than size changes or rearrangement. On the other hand, her experiments indicated that children of this age are also good at detecting small substitutions, a result at variance with the present data. It should be pointed out, however, that it is difficult to compare results on transformations from different studies because of the lack of appropriate scaling of the magnitude of the changes involved. In addition, Vurpillot's work, like that of Gibson, Gibson, Pick, and Osser (1962), involved detection of differences in a matching-to-sample task. Little is known about attentional or search patterns in detection vs. memory tasks, or whether the differences easiest to detect are those which are most often retained in memory.

Concerning the relationship between verbal measures and recognition in the present experiment, for the *S* variables, verbal measures were poor predictors of accuracy of recognition. This finding is of particular interest in light of the heavy verbal loading found in the test batteries most frequently used to assess perceptual functioning in minority children. In the present study, black and Chicano children said less than white children, but the volume of words bore no relation to the visual recognition measures. In terms of accuracy of recognition, responsiveness to the organization of the pictorial materials, and types of mistakes made on transformations, the 3 ethnic groups were highly similar. The multidimensional scaling of the similarity judgments produced a pattern of responding that was virtually identical for the 3 ethnic groups

The stimulus variables showed 2 types of relationship between verbal and visual measures. The pictures that contained more information (had a higher inventory of items) called forth more words in description and were also more difficult to recognize. Thus, there was a negative relationship between amount contained in a picture and amount remembered. On the other hand, the organized and unorganized versions of the pictures, which contained equal numbers of items and called forth the same number of words in description, nevertheless showed differences in both recall and recognition as a function of degree of organization. Thus, amount of organizational or structural information showed a positive relationship with amount remembered. It should be noted that an hypothesis that equates amount of organization with number of words used in description, such as the verbal-loop hypothesis (Glanzer & Clark, 1964), is not a useful equation in the type of pictorial recognition studied in this experiment.

In summary, the data of this study indicate that children are responsive to the organization of pictorial materials and that the nature of the stored representations reflects the amount of organization in the material viewed. There was little verbal indication of such responsiveness; that is, very few comments

were made in description or recall about relationships among the objects in the pictures, nor were more or different words used to describe organized scenes than unorganized scenes. However, information about relationships among the objects in the organized scenes was processed and retained for storage. When unorganized pictures were presented, which did not include meaningful relationships among the objects, other types of information, such as characteristics of small items, were processed and retained. Although we are still far from being able to specify the nature of the stored representations of pictorial material, the results of the multidimensional scaling technique suggest that useful models of memory representations can be constructed that will contribute to the development of a theory of pictorial memory.

INSTRUCTIONAL CONTROL OF SERIAL-LEARNING STRATEGIES[1]

WESLEY A. KAYSON[2]
Iona College

WILMA A. WINNICK
Queens College, City University of New York

Two sets of instructions were used in a serial-learning task to induce one group to form sequential associations and a second to use the position strategy. Performance was contrasted with control groups, and half of the *S*s in each of the 3 groups learned lists of high-association trigrams, with the other half learning low-association lists. Examination of the latencies with which responded, after learning, with the trigram that followed the presented or with the trigram at the serial position presented provided evidence that instructed groups had used the suggested strategies, but gave no indication of the consistent use of either strategy by control *S*s. Analysis of the error data found a significant effect of instruction, with positional instruction superior, and a significant interaction between instructions and association value, with position instructions highly effective for the low-association list

Recent attempts to delineate the effective stimulus underlying serial verbal learning have focused upon 3 possible cues for the anticipatory response required in learning of this type: (*a*) the immediately preceding item, (*b*) a combination of 2 or more preceding items (an elaboration of the first), or (*c*) the identification of the ordinal position of the item. Young (1962) has viewed these as possible hypotheses that *S* might adopt in serial learning (SL).

Most attempts to identify the stimulus in serial learning have proceeded by utilizing transfer techniques to seek out indications of the cues used in serial learning. In such studies, learning of a serial list is typically followed by a second learning task, the aim of which is to detect the indicators of the cues used in SL. Thus, the amount of transfer has been assessed from the learning of one serial list to the learning of a second list in which the items from the original list occupy the same or different positions; this technique was used by Young (1962) to evaluate the positional hypothesis. More commonly used is transfer from SL to paired-associate learning (PAL) where, for example, items that were contiguous in previous SL are used to form pairs for PAL: learning of such items is compared with the learning of items that had not been in sequence in SL (Young, 1962). In another variation of the transfer technique, SL is the second task, and the first learning encourages or suggests cues (usually positional) that might aid or hinder subsequent SL. In a test of the efficacy of the positional cue, Ebenholtz (1963) studied transfer from PAL, where spatial position cues were paired with verbal items, to SL, in which items occupied the same or different spatial positions. In another PAL–SL transfer study, Winnick and Dornbush (1968) followed PAL, in which syllables were either in the positions indicated by the numerals or in other positions. These experiments and others summarized by Young (1968) lead one to agree with Young that the issue of effective stimulus for serial learning has not yet been resolved.

The present study proposed to view the cues mentioned as providing the basis for a plan or strategy of learning that might be consciously chosen by *S*, suggested by the experimental materials, or dictated by the instructions employed in the experiment. In contrast with previous studies—most of which have searched, after learning has taken place, for evidence indicating the use of one or the other of these cues—the present study has attempted, by the instructions used, to induce *S*s to employ one or the other cue as a strategy for the learning of the serial list.

---

[1] This article is based upon Experiment I of a dissertation submitted by the first author in June 1970 to the City University of New York in partial fulfillment of the requirements for the PhD degree.

In an attempt to determine the relative effectiveness of such strategies, the present study has used instructions to suggest the strategy of tying successive items together (Young's 1962 serial hypothesis) or of identifying the ordinal position of the items (the positional hypothesis). The possibility that the effectiveness of a particular approach might be functionally related to the particular materials learned was examined by the use, in separate groups, of lists composed of either low-association (LA) or high-association (HA) nonsense syllables. It seemed reasonable to expect that HA syllables would provide associative bases for linkages, and that the serial strategy would therefore prove more feasible for these materials. By contrast, the lack of potential in LA nonsense syllables for associative linkages suggested that the positional strategy might be more effective for these materials.

Method

Subjects. Ninety volunteer *S*s from introductory psychology courses in the Queens College summer session participated in the experiment. They were individually assigned to 1 of the 6 groups in the order of their appearance in the laboratory, such that the number of *S*s per group was equal after every sixth *S*. Two *S*s were dropped from the experiment, one for failing to follow instructions and one due to *E* error. One of the dropped *S*s was in the HA-position group and the other in the LA position group.

Apparatus and materials. The stimulus items consisted of 2 sets of consonant-vowel-consonant (CVC) trigrams selected from Archer's (1960) list. The LA syllables were between 9% and 41% association value, and the HA syllables were between 73% and 95%. To control for any possible effects due to item ordering within the lists, 3 different orders of these syllables were formed, so that pairs of such HA and LA lists provided 3 replications of the experiment. The syllables were typed in capital letters on a standard memory-drum tape and presented on a Lafayette memory drum at a 2-sec. rate. The same interval was used between movements of the memory drum to pace recall. There was an intertrial interval of approximately 30 sec.

Experimental design. Six independent groups of *S*s were individually tested. One group was instructed to learn the list by associating each nonsense syllable with the following one (Group S). The second was told to learn the list by associating each nonsense syllable with the number of its position in the list (Group P). The third (control) group was given only standard instructions, with no suggestions about how to learn the list (Group C). Half of the *S*s in each group were presented with a list composed of HA syllables, and half learned lists composed of LA syllables. Randomly selected pairs of HA and LA lists formed 3 replications of the basic experiment. Thus, a $3 \times 3 \times 2$ factorial design was employed, with 3 levels of instruction, 3 replications, and 2 levels of associative value. The 6 distinct groups were designated as S–HA, S–LA, P–HA, P–LA, C–HA, and C–LA.

Procedure. All *S*s served individually, learning the list to a criterion of one perfect trial by the serial recall method for "the identification and assessment of processes in serial learning [Battig & Lawrence, 1967, p. 178]." In this method, learning trials which exposed the items alternated with blank exposures during which *S*s were to attempt recall. Before the first learning trial, each *S* was given the following modified standard learning instructions:

> This is a memory test. You are to learn the nonsense syllables that appear in the window of the machine in the right order as quickly as you can. When I start the machine the syllables will appear in the window one after another until 12 have been shown. Try to learn them as they appear.

After the twelfth syllable was shown and before the first recall trial, the following instructions were given:

> Now, right after an asterisk has appeared in the window a blank line will appear. Then you are to say what the first syllable is. Then another blank line will appear in the window. While that line is there, you are to say what the second syllable is. You are to continue in this manner until 12 lines have appeared in the window. Guess even if you are not sure.

After the first recall trial, *S* was told:

> Now the 12 syllables will be shown to you again for you to learn. This will again be followed by 12 blank lines. The procedure will continue in this way until you have learned all 12 syllables.

In addition, Group S was told:

> It has been shown that people learn this list faster if they form associations between the syllables. In other words they associate the first syllable with the second, the second with the third, and so on. For example, if the first syllable is "zop" and the second "kip," try to make an association between "zop" and "kip." If the third syllable is "buf," also try to make an association between "kip" and "buf." Remember, try to form associations between the syllables.

Group P was told:

> It has been shown that people learn this list faster if they remember the number of the syllable on the list. In other words, if "zop" is the first syllable, "kip" the second and "buf" the third,

say to yourself "first is 'zop,' second is 'kip,' third is 'buf,' " and learn the entire list in this manner. Remember, learn the entire list by remembering the number of the position that the syllable occupies on the list.

The *S*s in Group C were given only the revision of the standard serial instructions. In addition, every few trials, *S*s in Groups S and P were reminded during the intertrial interval of the method that they were to use to learn the list. The CVC syllables used in the instructions were all different from the syllables used during the learning task.

After the list was learned, each experimental *S* was given 2 kinds of reaction time tests to determine whether he had followed the instructions while learning the list. Each control *S* was also given both reaction time tests in an attempt to infer the strategy used. The equipment consisted of a standard reaction time key attached to a Hunter timer. The reaction time for each trigram was measured to the nearest hundredth of a second. When *E* read the appropriate instructions, he depressed the key and held it down until *S* gave a response, at which time he removed his finger and recorded the reaction time. The 2 sets of instructions that were given to each *S* were as follows: (*a*) "Now I am going to test you on how well you have learned the list. Would you please tell me which syllable is number ______?" These instructions were repeated for each serial position, with 3 different orders of randomly chosen numbers. (*b*) "Now I am going to test you on how well you have learned the list. Would you please tell me which syllable comes after ______?" These instructions were repeated for each trigram. Three different orders of randomly chosen trigrams were used as stimuli.

Half of the *S*s in each group received Instruction *a* first until 12 numbers were presented and then Instruction *b* until the 12 trigrams were presented. The order of instruction presentation was reversed for the remaining *S*s. All *S*s were given both sets of reaction time instructions.

It would be expected that *S*s given P instructions would make a stronger association between the number presented and the appropriate trigram than between successive trigrams. This stronger association should be manifested by a faster reaction time for Reaction Time Instruction *a* than for Reaction Time Instruction *b*, and Group P should therefore respond to Instruction *a* more rapidly than to Instruction *b*. Conversely, it would be expected that Group S would make stronger associations between successive trigrams than between the number of the trigram on the list and the trigram. This stronger association should result in more rapid responding to Reaction Time Instruction *b* than to Reaction Time Instruction *a*. The same reasoning should help infer which strategy control *S*s had used. The above should hold true for trigrams that are recalled correctly. When *S* answers incorrectly to either set of reaction time instructions, there is no way of knowing how strong the association is. Therefore, only trigrams which were responded to correctly after both Instructions *a* and *b* [illegible] used in this analysis.

Results

Reaction times. The first step in the analysis of data was a comparison of the reaction times obtained from the 6 groups. It was reasoned that if the instructions were followed, strong associations would be built up between successive trigrams for the S groups and between the number denoting position of the trigram on the list and the trigram for the P groups. Such strong associations should result in faster reaction times after learning when the "appropriate" rather than the "inappropriate" reaction time instructions were given.

Table 1 shows the mean reaction times for the 6 groups for the preceding stimulus items and the position numerals. The data are broken down into types of reaction time and the order of recall for HA and LA trigrams. Of the 30 HA experimental *S*s, 23 had faster reaction times when reaction time instructions were appropriate for the experimental instructions than when they were inappropriate. The probability of this occurring by chance according to the sign test is less than .004. The apparently slower reaction time for *S*s given the position (appropriate) reaction time instruction first ($\bar{X}$ = 4.13 sec.) as compared to the serial (inappropriate) instructions ($\bar{X}$ = 3.17 sec.) is due to the extreme delay in responding of one *S* in this group who took an average of 17.21 sec. to respond to serial reaction time instructions. In spite of this *S*, 7 out of 9 *S*s responded more rapidly to position reaction time instructions than to serial reaction time instructions. When reaction time instructions were appropriate for the experimental instructions, 22 of 30 LA experimental *S*s had faster reaction times than when the reaction time instructions were inappropriate. The sign test indicated that the probability of this occurrence was less than .008. It would appear that experimental instructions were followed by most *S*s.

It was also argued that it would be possible to infer the strategy used by control *S*s by comparing their reaction times

for position and serial recall instructions. Ten of the 15 LA control *S*s had faster reaction times when position reaction time instructions were used. The probability of this occurrence is equal to .15. Eight of the 15 HA control *S*s had faster reaction times when serial reaction time instructions were used. The probability of this occurrence is .50. Therefore, no assumptions regarding the preference of strategies for control *S*s are warranted.

Finally, it can be seen that the second time *S*s were asked to recall the syllables, their reaction times were faster than the first time they were asked to recall the syllables. It seems that *S*s did not expect to be tested on their recall of the syllables, and it took some time before they became adapted to the reaction time task. The finding that it takes *S* some time to adapt a set to respond rapidly is quite common in reaction time studies.

Since these data indicate that *S*s followed instructions, it is appropriate to evaluate the effect of differential instructions and association values by analyzing the trials to criterion, errors, and number of correct choices on the first-quarter trials by separate $3 \times 3 \times 2$ analyses of variance and Newman–Keuls Studentized range tests. To further analyze the data, serial position curves were compiled.

Trials to criterion. Mean trials to criterion and standard deviations for the 6 groups are shown in Table 2. A $3 \times 3 \times 2$ analysis of variance, with 3 types of instructions, 3 replications, and 2 association values, found a significant main effect of association value, $F\ (1, 72) = 6.64, p < .05$. This indicates that, as expected, the HA trigrams were learned in less trials ($\bar{X} = 8.24$) than were the LA trigrams ($\bar{X} = 10.31$). The main effect of instructions approached significance, $F\ (2, 72) = 2.74, .05 < p < .10$. This suggests that there is a tendency for P instructions to induce the most effective learning strategy and the fastest learning ($\bar{X} = 8.10$ trials), while the control instructions, where *S* must find his own strategy, resulted in the slowest learning ($\bar{X} = 10.40$ trials).

TABLE 1

Mean Reaction Time (in sec.) to Position Numeral and to Preceding Item for the Six Experimental Groups

Instructions	Trigram association: Low — Serial RT	Low — Position RT	High — Serial RT	High — Position RT
Serial	4.68(1)	3.89(2)	2.69(1)	2.98(2)
	3.11(2)	4.77(1)	2.59(2)	3.91(1)
Position	3.74(2)	4.13(1)	2.42(2)	2.80(1)
	3.58(1)	1.85(2)	3.04(1)	1.95(2)
Control	4.16(1)	2.91(2)	3.13(1)	4.25(2)

Note. Numbers in parentheses indicate order of testing. Abbreviation: RT = reaction time.

TABLE 2

Mean Trials to Criterion (and Standard Deviations) for the Six Experimental Groups

Trigram association	Instructions: Serial	Position	Control
Low	11.13	7.87	11.93
	(4.12)	(2.05)	(5.80)
High	7.53	8.33	8.87
	(3.62)	(3.56)	(2.67)

In order to determine the significance of the specific group differences, an internal comparison of the cell means was made by the Newman–Keuls Studentized range test. This found only that Group C–LA took significantly more trials to learn the list than Group P–LA ($\bar{X} = 11.93$ and 7.87, respectively, $p < .05$). Thus, the main reason for the borderline significance of instructions is the difference between Groups C–LA and P–LA.

Errors. Mean errors (intrusions and omissions) and standard deviations for the 3 types of instructions and 2 association levels are presented in Table 3. The results of the $3 \times 3 \times 2$ analysis of variance of the error data found significance in the main effect of instructions, $F\ (2, 72) = 6.90, p < .025$; the Instructions × Association Value interaction $F\ (2, 72) = 4.12, p < .05$; and the Instructions × Lists interaction, $F\ (2, 72) = 2.82, p < .05$. Again, the significant main effect of association value

TABLE 3

MEAN ERRORS (AND STANDARD DEVIATIONS) FOR THE SIX EXPERIMENTAL GROUPS

Trigram association	Instructions		
	Serial	Position	Control
Low	63.20 (22.25)	38.87 (12.32)	65.40 (30.44)
High	37.60 (18.43)	44.33 (23.82)	50.07 (20.14)

indicates that, as expected, more errors were made while learning LA trigrams ($\bar{X}$ = 55.82) than HA trigrams ($\bar{X}$ = 44.00). That the main effect of instructions is significant indicates that the P groups made the fewest errors ($\bar{X}$ = 41.60), while the C group made the most ($\bar{X}$ = 57.74). Again S groups were intermediate ($\bar{X}$ = 50.40) between P and C groups. Overall, the P instructions induced the most efficient strategy (in terms of errors), while the control instructions, leaving *S* to search for a strategy by himself, were least efficient. The significant Instructions × Association Value interaction indicates that this was especially true for the LA trigrams, whereas for the HA trigrams, the S instructions induced a more effective strategy, resulting in fewer errors, than either of the other instructions. A Newman–Keuls Studentized range test was performed to determine the exact locus of the experimental effects. This analysis indicated that the significant Instructions × Association Value interaction was due to the fact that in the LA groups, the P instructions resulted in fewer errors than either S instructions or C instructions ($\bar{X}$ = 38.87, 63.20, and 65.40, respectively, $p < .05$), while in the HA groups there were no differential effects due to instructions. Thus, it seems that for LA trigrams, the P instructions induced the most efficient strategy, while for HA trigrams, the type of instructions had little effect.

Number correct on first-quarter trials. An analysis of the number of correct responses on trials during the first quarter of learning was suggested by results of an experiment by Postman and Stark (1967), in which evidence supporting the serial hypothesis was found when the first few trials were analyzed, but not in the analysis of the number of correct responses on the entire list. Mean numbers of correct trigrams and standard deviations for the first quarter of learning are found in Table 4. An analysis of variance found no significant differences among any of the means. The most probable reason for the discrepancy between these results and those found by Postman and Stark lies in the different procedures used. Postman and Stark used a PA-SL transfer procedure, while this experiment used a procedure which induced various learning strategies by means of different instructions. Apparently, any strategy induced by a PA task can be tapped early in serial learning, whereas the differential effectiveness of strategies suggested by varying instructions does not appear until later in learning.

Serial position curves. Serial position curves for HA and LA groups are shown in Figures 1 and 2 respectively. It can be seen from Figure 1 that the shape of the curve for Group S–HA is somewhat different from that normally encountered, in that there is no major drop in the percentage of errors at the end of the curve. While this is a rather sharp departure from the typical serial position curve, it is exactly what would be expected if *S*s learned the list by the serial instructions; that is, if each *S* made a connection between each pair of syllables, one would expect the beginning of the list to be learned most rapidly, with

TABLE 4

MEAN NUMBER CORRECT (AND STANDARD DEVIATIONS) ON THE FIRST-QUARTER TRIALS FOR THE SIX EXPERIMENTAL GROUPS

Trigram association	Instructions		
	Serial	Position	Control
Low	2.02 (1.15)	2.89 (1.37)	2.83 (.91)
High	3.14 (1.18)	2.78 (1.06)	2.70 (1.52)

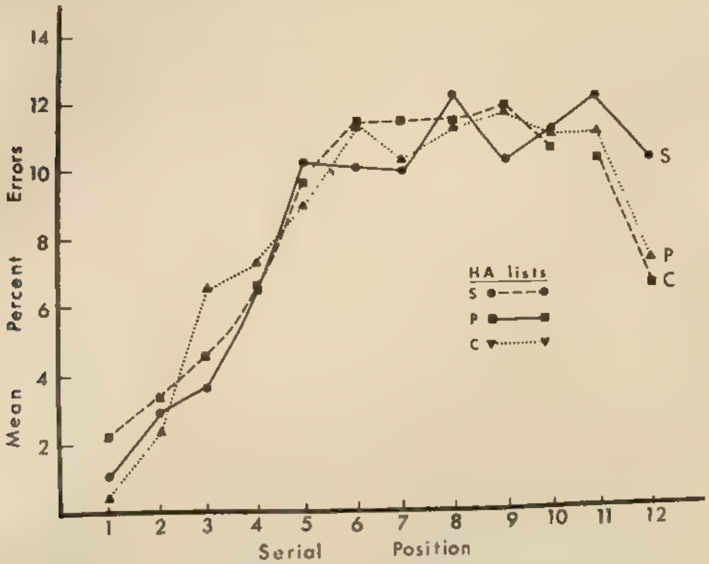

FIGURE 1. Serial position curves, showing percentage of errors for each serial position, for the 3 high-association (HA) groups. (Abbreviations: S = groups given serial instructions; P = groups given position instructions; and C = control groups.)

more and more difficulty occurring as *S* gets further and further into the list. The serial position curves for all low-association syllables, on the other hand, are more like the typical inverted-U-shaped serial position curves, with the ends showing fewer

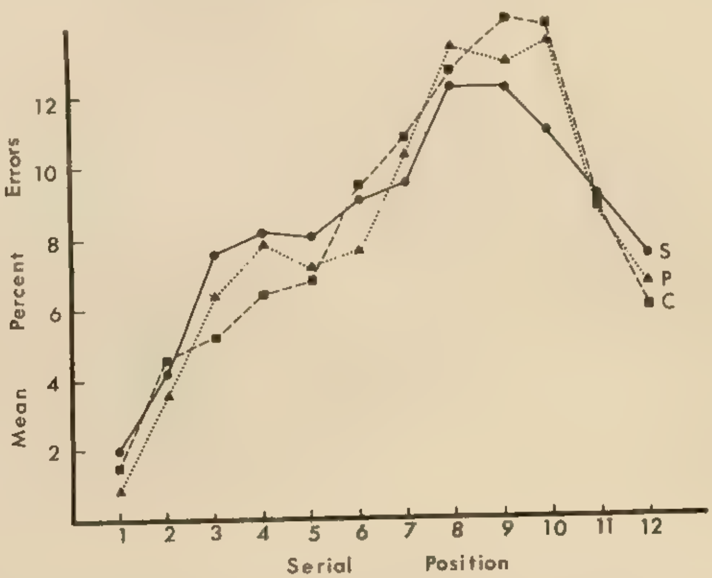

FIGURE 2. Serial position curves, showing percentage of errors for each serial position, for the 3 low-association (LA) groups. (Abbreviations: S = groups given serial instructions; P = groups given position instructions; and C = control groups.)

errors, and most errors occurring in the middle of the list.

Discussion

Two findings from this study seem worthy of further note. First is the effectiveness of instructions in influencing *S*'s learning strategy, especially for the error data. Most of the experimentation performed up to the present has been concerned with determining the strategy that *S*s prefer to use, rather than comparing the relative efficiency of various strategies (e.g., Brown & Rubin, 1967). The present experiment, on the other hand, is an attempt to compare the effectiveness of the specificity and position hypotheses when they are induced by instructions prior to learning. Although previous experiments have employed variations in instructions as an experimental variable, most have done so for other purposes, e.g., to contrast intentional (instructed) and incidental (noninstructed) learning (e.g., Dornbush & Winnick, 1967), to provide a basis for differences in motivation (e.g., Baron, 1967), or to provide information or misinformation about the learning situation (e.g., Holden & Rotter, 1962). The present experiment, by contrast, has provided instructions about specific procedures that are to be used to accomplish learning. That the instructions were acted upon by *S*s in this experiment seems to be indicated by the reaction time data, which showed that S groups built up stronger associations between one trigram and the next one on the list, and that P groups built up stronger associations between the number of the trigram on the list and the trigram than between successive trigrams. Furthermore, the significance of the instructional effect in the error data, as well as its borderline significance on trials to criterion, indicates that the specific suggestion of a strategy provides these *S*s with something of an advantage over control *S*s.

One possible explanation for these findings is that giving *S* instructions about how to learn the list allows him to start learning the list without having to search for a strategy. He would then learn the list more rapidly than if he had searched for a strategy, as long as the instructed strategy was not one which would hinder learning.

In the search for differences between the 2 instructed groups, the Newman–Keuls analysis found that Group P–LA made significantly fewer errors than either Group S–LA or Group C–LA. The latter 2 groups did not differ significantly from each other, indicating superiority of position instructions for the LA list. However, the Newman–Keuls analysis of the trials-to-criterion data showed that Group C–LA took significantly more trials to learn the list than Group P–LA, but found no significant difference between Group P–LA and Group S–LA. This is not meant to imply that *S* used only the strategy he was instructed to use. It is possible and not contradictory to the present results that some *S*s used some complex strategy based on the instructions.

The second finding of note is that the effectiveness of a learning strategy (as induced by instructions) is functionally related to the characteristics of the materials to be learned. That this was the case in the present experiment is indicated by the significant interaction between instructions and materials for the error data. This significant interaction revealed, first, that position instructions were more effective than specificity instructions with low-association trigrams, and second, that neither strategy had an advantage for high-association trigrams. This finding is quite understandable. Low-association trigrams, by their very nature, provide little basis for the interitem linkages demanded by the specificity strategy. The existence of numerical position in the list is therefore a feasible aid. As trigrams increase in association value, it should become easier to form interitem linkages, so that when high-association trigrams are used, the advantage of the position strategy is lost, and the strategies are of equal efficiency. It seems reasonable to predict that interitem linkages would be easier to form with words than with trigrams, and the position strategy should therefore have little advantage when words are used.

While the above reasoning is logical, at least one other possibility must be considered. It is feasible that, although *S*s were given instructions, and although reaction time data give a clue that those instructions were used, *S*s may have been using other cues in addition to and/or instead of the one suggested by the instructions.

The results from the present study indicate that the effectiveness of a particular strategy of learning may be functionally related to the characteristics of the materials to be learned. Caution suggests that there may also be a relationship to the method of learning employed. The present study, rather than using the more common method of anticipation, followed the suggestion of Battig and Lawrence

(1967) that the serial recall procedure is superior because it reduces the confusion induced by the anticipation method's "requirement that *S*s simultaneously try to learn each presented item and anticipate the following item . . . [p. 177]." Their conclusion that the recall procedure is more sensitive than the anticipation procedure for identifying the process in serial learning seems to be corroborated by the present results.

SEQUENCE OF RESPONSE DEVELOPMENT IN HUMAN EYELID CONDITIONING

ARCHIE B. LEVEY[1]
Clinical Psychiatry Unit, Medical Research Council, Graylingwell Hospital, Chichester, England

IRENE MARTIN
University of London

The acquisition of the conditioned eyelid response was examined fr standpoint of response patterning to determine whether respon develops in an orderly sequence independent of response frequenc analysis was confined to unreinforced trials in order to avoid maskin characteristic response shapes by the unconditioned response (UCR influence of response frequency was assessed by varying air-puff i and interstimulus interval. The 4 response shapes identified were (a conditioned response alone, (*b*) an unaccompanied response in the lat range of the UCR, (*c*) a double response combining *a* and *b*, and (*d*) a r in which *a* and *b* were indistinguishably blended. It was found th eyelid response exhibits an orderly sequence of development culmin the blended response, though this development is characterized by fr return to the earlier response types.

A lively interest in the analysis of specific response features and patterns of responding characterized the earlier experimental literature on conditioning (e.g., Bernstein, 1934; Hilgard, 1931; Humphreys, 1943; Marquis & Porter, 1939; Wendt, 1930). Attention was also focused during this period on the analysis of relationships between the conditioned response (CR) and the unconditioned response (UCR) (e.g., Grant, 1939; Hilgard, 1936; Miller & Cole, 1936). In subsequent years, the response itself tended to be taken for granted as interest in conditioning turned towards theory testing and the analysis of stimulus effects. The last decade, however, has seen a revival of interest in the description and analysis of response characteristics and of response changes during conditioning (e.g., Grevert & Moore, 1970; Grings & Schell, 1969; Kimble & Ost, 1961; Kimmel, 1966; Lockhart, 1972), including changes in overall response topography (e.g., Ebel & Prokasy, 1963; Gormezano, 1972; Grings, Lockhart, & Dameron, 1962; Prokasy, 1965; Prokasy, Ebel, & Thompson, 1963; Smith, 1968). At the same time, new measures have been dev d which describe topographic aspec the response with increasing accuracy (Edelberg, 1970, 1972; Pennypacker, 1964).

Objective measures of response efficiency have been reported for the conditioned eyelid response which provide a precise, quantitative description of the degree to which the developing CR anticipates the occurrence of the UCR (Levey & Martin, 1968; Martin & Levey, 1969). Investigation of these measures has shown that (*a*) they increase linearly toward a stable end point in the course of acquisition, (*b*) the increase is characterized by random fluctuations, (*c*) rate of increase is largely independent of response frequency, and (*d*) the end point may or may not involve optimal attenuation of the air puff, depending upon stimulus and *S* variables. The last finding is in accord with the observation that use of paraorbital shock produces efficient placing of the CR, though attenuation is not involved (Coleman & Gormezano, 1971). In the classical conditioning paradigm, response shaping is determined by *S* rather than by *E* (cf. Prokasy, 1965), and the increase in response efficiency may be regarded as a form of adaptive responding.

A tentative formulation that attempts to account for these findings has been

[1] Requests for reprints should be sent to Archie B. Levey, Medical Research Council, Clinical Psychiatry Unit, Graylingwell Hospital, Chichester, Sussex PO19 4PQ, England.

offered elsewhere (Martin & Levey, 1969, pp. 119–136) and will not be described in detail. Briefly, it is suggested that the conditioned stimulus (CS) and the unconditioned stimulus (UCS) are combined, from the beginning of acquisition, in an internally represented CS/UCS complex, to which the organism responds as a single stimulus entity, and for which a neuronal model is formed, analogous to Sokolov's (1963) model of the orienting stimulus. It is assumed that the earliest response to this stimulus complex is the formation of an internal response model. In early trials the stimulus complex evokes a UCR replica in the temporal range of the CS, which is incorporated in the response model and becomes the basis of the anticipatory CR. In the course of acquisition, the internal model of the response complex is progressively adjusted, through comparator mechanisms, to the combined characteristics of the stimulus complex. The point in acquisition at which an overt response is elicited depends on performance factors, and the response form is governed by the current state of the response model. The final response is an integrated complex that represents efficient use of all the information coded in the stimulus complex, and hence produces efficient responding.

The present study was undertaken to test some of the observable consequences of the formulation outlined above. (*a*) Presentation of the CS alone in early trials should be capable of eliciting an attenuated response in either the CR or the UCR latency range or both. (*b*) On intermediate trials the CS should elicit a combined response in which both CR and UCR components are identifiable. (*c*) On trials late in the acquisition series the CS should be able to elicit a response in which CR and UCR components are combined in a single entity. (*d*) The *S*s who respond late in the acquisition series, assuming response probability to be a function of various performance factors, should produce responses that reflect the development of the internal response model. A corollary of these inferences is that the developing response should exhibit an orderly sequence, independent of the level of response frequency.

The test of these propositions must rest with unpaired presentation of the CS, since occurrence of the UCS would mask the response shape by forcing a UCR. Accordingly, the study used the method of unreinforced test trials, though this carries the unavoidable limitation that the effect of partial reinforcement as a variable cannot be independently assessed. This procedure has the sanction of other recent investigations, however (e.g., Coleman & Gormezano, 1971), and in the present context the test trials can be regarded as a kind of "window" on the current state of the developing response complex.

Method

The *S*s were 72 naive adult males, screened for sensory defects, who were recruited as paid volunteers. The conditioning procedure involved *S*s being conditioned to a 1,000-cps 65-db. tone CS presented through headphones, and an air-puff UCS of 60-msec. duration, delivered to the cornea through 1-mm. tubing and terminated with CS termination. Stimulus presentations and durations were controlled by a Devices Digitimer. The eyelid response was recorded by means of an ORP-12 Cadmium Sulphide photocell whose output was fed, with the marker signals, to a 2-channel Elema Schönander Mingograph with a chart speed of 50 mm/sec. The *S*s were seated in a dimly illuminated cubicle, screened from the apparatus and from *E*. Thirty acquisition trials were given with 18 unreinforced test trials interspersed randomly throughout the series, with the limitation that no 2 test trials occur in succession. The same randomization order was used for every *S*. Immediately following the acquisition trials, extinction trials were run to a criterion of 5 successive nonresponse trials or a limit of 20 trials.

In order to manipulate response frequency, 2 experimental factors known to affect this variable were accounted for in the design. Half of the *S*s were conditioned at short (400 msec.) and half at long (800 msec.) CS durations, crossed with 2 levels of UCS intensity, weak (3 psi) and strong (6 psi) air puffs. Since personality variables, notably extraversion and neuroticism, are known to affect response frequency, *S*s were assigned to the 4 cells of the design on the basis of these 2 personality factors and their interaction, using pretest scores on the Eysenck Personality Inventory (Eysenck & Eysenck, 1964).

Responses were scored on each of the 18 test trials for all deflections of 1 mm. or more above the stable baseline. A response was scored as a CR if

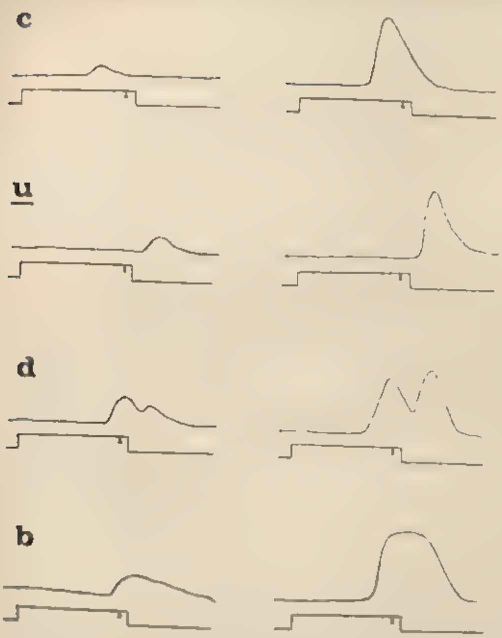

FIGURE 1. Chart tracings of the 4 response types discussed in text: conditioned response (CR) only (c), unreinforced responses falling in unconditioned response range (*UCR*) only (*u*), double CR/*UCR* (d), and blended CR/UCR (b). (The figures on the left represent early trials, while those on the right are taken from later trials. The marker indicates conditioned stimulus [CS] onset, duration, and offset. The arrow indicates the point at which the unconditioned stimulus would have occurred. The CS duration in all figures is 800 msec.)

it fell between an onset latency of 120 msec. and the offset of CS, and as a *UCR* if it occurred within 120 msec. following CS offset. (The italicized label will be used throughout this article to refer to unreinforced responses falling in the UCR latency range.) It should be emphasized that the latter responses, though defined by the UCR latency range, were not simply duplicates of the UCR, either in shape or amplitude. Many of them, particularly in earlier trials, were low in amplitude and did not show the characteristic sharp rise of the UCR to UCS presentation. It should also be noted that the findings of this study do not apply to voluntary-form responding, which did not occur in the sample studied.

Responses were then categorized into the 4 types illustrated in Figure 1. This categorization was done by a research assistant thoroughly familiar with conditioning records, but unaware of the purpose of the analysis.[2] The types identified were: CR only (C), *UCR* only (*U*), double response (D) and blended response (B). The categorization was objectively based on the latency criteria outlined and on the locus of inflection points in the wave forms in the case of double responses. On this basis a small number of multiple CRs was included in the CR-only category. Obvious spontaneous blinks, defined by their characteristic rise time, amplitude, and duration, were separately identified and excluded from the analysis. Coding reliability was assessed by independently rescoring one third of the records, resulting in a 95% overall agreement. While this type of categorization is crude, by comparison with the objective measures of response efficiency mentioned earlier, it served to identify the basic response shapes with which the study was concerned.

The sequence of response types was identified for each *S* by the following method: each first appearance of any response type was recorded for every *S* in order of occurrence. This yielded a code containing 4 successive elements. For example, if *S* gave the following sequence: *U*, C, C, *U*, D, *U*, D, C, C, B, C, D, it was coded as *U*-C-D-B, indicating that the progression of response types occurred in that order. This method of summary yielded 24 possible sequences representing the permutations of 4 elements. An appreciable number of *S*s showed only 3 of the response types. In this situation, it follows that the fourth element of the code can only be the remaining type, and these codes were therefore completed with the missing element. A few *S*s gave only 2 of the response types, and were randomly assigned to those codes in which the 2 relevant response types appeared first in the order observed. It is important to note that this method of coding takes no account either of the absolute number of responses of a given type, or of the order in which any of the response types, having first appeared, may recur prior to the emergence of the next type. The main hypothesis to be tested was that the 4 types occur in ordered sequence. A sequence such as C-*U*-D-B, should occur more frequently, for example, than the sequence D-*U*-C-B, while the sequence B-D-*U*-C should be unlikely. In other words, it was postulated that the developmental sequence begins with the single responses, progresses through the double response, and ends with the integrated blend response.

RESULTS

The total number of responses categorized was 499, divided into 240 C, 91 *U*, 79 D, and 87 B responses. The observed base level of responding immediately prior to the acquisition series was .069 for the shorter interval and .120 for the longer. These are average values based on 3 samples from each *S*, allowing for the 120-msec. *UCR* criterion, and are within the ranges usually observed in our laboratories.

[2] The authors are most grateful to Mary Acock, Medical Research Council, for her cheerful and competent performance of this task.

Only one double response occurred and this is consistent with chance expectation at the observed levels. Analysis of variance on the 2 × 2 sampling model of the design, summing over 18 trials, showed that total response frequency was significantly lower under the interaction of a short interstimulus interval and a weak air puff, $F\ (1, 68) = 4.19,\ p < .05$. Separate analyses showed the *U* response to be slightly more frequent under the stronger air puff, $F\ (1, 68) = 4.98,\ p < .05$, while the D response was significantly more frequent with the longer interval, $F\ (1, 68) = 4.02,\ p < .05$. The C and B responses were not differentially affected by experimental conditions. Twelve *S*s failed to produce responses to the unreinforced trials and were excluded from further analysis.

The fact that the 4 response types could be identified in substantial numbers lends immediate support to the notions discussed in the previous section. These results indicate that the unpaired CS is capable of eliciting responses in both the CR and UCR latency ranges, singly and in combination, including a completely blended composite of both responses. The question of interest, however, is the order in which these response types occurred. If they merely represent 4 discrete response shapes or patterns, it might be expected that each of the sequences would be equally probable. In fact, of the 24 possible codes, the 2 expected sequences, C-*U*-D-B and *U*-C-D-B, accounted for over 50% of all responders.

The assumption that each of the sequences is equally probable is open to several objections. In particular, any factors that govern the proportions of the response types would also dictate the relative frequencies of the various sequences. Thus, if chance alone determined the first response type, the predominance of C, noted earlier, would lead to a higher frequency of all codes beginning with C. Using the same argument for each position of the elements in the codes, the most probable sequence would be C-*U*-B-D, and the next most probable would be C-*U*-D-B, representing a spurious advantage to the sequence expected by the theoretical model. In the following analyses, therefore, the calculation of expected frequencies for each of the sequence codes used the joint probabilities of the response types, based on their overall frequencies, assuming independence. This afforded an effective control for base-level responding in relation to the asymmetric latency criteria for the C and *U* responses, for experimental factors, and for any unknown factors which may have determined the distribution of response likelihoods.

No hypothesis was offered to predict whether the CR would precede the *UCR*, or vice versa. In order to summarize the data, therefore, and reduce the number of codes to manageable proportions, the CR and *UCR* responses were considered separately. This yielded 6 sequence codes based on the permutations of 3 elements. It should be noted that this procedure offered the further advantage of accounting for all *S*s, since for those few *S*s who gave only 2 response types, the code could be completed with the missing element.

Table 1 summarizes the data for 3 analyses: CR omitting *UCR*, *UCR* omitting CR, and CR combined with *UCR*. The symbol C*U* in the code label on the left indicates the position of these elements in the sequence, while the symbol at the head of each pair of columns designates the element itself. Thus, the first entry in the top row of the table is the number of *S*s who gave the sequence C-D-B, the second is the expected frequency for that sequence, the third is the number producing

TABLE 1

Observed (O) and Expected (E) Frequencies of *S*s Responding within Six Sequence Codes

Code	C		U		CU	
	O	E	O	E	O	E
C*U*-D-B	42	16.94	34	10.11	44	19.05
C*U*-B-D	6	18.64	6	11.13	8	20.97
D-C*U*-B	6	8.57	7	9.41	5	7.52
D-B-C*U*	3	3.07	10	9.01	2	1.96
B-C*U*-D	2	9.64	1	10.88	1	8.48
B-D-C*U*	1	3.14	2	9.46	0	2.02

Note. See text for code explanation.

the sequence *U*-D-B, and so on. With one exception, to be discussed later, the experimental conditions had no important effect on the sequences and will not be considered separately in these analyses.

Inspection of the table shows that the predicted sequences, C-D-B and *U*-D-B, were overwhelmingly highest in proportion, while B-D-C and B-D-*U* were scarceley represented, χ^2 (5) = 53.95 and 74.40, respectively, $p < .001$. The joint function of CR and *UCR*, shown in the third pair of columns, follows the same pattern, χ^2 (5) = 50.16, $p < .001$, with greater symmetry. Further clarification of the relationship between CR and *UCR* was afforded by examining the first response of each *S*. The observed frequencies of the response types C, *U*, D, and B were 36, 16, 7, and 1, respectively, and yielded χ^2 (3) = 13.24, $p < .005$. Interestingly, the observed frequencies of the CR and *UCR*, ignoring the remaining categories, lie close to the observed proportions of the 2 responses overall, suggesting that the CR is more likely as a first response simply because it is more available.

The combination of a short interstimulus interval and weak UCS not only reduced the level of responding, but virtually excluded the unexpected response sequences. For example, 90% of the *S*s responding under these conditions showed the sequence C-D-B. In order to explore this unexpected finding, the 60 responding *S*s were divided into 2 equal groups of 30 early responders and 30 late responders, both across experimental conditions and separately within experimental co[illegible]ons, and the data were reanalyzed [illegible]ese analyses showed the predicted [illegible]onse sequences to be undifferentiated b[illegible]arly or late responding. By contra[illegible] the deviant sequences were virtually [illegible]ted to late responders and in the case [illegible] the within-conditions comparison, enti[illegible]so. This result is consistent with 2 expl[illegible]ory factors. Where the experimental [illegible]ndi-tions are such as to suppress respo[illegible]ding, late responses represent the beginn[illegible]g of response development. Where the [illegible]onditions facilitate responding, late resp[illegible]ding represents those *S*s who withold res[illegible]onses until late in their own developmen[illegible]l sequence, but whose patterns of responding show an internal sequence of development.

No hypothesis was offered as to the behavior of response sequences du[illegible] extinction. The following analysis [illegible] empirical and is offered merely as a description of the typical sequences. It should be noted that the categorization of responses is made difficult du[illegible] because the response complex [illegible] to shift on its time base, and this ma[illegible]lt in misclassification of some resp[illegible]. Fifty-four *S*s produced a total of [illegible]11 responses in extinction, of which 235 were either blended or double responses. In these trials, 45% of all *S*s responding gave response sequences that fell in those categories beginning with the blended response. The next most frequent category comprised those sequences beginning with the double response. These results suggest that the response complex is in some sense breaking down, though not necessarily regressing in an orderly fashion through the reverse of the response-type sequences. The results must be viewed with some caution, since the appearance and disappearance of responses late in the sequence may produce artifacts that seem to resemble disintegration. It is noteworthy, however, that those *S*s giving a large number of responses in extinction were those more likely to follow the graded sequences. Table 2 shows the distribution of response sequences for the 25 *S*s giving either 3 or 4 response types

TABLE 2

FREQUENCIES OF RESPONSE SEQUENCES FOR 25 *S*s GIVING THREE OF FOUR RESPONSE TYPES IN EXTINCTION, COMBINING CR AND *UCR* ONLY RESPONSES

Response	3	4	Total	Expected
C*U*-D-B	5	0	5	3.62
C*U*-B-D	0	0	0	6.76
D-C*U*-B	2	2	4	2.65
B-C*U*-D	4	0	4	6.38
D-B-C*U*	3	1	4	2.45
B-D-C*U*	3	5	8	3.14
Total	17	8	25	

Note. See text for code explanation.

in extinction, combining CR and *UCR* in one category. Expected frequencies were calculated on the basis of overall response proportions in extinction. The average number of extinction trials for this group was 17.72. It is evident that the reversed sequences B-D-C*U* and D-B-C*U* account for a disproportionately high number of responders, χ^2 (5) = 17.36, $p < .005$. This suggests the intriguing possibility that if *S*s go on responding long enough in extinction, the response complex tends to be dismantled in reverse order to its development.

Discussion

To summarize the results of this study briefly, it has been shown that the emergence of response types categorized as CR, *UCR*, double CR/*UCR*, and blended or integrated CR/*UCR* occurs for the most part during acquisition in an orderly sequence of response development. The sequence as such is independent of the experimental conditions examined, although the absolute numbers of a given response category are affected. Those experimental conditions that suppress responding appear to delay the onset of the sequence, while those that facilitate responding show evidence that internal response development occurs early in acquisition. The sequence does not exclude a return to earlier modes of responding and is probably best described as an overall emergent trend in a setting of ongoing random variation consistent with the fluctuation of efficiency levels mentioned earlier. However, in the present study, which was limited to partial reinforcement, it is possible that extinction processes also contributed to the return to earlier response types.

These results were anticipated in a surprisingly neglected early study by Grant (1939), though differences in experimental conditions, procedures, and methods of recording make it impossible to compare the 2 studies directly. Grant identified 6 response patterns, of which 2, labeled the "unimodal CR" and the "completed slope CR," resemble the responses labeled double and blended responses in the present study. He noted of the latter response that "this very efficient pattern generally occurs later in the conditioning series [p. 452]," and commented both on the implied sequence of patterns and on the tendency toward "regressive shifts to patterns which had been present in an earlier stage of the experiment [p. 460]." Grant's study, of which the authors were unaware at the time the present study was designed and analyzed, was specifically aimed at describing response patterns and their shifts in relation to the question of CR/*UCR* relationships. Though the measurements were made entirely on reinforced trials, the similarity of results is striking.

The view that response efficiency is independent of response frequency is consistent with the recent finding of Coleman and Gormezano (1971) that the precision and variability with which the CR peak is placed in relation to UCS onset are uncorrelated with response frequency. In the present study, CR frequency accounted on the average for only one quarter of the variance associated with the 4 response types, and, in general, correlations among response types were nonsignificant. Nevertheless, the finding that response suppression may delay the onset of response development requires some modification of this view.

The development by Prokasy (1972) of a two-phase model that successfully predicts acquisition curves in human eyelid conditioning may offer a lead. One of the parameters (K) of this model reflects a factor of delay during early acquisition trials which Prokasy (p. 143) attributes in part to variables that affect orienting behavior. It seems entirely possible that the low saliency of the weak UCS and short interstimulus interval in the present study may have resulted in failure to attend during the early trials. It is reasonable to suppose that if the stimulus processing mechanism is "idling" during this period, the postulated stimulus and response models will be delayed in formation.

The interest of the present results, apart from their general support of the theoretical model outlined earlier, centers on the eyelid response at UCR latency. The occurrence of 170 of these responses, either alone or in combination with the CR, is well above the base-rate expectation of 28.4 responses and suggests that they are not trivial. A similar response, occurring on unreinforced trials, has been described by Zeiner (1968) for several autonomic measures (galvanic skin response, heart rate, salivation, and pupil dilatation). In electrodermal conditioning, it is commonly referred to as the second interval response (SIR), first described by Grings et al. (1962). Several explanatory concepts were examined by these authors, viz., response substitution, inhibition of delay, temporal conditioning, CS

offset response, and disparity responding. Reasons were given to show that without modification, none of these explanations is entirely satisfactory. Part of the interest of identifying the *UCR* or SIR in eyelid conditioning is the fact that the orienting component, which is prominent in the electrodermal system, can be largely ignored. The behavior of the alpha blink, or CS reflex blink, has been shown to resemble that of the orienting response (Levey & Martin, 1967; McAllister, 1953). This blink occurs typically to onset of the CS, but rarely to offset at the stimulus intervals employed in the present study. (We have informally observed CS-offset alpha blinks, though only to tone stimuli of very long duration, e.g., 120 sec.) Thus, the mechanisms of CS offset and disparity responding do not apply to the eyelid response.

Zeiner (1968) has shown empirically, in an elegant experiment comparing a trace paradigm in which the CS extended beyond the UCS, with a delay paradigm, that the SIR in electrodermal conditioning is not merely a response either to offset of the CS or to contiguity between CS offset and UCS onset. He has also presented cogent reasons, which are equally applicable to the present results, suggesting that the SIR is not due either to simple response substitution or to inhibition of delay. His conclusion was that the SIR phenomenon represents one part of a dual process, in which the occurrence of 2 separate responses is attributed to separate mechanisms of preparatory responding, mediated by learned fear, and a modified form of stimulus substitution. It is our view that in eyelid conditioning at least, a two-process model does not readily account for the eventual blending and integration of the 2 responses, CR and *UCR*, and the present results suggest that both are intrinsic components of the classical conditioning process.

Indeed, the most interesting aspect of the response sequences described is not the nature of the 2 response components but the fact that they combine into an integrated whole. The fact that a blend of CR and UCR occurs in eyelid conditioning is not in doubt (Spence, 1956). What the present study shows is that the blended response, as well as the composite double response, is elicited by the CS in the absence of the UCS. This of itself indicates that they are in some sense integrated into a single response. It is important to note that the blended response does not necessarily result in optimum avoidance of the air puff. Doubt has recently been thrown on the ability of simple reinforcement mechanisms to account for response placement (Gormezano, 1972) as well as response probability (Prokasy, 1972). The view proposed here attributes response integration to the modeling of the CR/*UCR* response complex on the CS/UCS stimulus complex, and this is consistent with our present knowledge, though it cannot be proven.

If the CR and *UCR* are equally parts of the classical conditioning process, there remains the consideration of why the *UCR* in the present study should have been less frequent than the CR. The probability of occurrence on the CR or the *UCR* as a first response has been shown to be entirely consistent with its overall probability. It has also been shown that with a stronger UCS the UCR occurs more frequently, indicating that the CS is actively conveying this information. If, as suggested, the CS and UCS form a single stimulus complex, sharing the information content of both, the ability of the CS to elicit the *UCR*, or the UCS to elicit the CR, might be expected to be weaker than when the 2 stimuli are presented together. The second half of this proposition cannot be tested, since the UCS alone cannot give rise to an *observable* CR. In the absence of this unobtainable evidence, the difference in frequency of the CR and UCR offers no basis for rejection of the conclusion that the CR and the *UCR* are equally parts of the classical conditioning sequence, and that their integration into the double or composite response and finally into a blended response is an intrinsic part of the conditioning process.

Finally, though the results lend support to the theoretical model outlined, they also raise a very puzzling question. The data clearly show that on very early trials the CS is capable of eliciting a CR or a *UCR*, but not both. It might be noted that this situation is equally problematic for a two-process model. Nothing in the proposed model or in any current theory of classical conditioning predicts this phenomenon. It is not the purpose of this article to enter into discursive theorizing. The data seem to suggest 3 possibilities. First, the early trials may recruit insufficient response energy, in some sense, to support 2 responses. In this event, the *UCR* would be given only on a trial on which the CR had for some reason not occurred. Second, if 2 separate processes are involved, they may for unknown reasons be mutually exclusive or may interfere in the

early trials. Third, and most attractive in our view, the phenomenon can be handled within the confines of the proposed model. If it is assumed, following Estes (1950), that the comparator process mentioned earlier, by which it was suggested the integrated response complex is gradually built up, operates on each trial by scanning only a random subset of the information in the stimulus complex, the result is at least partially explained. If this were the case, the occurrence of a CR or a *UCR* or of no response in early trials would be a function of the particular subset sampled. On successive trials, further information would lead to progressive shaping and integration of the complete response model. This view is consistent with current views of information processing and is able to account for the gradual integration of the response.

No final answer can be given to the problems raised by the occurrence of the *UCR* and the CR/*UCR* complex in response to the CS. While, at this stage, the results lend support to the view of conditioning outlined earlier, they do not, of course, confirm it. The purpose of the present study was to establish firmly the empirical basis of response development sequences in eyelid conditioning. Further work will be required to elucidate the underlying mechanisms and to arrive at a satisfactory explanatory formula.

HAPTIC EQUIVALENCE MATCHING OF CURVATURE BY BLIND AND SIGHTED HUMANS[1]

PHILIP W. DAVIDSON[2] AND TERESA T. WHITSON
Washington College

The relations between active handling, accurate haptic curvature matching, and task difficulty were studied using increases in the number of stimuli contained in comparison arrays to vary task difficulty. Blind *S*s were more accurate than sighted *S*s as task difficulty increased and marked differences in exploratory search were noted between blind and sighted *S*s. Moreover, the blind's characteristic search strategy, infrequently used by the sighted, led to improved matching by sighted *S*s restricted to its use. Also, in the larger Comparison-Array conditions, the more stimuli in the comparison arrays the more similar was the scanning of sighted *S*s in each condition to that of the blind. It was concluded that an interaction between task requirements and search style may in part determine accuracy in judgments of form properties like curvature.

Skill in haptically judging form properties such as length, proportion, or curvature seems to depend upon the particular pattern of active finger, hand, or arm movements used to explore the stimulus. However, little is known of the role of such movements in perception.

A recent study by Davidson (1972a) attacked one aspect of this question, the relation between the stimulus property being judged and the style of search. The experiment compared blind and sighted *S*s in discriminating curved stimuli by hand. The results showed that blind *S*s (*a*) were more accurate than the sighted with the most difficult curves, and (*b*) employed a scanning strategy infrequently used by the sighted, one leading to improved judgments by sighted *S*s restricted to its use.

The blind's strategy, called gripping, entailed using three or four fingers to simultaneously explore numerous points along the curve. Sighted strategies, although similar to gripping in hand and arm motion, involved successive search through pinching, or sweeping, the curve with one or two fingers. Davidson (1972a) concluded that gripping probably was suitable for prehending curves of low discriminability since it provided more stimulus information than other methods.

The present experiment examined another related aspect of this question, asking if the effectiveness of search strategies is influenced by the difficulty of the task itself, apart from the nature of the stimulus attribute. We used curvature equivalence matching, varying task difficulty by systematically changing the number of alternatives to be compared to the standard. The larger the number of stimuli in the comparison array, the greater the burden placed on immediate recognition memory and the more difficult the task (Goodnow, 1971). Part I compared the unrestricted exploratory search of blind and sighted *S*s while Part II tested the effectiveness of these search strategies.

METHOD

Subjects. Twenty-four *S*s with normal vision (M_{age} = 15 yr., 5 mo.) and 23 congenitally totally

[1] This research was supported by U.S. Public Health Service Research Grant 1-R01-EY-00807-01 from the National Eye Institute to the first author. Preparation of the manuscript was supported in part by grants to the University of North Carolina from the Maternal and Child Health Services (Project 916 to the Division for Disorders of Development and Learning) and the U.S. Public Health Service (Grant HD-03110 to the Biological Science Research Center). The authors gratefully acknowledge the cooperation of the Maryland School for the Blind and the Kent County High School. We also wish to thank M. Belcher and M. blind *Ss* (M_{age} = 19 yr., 0 mo.) participated in Part I. The blind and sighted *Ss* were matched approximately for IQ based on Verbal Scale scores on the Wechsler Intelligence Scale for Children (M_{IQ} = 102, SD = 9). Ninety paid undergraduate volunteers participated in Part II.

Stimuli. Seven different concave curves (as illustrated in Davidson, 1972a) were used, with arc heights of 2, 4, 6, 8, 10, 12, and 14 mm.

The task. The blindfolded *S* felt first the standard stimulus for 8 sec., then successively presented comparison stimuli for 8 sec. each to match the standard. The 2-, 4-, and 6-mm. curves served as standards (the greatest differential scanning effects reported by Davidson, 1972a, occurred with these three stimuli), each appearing 8 times in a random order for a total of 24 trials.

Task difficulty was varied by changing the number of curves appearing in comparison arrays and the same three difficulty conditions were used in both Parts I and II. In the first condition, each comparison array contained one curve (i.e., a *same–different* task), in the second, comparison arrays contained three curves (the standard plus two randomly selected others), and in the third, comparison arrays contained five curves (the standard plus four randomly selected others). The standard and comparison stimulus were the same 50% of the time in the One-Comparison condition and stimulus combinations and orders were randomized for all Comparison-Array conditions. No stimulus appeared twice in the same comparison array. Stimuli were presented following Davidson's (1972a) procedure.

Part I procedure. Seven blind and eight sighted *Ss* were tested in the One-Comparison condition, and groups of eight blind and eight sighted *Ss* were tested in the Three- and Five-Comparison conditions. Each *S*'s exploratory activity was videotape recorded and the recordings analyzed by two independent scorers following Davidson's earlier procedures (1972a). The scorers categorized an *S*'s scanning each time he felt a curve, noting only whether particular predefined methods occurred. The tapes were scored for gripping, pinching, and top sweeping, the three scanning strategies differentiating blind and sighted *Ss* in Davidson's (1972a) study and defined and illustrated there.

Part II procedure. In each of the three task conditions, 10 *Ss* were restricted to using only gripping, 10 *Ss*, to only pinching, and 10 *Ss*, only top sweeping. Each *S* was trained in using the appropriate scanning method before testing began.

RESULTS

Part I matching errors. The upper part of Table 1 gives the mean error scores from Part I. A two-way analysis of variance revealed effects of Vision, F (2, 41) = 11.71, $p < .01$, and Comparison Array Size, F (2, 41) = 48.78, $p < .01$. Subsequent t tests indicated that blind and sighted *Ss*' errors did not differ in the One-Comparison condition, t (41) = 1.3[illegible], $p > .05$, but that the blind made fewer errors in the Three-Comparison, t (41) = 2.46, $p < .01$, and the Five-Comparison condition, t (41) = 1.99, $p < .05$. Newman-Keuls tests showed that errors increased for both blind and sighted *Ss* with each increase in comparison array size (p < .01 for all comparisons). No change in errors occurred over trials, and IQ had no influence on errors, regardless of Vision or Comparison-Array condition.

Part II matching errors. The mean error scores from Part II are shown in the lower portion of Table 1. A two-way analysis of variance revealed effects of both Scanning, F (2, 81) = 4.03, $p < .01$, and Comparison Array Size, F (2, 81) = 53.31, $p < .01$. Newman-Keuls tests revealed that (*a*) gripping led to fewer errors than both pinching, $p < .01$, and top sweeping, $p < .01$, but pinching and top sweeping did not differ from one another, $p > .05$, and (*b*) errors increased with successive increases in comparison array size (p < .01 for all comparisons).

Comparing the Grip groups with the combined errors of the Pinch and Top Sweep groups showed that the three strategies led to similar errors in both the One-Comparison, t (28) = 1.31, $p > .05$, and the Three-Comparison condition, t (28) = 1.07, $p > .05$. However, gripping led to fewer errors than other methods in the Five-Comparison condition, t (28) = 2.36, $p < .02$. This outcome departs from our findings in Part I where, with scanning free to vary, the between-groups difference in the Five-Comparison condition was somewhat less than the Three-Comparison difference.

Analysis of scanning in Part I. After a check for interscorer agreement (the scorers agreed 83.9% of the time), following Davidson's (1972a) procedure we calculated the percentage of an *S*'s judgments in which the scorers reported seeing each scanning strategy and then obtained group averages. The resulting distributions for blind and sighted *Ss*, shown in Figure 1, were compared with separate Mann-Whit-

TABLE 1

Mean Curvature Matching Errors

Group	Number of Stimuli in Comparison Arrays					
	One		Three		Five	
	$\bar{X}$	SD	$\bar{X}$	SD	$\bar{X}$	SD
Part I: exploratory scanning unrestricted						
Blind	6.57	1.76	10.37	2.44	15.62	1.99
Sighted	8.62	2.68	13.61	2.68	18.25	2.94
Part II: exploratory scanning restricted						
Grip	8.20	2.40	10.90	2.91	14.40	2.61
Pinch	9.40	1.74	11.40	2.76	16.60	2.28
Top sweep	9.40	2.57	12.80	2.48	17.00	2.64

ney *U* tests for each scanning strategy within each Comparison-Array condition.

In the One-Comparison condition, sighted *S*s pinched more often than the blind, U (7, 8) = 7.0, $p < .01$, while the blind *S*s gripped more often than the sighted, U (7, 8) = 13.0, $p < .05$, results paralleling Davidson's (1972a) previous study. The outcome with larger comparison arrays, however, differs from earlier findings for sighted *S*s. In the Three-Comparison condition, sighted *S*s' gripping showed a large increase compared to One-Comparison condition sighted *S*s, although still used less often than by Three-Comparison condition blind *S*s, U (7, 8) = 12.0, $p < .05$. At the same time, pinch usage by these sighted *S*s was similar to that of Three-Comparison blind *S*s, U (7, 8) = 23.5, $p > .10$. In the Five-Comparison condition, no significant scanning differences were indicated, a result perhaps accounting for the diminished error difference between blind and sighted *S*s in this condition compared to the Three-Comparison condition. (Top sweeping by all groups was low with no consistent changes as a function of Comparison-Array condition).

We summarized the percentage of judgments within successive four-trial blocks in which each strategy occurred to get a better view of the changes that took place in sighted *S*s' scanning as comparison array size increased. The variability of these scores made any meaningful statistical analysis difficult. However, the data for sighted *S*s did suggest a decrease in gripping over trials and an increase in pinching over trials in the One-Comparison condition, trends which did not occur in either the Three- or Five-Comparison conditions. There were no consistent effects of trials on top sweeping by sighted *S*s, or upon usage of any of the three strategies by blind *S*s.

Discussion

The present study extends Davidson's (1972a) paper in several ways. First, it appears that the contribution to perceptual accuracy made by exploratory search may be based upon an interaction between the task requirements and the style of search. This conclusion was suggested by Davidson (1972a) with respect to the nature of the stimulus attribute being judged, and seems extended by our data to also include the nature of the task paradigm.

Second, a scanning strategy that permits simultaneous prehension of a stimulus attribute seems to withstand increasing task difficulty better than methods that sample more successively (at least with regard to relational attributes such as curvature). Davidson (1972a, 1972b) has speculated that simulta-

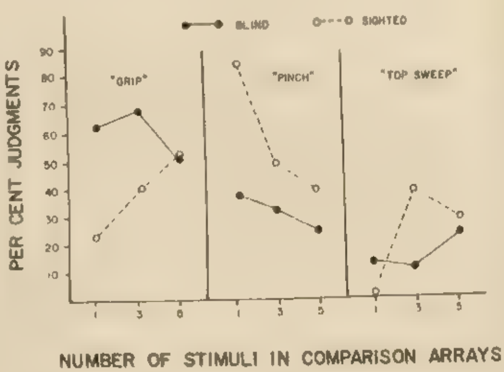

Figure 1. The percentage of judgments in which blind and sighted *S*s in Part I used the scanning strategies. (More than one strategy could occur in each of an *S*'s 24 trials. Mann-Whitney *U* tests revealed that blind *S*s gripped more than the sighted in the One-Comparison condition, $p < .05$, and Three-Comparison condition, $p < .05$, and the sighted pinched more than the blind in the One-Comparison condition, $p < .01$.)

neous prehension may help to pattern the relationship, reducing the requirement for integrating successive inputs in memory. If the increases in task difficulty in the present study are viewed as increases in task immediate recognition memory demand (as has been argued by Goodnow, 1971), then our results suggest that such scanning may also contribute to better recognition memory for form.

The greater accuracy of blind *S*s compared to the sighted is consistent with other studies of curvature categorization by the blind (Davidson, 1972a; Hunter, 1954), extending these previous results to the equivalence matching situation. This finding suggests that curvature is one form property that requires some haptic perceptual experience before it can be accurately perceived.

The link between perceptual accuracy and scanning style, found initially by Davidson (1972a) and replicated here, is a straightforward extension of previous findings for judgments of other form properties involving comparisons either of blind and sighted humans (Davidson, Barnes, & Mullen, in press; Hatwell, 1959) or young children (Abravanel, 1968). Moreover, the scanning differences between sighted *S*s depending on comparison array size suggests that modification of exploratory activity may be one result of perceptual experience.

PICTURE-WORD DIFFERENCES IN DISCRIMINATION LEARNING: I. APPARENT FREQUENCY MANIPULATIONS[1]

JOEL R. LEVIN[2]
University of Wisconsin—Madison

ELIZABETH S. GHATALA
Weber State College

LARRY WILDER
University of Wisconsin—Madison

A discrimination-learning task was administered to a sample of sixth graders. Stimulus materials consisted of either pictures or words for which frequency judgments had been obtained in a previous experiment. Picture and word items were selected which differed either substantially or minimally in apparent frequency measures. While the usual picture-over-word effect was found when picture–word apparent frequency differences were large, it vanished when pictures and words were equated in terms of apparent frequency. These results, coupled with some recent data, provide for a fairly complete account of picture–word differences in discrimination learning.

It has recently been demonstrated that pictures are more easily learned than words in a discrimination task, for both children (Rowe, 1972; Wilder & Levin, 1973) and adults (Rowe, 1972; Rowe & Paivio, 1971; Wilder & Levin, 1973). To date, one of the more popular explanations of this effect has been that pictures are more likely than words to produce a simultaneous verbal–imaginal encoding, and that dually coded materials are better recalled (Paivio, 1971). However, guided by the frequency theory of verbal discrimination learning originally proposed by Ekstrand, Wallace, and Underwood (1966), the present authors conducted an experiment which suggested that picture–word effects in discrimination learning may be attributable to differences in the subjective (apparent) frequency associated with the two types of material (Ghatala, Levin, & Wilder, 1973).

In that experiment, sixth graders were administered either a picture or word frequency judgment task in which line drawings of familiar objects or their printed verbal labels were presented for varying numbers of exposures, with *S*s later asked to estimate the number of times a particular picture or word had been previously shown. It was found that the mean judgments for pictures were higher than the mean judgments for words, even though the actual presentation frequencies of the two were the same. In addition, the average variability associated with items of the same presentation frequency was lower for pictures than words.

According to frequency theory, discrimination between the "correct" and "incorrect" members of a pair in a verbal discrimination task is based on the frequency differential between them, with more subjective frequency "units" accruing to the correct member of the pair than to the incorrect member through such factors as differential rehearsal favoring the former. The Ghatala et al. (1973) results are consistent with a frequency theory interpretation of picture–word differences

in discrimination learning since: (*a*) the finding that pictures were higher in mean apparent frequency than words suggests that a subjective frequency unit produced by a picture is larger than a frequency unit produced by a word; and (*b*) the finding that *S*s were less variable in estimating the presentation frequencies of pictures as compared to words suggests that differences in presentation frequency are more likely to be discriminated when the items are pictures than when they are words. Both findings lead to the prediction of superior discrimination learning when the materials are pictures—the first, because the absolute frequency difference between correct and incorrect items is larger for picture pairs than for word pairs; the second, because lower variability associated with correct and incorrect items in picture pairs renders them more discriminable than word pairs.

The present experiment was conducted to test the hypothesis that picture–word differences in discrimination learning are a function of apparent frequency differences associated with the two types of material. How apparent frequency judgments of pictures and words were obtained and manipulated is discussed in the following section.

Method

In the Ghatala et al. (1973) study, 19 sixth-grade *S*s judged the frequencies of 39 pictures, 20 of which had been presented once, 10 twice, 6 three times, and 3 four times. Another 19 *S*s gave frequency judgments for the printed labels which occurred with the same presentation frequencies as their corresponding pictures.

Manipulation of apparent frequency means. A comparison of the mean apparent frequencies of individual picture and word items revealed that the mean of pictures was reliably ($p < .001$) higher. However, while the mean judgments of pictures (at each presentation frequency) were, in general, higher than those of words, there was some overlap in the distributions. In particular, from among the items presented once, 8 of the pictures could be matched fairly closely with 8 of the words. Similarly, 4 pictures and 4 words were selected from among the items presented twice, and 2 pictures and 2 words were selected from among the items presented 3 times. Pairing items within presentation frequencies resulted in 7 picture pairs and 7 word pairs which differed minimally in mean apparent frequency (small-difference items). The mean apparent frequency of the pictures used in the small-difference items (averaged over the 14 pictures) was 1.42. The mean apparent frequency of the 14 words also averaged 1.42.

Next, 14 pictures and 14 words were selected to form pairs which differed considerably in mean apparent frequency (large-difference items). Four picture pairs and 4 word pairs were formed from items presented once, 2 pairs of each stimulus type were formed from items presented twice, and 1 pair apiece were formed from the items presented 3 times. The mean apparent frequency of the pictures was 1.74, and that of the words was 1.16.

The 14 picture pairs (7 small-difference items plus 7 large-difference items) comprised 1 discrimination list, and the 14 word pairs comprised another. In forming each list, an attempt was made to equate a pair's correct and incorrect members in apparent frequency. This was done in order to ensure that any between-materials (pictures and words) apparent frequency differences were manipulated independently of within-materials (correct and incorrect members) apparent frequency differences.

Three presentation orders of each list were constructed such that: (*a*) within each order, the occurrence of small- and large-difference items was random; (*b*) within an order, the correct member was located on the right for half of the pairs and on the left for the other half; and (*c*) across orders, the spatial location of the correct member of each pair was varied randomly with the restriction that it not occur in the same position across all 3 orders. The randomization scheme for constructing the 3 presentation orders was the same for picture and word lists, i.e., each order's sequence of small- and large-difference items, as well as its spatial location of correct members, was the same for the 2 lists.

The pictures were line drawings (3 × 3 in.) which were pasted side by side on sheets of 8½ × 11 in. paper. The sheets were then placed in a 3-ring notebook binder. The words were typed in primary type, side by side, on sheets of paper which were placed in a separate 3-ring binder. Asterisks were used to indicate the correct member in each pair.

Manipulation of apparent frequency variances. From the same pool of items used to construct lists varying in mean apparent frequency, picture and word items were selected on the basis of the variance in apparent frequency associated with each item. The variance of these judgments differed for pictures and words, being statistically smaller ($p < .001$) for pictures. Once again, there was some overlap between the distributions. Small-difference items were constructed from 14 pictures (8 selected from among the "one" items; 4 from among the "two" items, and 2 from among the "three" items) and 14 words (selected in the same numbers as the pictures from the 3 presentation frequencies) which differed little in variability. Within presentation frequencies, picture pairs and word pairs were formed which differed minimally

in variance. The average variance of the pictures was .54, and that of the words was .52.

Fourteen pictures and 14 words which differed widely in variance (lower for pictures) were used to construct the large-difference items. The pictures and words were selected from presentation frequency levels in the same numbers given above. As in all previous cases, pairs were constructed from items within a presentation frequency. The average variance for the 7 picture pairs so constructed was .39. The mean variance for the word pairs was .80.

As before, the 7 small-difference and 7 large-difference items within each stimulus type were combined to form a 14-pair picture list and a 14-pair word list. The procedures used in creating the lists were the same as those previously described.

Finally, it should be noted that in selecting items to investigate one of the measures of apparent frequency (either means or variances) an attempt was made to control the other measure, even though this could not be done perfectly. For example, the average variances of picture and word items selected for a small difference in mean judgments were .45 and .65, respectively. For large-difference items, these figures were .55 and .61. With regard to items selected for small differences in variance, the mean apparent frequencies were 1.64 for picture pairs and 1.40 for word pairs. For the items with large variance differences, the corresponding means were 1.49 and 1.41.

Subjects. The *Ss* were 80 sixth-grade children (mean age = 12.4 yr.) randomly selected from two elementary schools located in middle-class neighborhoods in Ogden, Utah. Twenty *Ss* were assigned (according to a block-randomized procedure) to each of the 4 conditions formed by the combination of 2 materials (pictures or words) and 2 measures (means or variances). Following Walster and Cleary's (1970) suggestions for equating "statistical" significance with "practical" significance, the number of *Ss* required was based directly on the simultaneous specification of effects considered important (differences in excess of 1 within-cells standard deviation for the large-difference items) and those considered trivial (differences less than $\frac{1}{4}$ of a within-cells standard deviation for the small-difference items).

Results

Performance on the discrimination task is summarized in Table 1. For both mean and variance manipulations, the results are clear-cut. With large-difference items, pictures and words differ substantially: means, $F(1, 38) = 13.58$, $p < .001$; variances, $F(1, 38) = 6.48$, $p < .05$; whereas with small-difference items, they do not ($F < 1$ for both means and variances).

TABLE 1

Mean Number of Correct Discriminations in Two Trials on Items with Large or Small Mean and Variance Differences (Maximum Score = 14)

Measure	Large difference		Small difference	
	Pictures	Words	Pictures	Words
Means	12.30	10.20	11.70	11.45
Variances	12.15	10.45	11.80	11.60

While there was marked improvement over trials, in no case did this interact with the above picture–word effects (all ps $> .05$).

Discussion

Based on the assumption that discrimination learning consists of discriminations of subjective frequency differences between items (Ekstrand et al., 1966), and given the empirical finding that apparent frequencies associated with pictures and words differ (Ghatala et al., 1973), we were able to anticipate the usual picture-over-word superiority in discrimination learning (Rowe, 1972; Rowe & Paivio, 1971; Wilder & Levin, 1973) when apparent frequency differences between pictures and words were maintained. On the other hand, when pictures and words were equated in terms of either apparent frequency means or variances (as determined from an earlier study), no discrimination-learning differences between the two types of material were detected.

When one considers the (almost incredibly) straightforward pattern of results, it is tempting to pit plausible rival constructs against the authors' preferred account of the effects in terms of apparent frequency differences. Thus, it might be argued that when apparent frequencies were manipulated to create large- and small-difference items, other attributes were inadvertently manipulated concomitantly. Normative word frequency (f) as indexed by the Thorndike–Lorge (1944) norms, and measures of meaningfulness (m) and concreteness (C)—all of which have been found to influence the ease of verbal discrimination learning—may have been differentially represented in the large- and small-difference word pairs. However, based on an inspection of the present words for which norms were available (Paivio, Yuille, & Madigan, 1968), it was found that all the words were uniformly

high in f, m, and C, with no discrepancies between large- and small-difference items evident. Of course this finding was to be expected given that the present stimuli were selected to be picturable (i.e., concrete) and familiar to elementary school children (i.e., frequent and meaningful).

While there are potentially a multitude of uncontrolled factors which may have contributed to the observed effects, a reviewer of this journal has pointed out one in particular which will be considered in detail. If it is assumed that apparent frequencies of pictures are correlated with those of their verbal labels (the corresponding words), *and* if it is further assumed that the words corresponding to, say, large-difference pictures are not equally divided between large- and small-difference items (due to nonrandom assignment of items to conditions), then it is possible in the present study that *apparent frequency* has been confounded with the *specific items* appearing in the various conditions. For example, if the large-difference pictures (which tend to produce higher and less variable judgments than the small-difference pictures) correspond to words with high means and low variances, *and* if more of these words happened to be assigned to the small-difference than to the large-difference condition, then the pattern of results in Table 1 may be easily explained in terms of item-specific peculiarities; that is, large-difference pictures would be expected to be best, large-difference words worst, with the two other conditions in between. The same argument can be made if words corresponding to small-difference pictures ended up more frequently in the large-difference than in the small-difference condition.

Fortunately, a thorough examination of the present materials suggests that this account of the results is not satisfactory. In the first place, for the items equated on the variance measure, the words corresponding to large-difference pictures were almost equally divided between the large- and small-difference conditions, as were the words corresponding to small-difference pictures (a total of 10 vs. 12 cases, in the direction *opposite* to the hypothesis). Second, although an inspection of the items equated on means indicated a tendency toward unequal division in the direction specified by the hypothesis (a total of 15 vs. 6 cases, $p < .10$), further scrutiny of the Ghatala et al. (1973) data revealed that the correlation between picture and word items presented once was low ($r = .14$) and statistically nonsignificant, thereby mitigating against the reviewer's first assumption. Thus, the specific-item hypothesis, with its assumptions of picture–word correlations and selective item assignment, cannot account for the pattern of results observed here: In the case of the variances, there was no differential item selection; and in the case of the means, the picture–word correlation was low.

While it is not possible to state with certainty which of the two measures, means or variances, has the more predominant influence on picture–word differences in discrimination learning (since the two measures covary, and this problem was not completely controlled for here), speculations may be made on the basis of some previous research. In one published study (Ghatala & Levin, in press-a) and in other unpublished work, it has been found that pictures and words differ more reliably with respect to variability in apparent frequency (pictures being lower) than with respect to mean apparent frequency. If this result continues to be replicated in further controlled experiments, it would indicate that pictures are easier to discriminate than words because the subjective frequency units associated with them are more stable.

Even though a frequency theory (Ekstrand et al., 1966) explanation of the present effects is appealing—in particular, with regard to the operationalization of the manner and contexts in which frequency units accrue—it must be realized that the validity of an apparent-frequency construct is not enhanced unless one can explain *why* pictures and words differ in apparent frequency. However, such an attempt has been made by Ghatala et al. (1973). Essentially, the argument is that pictures and words differ substantially in terms of *S*'s preexperimental encounters with them. Thus, while *S*s have likely read the experimental words on numerous preexperimental occasions, they have never encountered (preexperimentally) the particular experimental line drawings. By adapting Weber's law to this type of situation, it is readily understandable why the presentation of a picture (initially low in preexperimental exposure) should constitute a larger—and, evidently, more stable—subjective frequency unit than the presentation of a word (initially high in preexperimental exposure).

Based on this rationale, some interesting extensions have been made (cf. Ghatala & Levin, in press-a, in press-b). However, there are additional verbal discrimination and recognition memory phenomena with which the

"background-frequency" explanation must deal before it can be considered viable. Whether or not it can negotiate them successfully remains to be seen.

A PREVIEW-CONSTRAINT MODEL OF ROTARY ARM CONTROL AS AN EXTENSION OF FITTS'S LAW [1]

TARALD O. KVÅLSETH [2]

School of Industrial and Systems Engineering, Georgia Institute of Technology

A first-order linear model relating movement time to Fitts's movement variable and a preview variable was formulated and validated experimentally using 15 undergraduate students as *S*s. Without preview constraint, the rotary arm movement task produced a maximum movement information or index of task difficulty (ID) rate of 4.7 bits/sec, which, when preview constraints were imposed, was reduced to 3.9 bits/sec as compared to a marginal preview ID rate of 12.5. The movement variable was found to account for about 70% of the total contribution to movement time. The error rates were determined to be highest in the no-preview-constraint case and were significantly ($p < .05$) affected by both movement and preview ID.

The interrelation between movement time (Y), amplitude (A), and accuracy or target width (W) for terminating the movement for serial motor tasks was first formulated within an information-theoretic context by Fitts (1954). Arguing by analogy from Shannon's channel capacity Theorem 17 (Shannon & Weaver, 1949), Fitts proposed the simple relationship

$$Y = a + bX_1 + \epsilon; \qquad [1]$$
$$X_1 = \log_2(2A/W) \text{ bits},$$

where X_1 is considered to be a measure of the amount of entropy or information in each movement, ϵ is the error term, and a and b are constant parameters. The validity of this linear model has been clearly confirmed by Fitts and other investigators (cf. Welford, 1968, Chap. 5) through a number of experiments such as those involving tasks for which *S*s were required to move a stylus or pen quickly between 2 targets of width W and distance apart A.

Fitts's model was concerned with linear arm movements without any constraint on the movement path or the preview. A linear second-order model for hand movements with path constraints was recently formulated by Kvålseth (1973); however, as far as this author is aware, no quantitative model has so far been formulated and validated that incorporate preview constraints for serial motor movements involving, specifically, arm rotations (Crossman, 1960, studied the effect of preview on continuous tasks involving pursuit tracking). The present investigation was designed to study the effect of such variable preview in laboratory experiments.

The basic hypothesis to be tested was that the movement time Y is linearly related to a new index of task difficulty (ID) variable

$$X = \log_2\left[\gamma\left(\frac{2A}{W}\right)^{\alpha}\left(\frac{1}{P}\right)^{\beta}\right], \qquad [2]$$

where P is the preview (distance) and α, β, and γ are unknown constant parameters. This model may be placed within an information-theoretic context that represents essentially a generalized extension of Fitts's interpretation of the variable X_1 (cf. Fitts & Posner, 1967, pp. 112–117) without proposing that it be considered as a necessarily true paradigm of human behavior relevant to the motor task considered in this study. Thus, the quantity X may be interpreted as the information generated by or the entropy associated with the selection of any one movement from an ensemble of equiprobable movements; the term in the square bracket of Equation 2 being the number of elements in the en-

---

[1] The author wishes to thank W. B. Cross for assisting with data collection.

semble. The unit of X may then be considered as being "bits" with the constraint imposed that all values of the different variables and parameters considered are such that $X > 0$.

Effectively, the variable P is such that $0 < P \leq (A + W/2)$. For the case of no preview constraint, $P = (A + W/2)$ or alternatively, it may be considered that $\beta = 0$, so that the resulting expression for X is simply a generalization of X_1 in Equation 1; the identical linear model of Equation 1 is still seen to apply. For the preview-constraint case, the linear relationship between Y and X can, after a few simple algebraic manipulations, be expressed alternatively in terms of the following first-order linear model,

$$Y = a + bX_1 + cX_2 + \epsilon; \qquad X_2 = \log_2(1/P) \tag{3}$$

where the ID variable X_2, which may assume negative values and did so exclusively in the present study, is not to be interpreted as a direct information or entropy measure in the information-theory sense. The coefficients a, b, and c are unknown constant parameters to be estimated, and ϵ is the experimental error.

Method

Apparatus and task. The experimental apparatus designed for this experiment is illustrated in Figure 1. It consisted of a black box containing a 1½-v. battery that provided the input voltage to a linear potentiometer whose output terminals were connected to a single-channel strip chart recorder. The potentiometer was fixed to the inside of the box with its rotary wiper or shaft emerging through a hole in the center of one side of the box. This shaft was attached to a round control knob 2¼ in. in diameter so that any angular displacement of the control knob produced a proportional variation in the output voltage of the potentiometer, which was thus used as a displacement transducer. A 2½-in.-long pointer (measured from the center of the control knob and the shaft) was mounted onto the knob such that it barely cleared a scale attached to the box. Thus, a control–display ratio of 1 was used. Such an easily replaceable scale, which was placed such that the end of the black pointer reached approximately halfway across it throughout its length, had a marked target area of width W degrees; the centers of the target areas were separated by a distance A degrees.

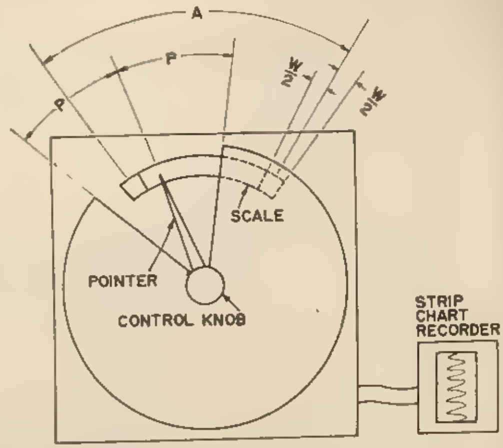

FIGURE 1. A plan view of the apparatus.

Preview constraint was incorporated into the experiment by attaching a black circular cardboard plate to the bottom of the control knob. The diameter of the plate was slightly larger than that of the outer side of the scale measured from the center of the control knob (see Figure 1). This plate, which was easily removable, had a radial slit in it of $2P$ degrees and was placed such that the pointer was in the center of the slit. Several such plates and scales were designed to provide different experimental conditions involving different values of A, W, and P.

The apparatus was placed on the top of a table, and *Ss* stood in an upright position. The experimental task required *S* to move the pointer back and forth between the 2 target areas of a scale by turning the control knob; this movement had negligible friction. Because of the preview constraint, *S* could only see the scale a distance of P degrees ahead of the pointer throughout a complete movement between targets. For such serial movements, which were simultaneously recorded on the strip chart, *Ss* were told to minimize their movement times, while at the same time trying to maintain low error rates. An error was considered as being committed whenever a pointer movement terminated outside 1 of the 2 targets.

Subjects. A total of 15 unpaid *Ss* were used in the experiment, all of whom were right-handed male undergraduate students. Five of these performed the experiment without any preview constraint, while the remaining 10 *Ss* were subjected to preview constraints.

Experimental procedure. The 12 experimental conditions used consisted of all combinations of angular movement amplitudes $A = 30°, 60°, 90°$ and target widths $W = 5°, 10°, 15°, 20°$, with preview $P = W$. The order of these conditions was randomized and different for each *S*. Prior to each run, the pointer was lined up with each of the 4 boundary lines of the target pair, and the strip chart was run a short distance for each of these 4 pointer settings so as to identify the equivalent target

boundaries on the strip chart. Then, with the strip-chart recorder turned off, S was given a 10-sec. practice session. Following a practice session and an approximate 5-sec. rest period, S performed the experiment for 15 sec. while the strip-chart recorder was turned on. From this chart, E was able to obtain the total number of moves made by S and hence the mean movement time during the 15-sec. interval. The chart also provided information about the error rate by simply observing the fraction of moves by the recorder pen that fell short or far of the target boundaries. Movements that resulted in errors were included in the determination of the mean movement time.

Results and Discussion

No-preview-constraint case. On the basis of least squares regression, the relationship between rotary arm movement time and movement ID was estimated as

$$\hat{Y} = -21.02 + 21.31\,X_1, \qquad [4]$$

where the unit of $\hat{Y}$ is 10^{-2} sec. The parameter estimates are based on average movement time over each 15-sec. period and then over Ss. The coefficient of multiple determination for this relationship was determined to be $R^2 = .96$, indicating an excellent fit for this regression or a highly significant ($p < .0005$) correlation between Y and X_1 of $r = .98$ (summary data are given in Table 1). On the basis of these data, the maximum information rate for this type of movement task is seen to be constant for different X_1 values at approximately 4.7 bits/sec; $1.58 \leq X_1 \leq 5.17$ in this experiment. This information rate is slightly lower than that for linear serial hand movements (determined by Kvålseth, 1973, to be 5.5 bits/sec) and .4 times that for arm movements in reciprocal tapping tasks (cf. Fitts, 1954).

Preview-constraint case. Least squares estimation for Equation 3 based on average movement time in 10^{-2} sec. (averaged for each S during 15-sec. period and then averaged across the 10 Ss) resulted in the following relationship,

$$\hat{Y} = 8.97 + 26.06\,X_1 + 8.03\,X_2. \qquad [5]$$

This first-order model gives an excellent fit to the experimental data with $R^2 = .98$. The regressor X_1 is by far the most "significant" of the 2 regressors in terms of its contribution to (the calculated valu[illegible] Specifically, on the basis of the [illegible] determination coefficients, which [illegible] found to be .93 and .41 for X_1 and [illegible] respectively, X_1 accounts for appr[illegible]mately 70% of the total contribution to [illegible] by the 2 regressors. However, as is se[illegible] from the data in Table 1, the addition[illegible] effect of X_2 is significant at the .05 [illegible]

From Equation 5, it seems plausib[illegible] to test the statistical hypothesis that $c = [illegible]/3$. The appropriate t statistic for this test was found to take on the value .20 with 9 degrees of freedom so that this hypothesis is clearly accepted at the .05 level. Thus, Equation 3 may be replaced by the model

$$Y = \beta_0 + \beta_1 X_3 + \epsilon;$$
$$X_3 = \log_2(2A/WP^{\frac{1}{3}}), \qquad [6]$$

where β_0 and β_1 are unknown constant parameters and ϵ denotes the error term. The ID variable X_3 is then the equivalent of X_1 when preview constraint is imposed and, although it is seen that X_3 may possibly assume negative values, only positive X_3 values were used in the present study.

On the basis of a least squares regression of Y on X_3, employing the same values of the variables Y, A, W, and P as those used in arriving at Equation 5, the estimates for β_0 and β_1 were determined to be

$$\hat{\beta}_0 = 12.00, \quad \hat{\beta}_1 = 25.72,$$

providing an R^2 of .97; the analysis of variance data corresponding to the test of the hypothesis that $\beta_1 = 0$ are given in Table 1. The resulting rate $dX_3/d\hat{Y} = 3.9 \approx \partial X_1/\partial\hat{Y}$ is seen to be 17% lower than the maximum information rate for the no-preview-constraint case. Furthermore, the marginal ID rate $\partial X_2/\partial\hat{Y} = 12.5$ is observed to be comparable to the maximum ID rate obtained by Fitts (1954) for linear arm movements.

Error rates. The percentage of movements that missed the indicated targets tended to be consistently higher in the no-preview-constraint case than when preview constraints were imposed, although the instructions to Ss were the same in the 2 cases. In the former case, the

average error rate (average across Ss for each of the 12 experimental conditions) ranged approximately 5%–15% and was highest for large X_1 values without appearing to be entirely systematically related to X_1. The average of this error rate across the X_1 values used was found to be about 10%, which was twice that of the preview-constraint case. In general, the errors appeared to be about equally distributed between overshoot and undershoot errors. For the preview-constraint case, it was established that task difficulty, as reflected by values of X_1 and X_2, had a significant effect on the error rate. The average error rates for each S were paired according to low index of difficulty level ($1.58 \leq X_1 < 3.58$ and $-4.32 \leq X_2 < -3.32$) or, equivalently ($.14 \leq X_3 < 2.48$) and high difficulty level ($3.58 \leq X_1 \leq 5.17$ and $-3.32 \leq X_2 \leq -2.32$) or, equivalently ($2.48 \leq X_3 \leq 4.40$) and, on the basis of the Wilcoxon signed-ranks test, the hypothesis of no difference between these levels was rejected at the .05 level.

Conclusion

This study has generalized Fitts's law for simple linear and serial arm movements to incorporate temporal motor responses involving rotary arm movements with preview constraints. It was demonstrated that the imposition of preview constraints on such peripheral motor tasks had a significant effect on movement time, error rates, and maximum information rate. The simple first-order linear models relating movement time to movement variable X_1, the preview variable X_2, and the composite variable X_3 were clearly appropriate formulations providing excellent fits to the experimental data generated. Of the 2 variables, X_1 and X_2, the latter was found to be the least "important" one in explaining the variation in movement time; its contribution to movement time was determined to be less than half that of X_1. Further observations resulting from imposing preview constraints were that the average error rate was reduced by some 50% while the maximum information rate was 17% below that of the no-preview-constraint case.

No attempt was made in the present study to determine if practice had any influence on the degree to which the preview constraint effected movement time. It is conceivable that there is an interaction between practice and preview so that the preview constraint has a greater effect on movement time early during the task performance than it has later when S may not have to rely as much on preview information. This point ought to be worth pursuing in another study.

The effect of preview constraints on the task parameters as determined in this study applies to simple, serial, and 1-dimensional rotary arm movements and may be quite different for other types of motor tasks. A further investigation is planned with objectives similar to the present study but involving linear movement tasks with and without different types of movement path constraints.

HABITUATION OF THE DIGITAL VASOCONSTRICTIVE ORIENTING RESPONSE

STEN E. LEVANDER[1]

DAISY SCHALLING[2]
Department of Forensic Psychiatry, Karolinska Institutet, Stockholm, Sweden

Changes in finger volume (FV) and finger pulse volume (PV) were measured by two pneumoplethysmographic methods. Eleven identical randomly spaced auditory stimuli were given. Five different habituation estimates were calculated; H-score, parametric beta, parametric correlation, Kendall's tau, and nonparametric beta. Both FV and PV responses habituated, PV responses faster than FV. The correlations between FV and PV responses were significant and moderately high. Some surprisingly low correlations were obtained among the different habituation estimates, indicating that the choice of habituation estimate is of great importance, and might influence the result profoundly. Differences in response latency found between FV and PV responses were discussed in terms of measurement technique.

Much psychophysiological research in recent years has been directed toward exploring empirical and theoretical aspects of habituation of orienting responses in different autonomic systems (Frankenhaeuser, Fröberg, Hagdahl, Rissler, Björkvall, & Wolff, 1967; Groves & Thompson, 1970; Lader & Wing, 1966; McDonald, Johnson, & Hord, 1964). Speed of habituation of electrodermal responses has been found to be a highly stable individual characteristic (Crider & Lunn, 1971) and there is evidence for at least moderate genetic determination (Lader & Wing, 1966).

Habituation is in general rapid for skin conductance (SC) responses. In regard to habituation of the digital vasoconstrictive response the evidence is equivocal. Davis, Buchwald, and Frankmann (1955) found significant habituation for pulse volume (PV) but not for finger volume (FV) responses. This dissociation was interpreted to indicate that PV and FV changes are dependent on different physiological systems. The difference in response latency found between the two measures was regarded by these authors as further evidence for this hypothesis. Their conclusions have been cited in subsequent review, e.g., Martin (1961). Burch (1961) also found habituation for PV responses. Unger (1964) found that 12 of 20 subjects reached a habituation criterion of three successive PV nonresponses to successive number of stimuli up to 36 stimulus presentations. Using the same habituation criterion Koepke and Pribram (1967) found that about half of the subjects habituated in PV, also with a variable number of tone stimuli up to 40. However, in a study by Lader (1965) there was no significant difference between the first four and the last four PV responses to repeated tone stimuli. Hare (1968) found indications of great intraindividual variability and resistance to habituation for PV responses in criminal subjects. Further, he noted that it was not unusual for several nonresponses to be followed by a number of responses of appreciable size.

The purpose of the present study was to investigate simultaneously the habituation of FV and PV responses to repeated auditory stimuli by a direct pneumoplethysmographic technique. Since there is a tendency to dishabituation in the vasoconstrictive orienting response, the use

of the simple habituation criterion of three successive nonresponses is questionable. Therefore different methods of estimating habituation were applied.

Method

Procedure

Subjects. Nineteen conscripts, 19–21 yr. old, served as *Ss*. Participation was voluntary and *Ss* were paid. The *Ss* were in good physical and mental health.

Auditory stimuli. Eleven sine-wave tones of 1,000 Hz., approximately 100-db. intensity, and 1-sec. duration were administered through a loudspeaker. This was placed 1 m. to the right of the subject. The intervals between the tones were randomized and varied between 35 and 60 sec.

Measurement of finger volume. A pressure recording system (Elema EMT 32) with a pressure transducer of capacitor microphone type and amplifier with a stepwise variable time constant was used. The transducer was connected to a plastic oncometer cuff via a short rigid plastic tube. The cuff was mounted airtight on the left long finger of the subject. To eliminate the fast pulse volume deflections, the recordings were made with a high time constant (3 db. down at .3 Hz.).

Measurement of pulse volume. A pressure transducer of piezoelectric type (Elema EMT 510, see Lund, 1964) was connected to a plastic oncometer cuff via a short rigid plastic tube. The cuff was mounted airtight on the left index finger of the subject. Time constant for the outfit was 2 sec. (transducer connected directly to the galvanometer amplifier of the Mingograph).

Recording instrument. An inkwriter of the Elmqvist fast-response type (Mingograph 81) was used. As a control variable the left-hand long-finger temperature was continuously monitored by a thermistor device.

Procedural detail. The experiment was performed in September, a period with stable weather conditions. The barometric pressure varied between 747- and 763-mm. Hg. The *Ss* came to the laboratory in the afternoon, after their normal duties. They were placed in an examination chair in a quiet room, in which the temperature varied between 21.5° and 23.5° C. The finger temperature of the subjects varied between 21.5° and 34.8° C. at the beginning of the stimulation period. A constant, faint, indirect light was used. The recording apparatus was kept in an adjoining room, from which the experimenter could observe the subject through a small window.

The left arm and hand of the subject was placed on a soft support so that the limb was in a position of rest, and so that the fingers were at the level of the sternal angle.

The procedure was explained to the subject, and several deep inspirations were practiced. Then the recordings were started. Thereafter all instructions to the subject were given through a tape recorder via a loudspeaker.

The experiment started with 10 min. of rest. Then the 11 tone stimuli were administered.

Treatment of Data

Of the measures obtained, only data pertaining to habituation of responses are reported in this paper (cf. Lidberg, Schalling, & Levander, 1972).

Finger volume. Any observable decrease of the finger volume occurring between 1.6 and 10 sec. from the onset of the stimulus was considered as a response. Responses within 1.6 sec. were disregarded. (There were eight such responses, 5% of the total number of responses.)

A response was quantified as the difference, in mm. recording paper, between the maximal deflection during 10 sec. after the stimulus and the mean level during 10 sec. before the stimulus. This value was then corrected for transducer sensitivity, electrical amplification, and the volume of the finger tip inserted into the cuff.

Pulse volume. Any observable decrease of the pulse volume occurring between 1.6 and 10 sec. from the onset of the stimulus was considered as a response. Responses within 1.6 sec. were disregarded. (There were six such responses, 4% of the total number of responses.)

A response was quantified as the difference, in mm. recording paper, between the mean of the three smallest consecutive deflections during 10 sec. before the stimulus, and the mean of the three smallest deflections during 10 sec. after the stimulus. The difference was expressed in percent of the mean of the three smallest deflections during 10 sec. before the stimulus.

Response latency. As the time constant of the two recordings differed, no meaningful comparisons between response latencies of FV and PV were possible.

Habituation. Five estimates of habituation were calculated. Parametric correlations and regressions were calculated for response size on the logarithm of stimulus numbers. The third of a series of 3 successive nonresponses were regarded as the end of a response sequence. Most subjects, however, did not reach that criterion, and thus their response sequence consists of 11 responses. As there was a significant positive correlation between slope and intercept (estimated first response) for the parametric regression equations, a habituation estimate (H score) according to the procedure described by Montagu (1963) was calculated, in which correction for differences in estimated first response is applied.

As the use of parametric statistics requires normal distributions, homoscedasticity, and linearity of regression equations, and as these requirements are not strictly satisfied in the present data, as in most other studies, two nonparametric methods were also applied. Kendall's tau is a nonparametric correlation coefficient, which is relatively insensi-

tive to ties as compared with the Spearman rank correlation coefficient. However, a correlation coefficient estimates not only the slope of an assumed regression curve, but also deviations of responses from the curve. Sen (1968) has described a nonparametric regression statistic, nonparametric beta, based on the theoretical work of Kendall. Calculation of individual confidence limits is possible.

Thus five main habituation estimates were calculated on the present data, three parametric estimates based on the plot of response size on log stimulus number—product-moment correlation (r), linear regression (beta and H score)— and two nonparametric estimates—Kendall's tau and nonparametric beta. Further, some other simple estimates of habituation were calculated to allow for a direct comparison with the findings in some earlier studies (t test between means of first four and last four responses, the Wilcoxon test, and number of responses to the criterion of three successive nonresponses).

Results

Mean responses to tones in FV and PV, expressed as percent of the first response of each subject are shown in Figure 1. The trend appears to be linear and decreasing for both measures, though it appears more pronounced for PV than for FV. The slopes of the regression lines were −.40 for FV and −.55 for PV.

The correlations between mean responses in FV and PV were .62 over subjects and .44 over stimuli. For individual subjects the correlations varied between −.22 and .98, 25% of the subjects having correlations above .90. Two subjects who had many spontaneous fluctuations obtained very low correlations, −.22 and .11.

The distributions of H score, parametric beta, tau, and nonparametric beta justified the use of the t test to estimate if there was a significant habituation trend for the group in FV and PV. The t values for mean habituation are seen in Table 1. For PV, all t values were highly significant, whereas for FV two estimates (tau and H score) were significant, one was almost significant (parametric beta), and one was nonsignificant (nonparametric beta). For FV, no subject reached the habituation criterion of three successive nonresponses.

* $p < .10$.
** $p < .05$.
*** $p < .01$.
**** $p < .001$.

There was a significant difference between the mean of Responses 2–5 and 8–11 (t = 3.43), and also significant habituation estimated by the Wilcoxon test (T = 28) for FV.

Of the five habituation estimates used only tau can be used for direct comparisons between FV and PV in regard to difference in habituation rate. A t test for correlated means showed that PV responses habituated significantly faster than FV responses, $t = 18.1$, $p < .001$.

Correlations among the five habituation estimates, first response obtained, and estimated first response (from the H-score procedure) are shown in Table 2 (FV) and Table 3 (PV). The correlations ranged from .66–.95 for FV and from .49–.92 for PV.

In Table 4 intercorrelations between FV and PV measures including estimates of habituation and obtained first response are given. The correlations ranged from .38–.73, with the correlations obtained between identical habituation estimates being generally slightly higher.

DISCUSSION

Mean habituation was highly significant for PV for all habituation estimates. For FV the result of the statistical analysis was inconclusive. As judged from the statistically most appropriate habituation estimate, nonparametric beta, FV responses did not habituate in this study. However, significant habituation for FV was obtained for all the other habituation estimates used except for the simple criterion of three successive nonresponses. In line with the findings of Davis et al. (1955) there was in the present data a significantly faster habituation for PV than for FV. However, in contrast to Davis et al., FV responses habituate as judged from most habituation estimates including that used by Davis et al. (Wilcoxon test). This discrepancy might be due to differences in the recording system. The transducer system in the present study ensures optimal reproduction of the human pulse wave (Cronvich & Burch, 1969). The

disadvantages of the pneumoplethysmographic technique, e.g., sensitivity for movements of the hand and for leakage in the pneumatic system, can easily be overcome as such artifacts are readily identified in the records (Lader, 1967). Impedance plethysmography as used by Davis et al. is an indirect method.

Lader (1965) did not find significant habituation for PV using *t* test between mean size of first four and last four responses as habituation estimate. This finding might in part be explained as an effect of the type of response measure used by this author. A PV response was defined as the difference between the *smallest* pulse volume deflections occurring within 10 sec. of the onset of the stimulus and the *average* of six consecutive beats immediately before the stimulus. In that way, statisically, some of the responses obtained may be artifacts.

Increased drowsiness as a monotonous experimental situation proceeds may result in dishabituation and an uneven course of the curves. In the study by Lader (1965), which included a rest and a tone stimulation period, the pulse volume responses diminished at first, but they tended to increase again; this increase was accelerated by administration of barbiturates. Habituated and small cardiovascular responses tend to reappear and become large during drowsiness and sleep (McDonald et al., 1964; Pampiglione & Ackner, 1958). In the present study, the subjects were tested in the late afternoon, after a day's work, which might have made them prone to drowsiness. It is noteworthy that despite this the estimates of mean habituation in PV used in the present study were highly significant.

Davis et al. (1955) found that response latency was greater for FV than for PV. Operationally the two variables are defined in terms of different frequency spectrum, i.e., bandwidth, regardless of the fact that the time derivate ($\dot{v}$) of very large FV responses might approach the corresponding value for ordinary PV deflections. Electronically the two measures are separated by means of low pass (FV) and high pass (PV) filters. Such filters introduce delays of transient signals, different for different frequency bands. Thus a recorded difference in response latency between [illegible] and PV, is, at least in part, an artifact, [illegible] duced in the electronic system. For [illegible] large responses and the high frequency li[illegible] used in the present study this delay was 2 [illegible] Thus, although a highly significant difference in response latency was found between FV and PV, FV response latency being greater this finding cannot be interpreted in physiological terms. Davis et al. (1955), who found a similar difference between FV and PV, have interpreted their findings as a physiological difference.

Physiologically it is reasonable to regard FV as reflecting the tone in the venules and small veins (capacitance vessels) and PV as reflecting the tone in the arterioles and precapillaries (resistance vessels). One might expect a dependency between these two measures both on a blood flow dynamics and a neural basis. In the finger skin vessels, both for capacitance and resistance vessels, there are exclusively vasoconstrictive sympathetic fibers with noradrenaline as the transmitter (Shepherd, 1963).

The correlation between FV and PV responses was significant but moderately high. There were great interindividual differences with regard to intraindividual correlations, ranging from −.22–.98. The interpretation of these differences is uncertain. The strictly defined mechanical method of evaluation of responses used, which did not allow for adjustments due to, e.g., spontaneous fluctuations may be a source of error variance. However, a more flexible evaluation of the responses would probably have diminished the reliability of the measures.

Within each system the correlations among the five different habituation estimates are sometimes surprisingly low, indicating that the choice of habituation estimate profoundly influences the conclusion as to whether habituation has or has not occurred in the system.

Three of the habituation estimates used in the present study are of special interest: H score, because this measure has been widely accepted and used as a habituation estimate, and tau and nonparametric beta, because these two measures have certain statistical

advantages. Intercorrelations between FV and PV for these habituation estimates are somewhat lower than the corresponding intercorrelations within PV and FV. There is thus a certain independence, intraindividually, between the FV and PV response sequences with regard to habituation. This might be interpreted partly as an effect of the measurement procedure and partly as a physiological difference, the relative importance of which is uncertain.

It might be concluded that both FV and PV responses habituate, that PV responses habituate faster than FV responses, and that there is a certain independence between the two physiological variables, in regard to both the individual response sequence and habituation.

MEMORIAL STRATEGY AND IMAGERY

AN INTERACTION BETWEEN INSTRUCTIONS AND RATED IMAGERY[1]

DONALD ROBBINS,[2] JAMES F. BRAY, JAMES R. IRVIN, AND PHILLIP S. WISE

Emory University

Two studies are reported in which memory instructions (interactive imagery, separation imagery, and rote repetition) and rated imagery values of the stimulus and response terms (high and low) were manipulated in a paired-associate task. The results indicated that interactive-imagery instruction led to superior performance in contrast to separation-imagery or rote-repetition instruction only with high-imagery cues. This interaction between memorial strategy and rated imagery is a confirmation of the "elusive" interaction expected by Paivio's conceptual-peg hypothesis.

Mental imagery has been shown to lead to very high levels of recall performance in paired-associate memory tasks (e.g., Paivio, 1969, 1971). In these studies, when rated imagery (Paivio, Yuille, & Madigan, 1968) was varied, Paivio (1969) found imagery effects for both the stimulus and response members of a noun pair, although the stimulus effect is apparently larger. In particular, Paivio (1969) and Humphreys and Yuille (1973), among others, have constructed noun–noun pairs representing a factorial combination of high and low imagery values for each member. They have found the following ordering of paired-associate performance for the 4 pair types: high–high (HH) > high–low (HL) > low–high (LH) > low–low (LL).

Studies have also been conducted where *S*s have been given specific instructions on how to memorize, using high-imagery noun–noun pairs. Substantially better recall performance has been found for *S*s given interactive-imagery instructions in contrast to those given rote-repetition (Bower & Winzenz, 1970; Schnorr & Atkinson, 1969; see also Paivio, 1971, for an excellent review) or separation-imagery instructions (Bower, 1970).

Thus, we have 2 classes of studies: those varying rated imagery of the stimulus and response members of noun–noun pairs and those manipulating the instructional set (or memorial strategy) using pairs of nouns high in rated imagery. In order to determine if the same processes are operating in both types of studies, there is a need to study the possible nteraction between the two. As a result, imagery effects may be better understood if we manipulate memorial strategy instructions as well as rated imagery values. Paivio (1971) studied the interaction between rated imagery and imaginal and verbal mediators. He reported mixed success in finding a statistically significant interaction between instructional set (imaginal, verbal mediation, and rote repetition) and imagery values (noun pairs of high or low rated imagery).

EXPERIMENT I

In Experiment I, 3 groups of *S*s were given either interactive-imagery, separation-imagery, or rote-repetition instructions in memorizing a list of paired associates. The list contained pairs in which the stimulus and response members were a factorial combination of high and low imagery values.

Method

Subjects. Sixty *S*s, obtained from the introductory psychology *S* pool, partially fulfilled a course requirement by participating in a 45–60-min. session.

Material and design. Each *S* was given a list of 20 noun–noun pairs using a paired-associate study–test procedure. Four types of pairs were used, in which the stimulus and response members of a pair were of HH, HL, LH, or LL imagery values, re-

---

spectively, based on the Paivio et al. (1968) norms. Five pairs of each type were used, yielding a 20-pair list. The mean values on the imagery scale were 6.72 and 2.16 for high- and low-imagery nouns, respectively. It should be noted that for the material used in this study the correlation between rated imagery and rated concreteness was .97, and that between rated imagery and rated meaningfulness was .90.

The *S*s were randomly assigned to 1 of 3 groups and were instructed to memorize the noun pairs by either overt rote repetition of the noun pairs (RR), constructing an interactive visual image (II), or constructing an image of the objects denoted by the nouns in a noninteracting and separated "visual space" (SI), after Bower (1970). There were 20 *S*s in each group.

Procedure. Each *S* was tested individually. A paired-associate study–test procedure was used. On each study trial, *S* was shown a sequence of 20 noun pairs at a 6-sec. rate with a Kodak Carousel projector. On these study trials, *S* was to memorize the noun pairs in accordance with the instructions given at the beginning of the study. On study trials, the nouns were adjacent to each other, separated by a dash. A study trial was then followed by a test trial, on which the stimulus member of each pair was presented at a 6-sec. rate on the left-hand side of the slide, followed by a dash. The responses were made vocally by *S*. No information was given to *S* on the test trials. Study and test trials were alternated until *S* met a criterion of 3 consecutive successful recalls of the entire list. For each *S* on each trial, the list was presented in a different random order on both study and test trials with the restriction that 3–5 items intervene between a study trial of a particular pair and a test of that pair (and vice versa). After reaching criterion, *S* was engaged for the next minute; generally, *S*s were asked how they memorized the noun pairs. They were then told to recall all of the words in the study in any order.

Results

Since much of the research investigating instruction or strategy effects are single-trial studies, we will report first-test-trial data primarily. The mean proportions of correct responses on the first test trial for all 3 groups for the 4 pair types are shown in Figure 1. For the HH and HL pairs, Group II showed higher levels of recall than either Group RR or SI, with little differences between the 3 groups for LH and LL pairs. In addition, recall performance for Group II was ordered HH > HL > LH > LL, while that for Groups SI and RR was ordered HH > HL = LH > LL.

These observations were confirmed by an analysis of variance (as shown in Table 1) that revealed significant effects due to stimulus and response imagery and the Group × Stimulus Imagery interaction. This overall analysis was partitioned into 2 orthogonal components—one comparing Groups SI and RR, and the other comparing Group II with Groups SI and RR combined. The analysis comparing Groups SI and RR revealed significant effects of stimulus imagery, $F\ (1,\ 38) = 27.30$, $p < .05$, and response imagery, $F\ (1,\ 38) = 13.82$, $p < .05$, but not of group, $F\ (1,\ 38) = 1.65$, $p > .05$, or any other comparison. The analysis comparing Group II to Groups SI and RR combined revealed that the group effect was not significant, $F\ (1,\ 58) = 2.93$, $.05 < p < .10$, although the 3 effects found for the overall analysis comparing the 3 groups including the interaction were. The analysis of the mean total number of errors per subject item to criterion performance was similar to that of the first test trial. Since the statistical analyses of the mean total errors resulted in the same statistical conclusions as those for the first test trial, as shown in Table 1, these data are not presented, in order to avoid redundancy. In addition, high levels of recall of the pairs were found for all con-

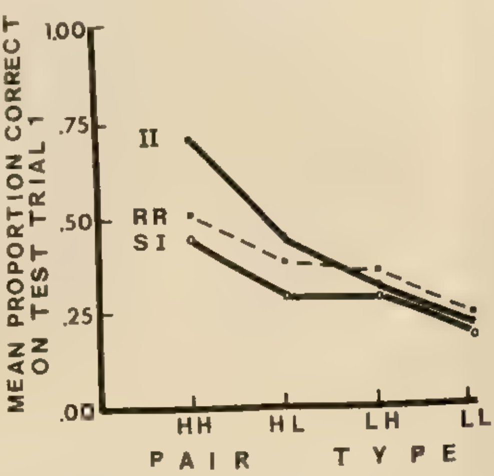

FIGURE 1. Mean proportion of correct recalls as a function of pair type (H = high imagery, L = low imagery) for the groups given interactive-imagery (II), separation-imagery (SI), or rote-repetition (RR) instructions in Experiment I.

ditions on the free-recall task, with little difference between groups.

Discussion

The major results of this study revealed that *Ss* given interactive-imagery instructions showed superior recall performance on the first test trial only for HH and HL pair types in contrast to *Ss* given either separation-imagery or rote-repetition instructions. These results confirm previous findings where only HH pairs have been used (Bower, 1970; Bower & Winzenz, 1970; Schnorr & Atkinson, 1969). The results of the present study also indicate that the superiority resulting from interactive-imagery instructions depends on the rated imagery value of the stimulus term. Specifically, Group II was superior in recall performance only for pairs with high-imagery stimuli. No difference due to instructions was found for pairs with low-imagery stimuli. Furthermore, the recall performance on the first test trial for *Ss* given interactive-imagery instructions was ordered HH > HL > LH > LL. The results also revealed no difference between Groups SI and RR. In addition, in contrast to Group II, the recall performance on the first test trial for Groups SI and RR was ordered HH > HL = LH > LL. Since a number of investigators have reported HL > LH when no specific instructions are given (e.g., see Paivio, 1969, 1971) we attempted to replicate the interaction found between instructions and rated imagery.

Experiment II

In an attempt to replicate the major results of Experiment I, 2 groups of *Ss* were given either interactive- or separation-imagery instructions in a paired-associate study–test procedure. Half of the noun–noun pairs were HL and the other half LH in rated imagery values.

Method

Subjects. Forty *Ss*, obtained from the introductory psychology *S* pool, partially fulfilled a course requirement by participating in a 15–20-min. session. None of these *Ss* had participated in Experiment I.

Procedure. The *Ss* were tested in small groups of up to 5 people. These small groups were randomly assigned to 1 of 2 groups ($n = 20$) and were instructed to memorize the noun pairs by either constructing an interactive visual image (II) or by using separation imagery (SI), as in Experiment I. A 46-pair list was used. On each slide, one word was at the top and the other at the bottom. Half of the noun–noun pairs were HL, while the other half were LH. On the study trial, the pairs were presented at a 6-sec. rate with a Kodak Carousel projector. The first 3 and last 3 pairs represented a primacy and a recency buffer, respectively. These pairs were not tested. The test trials were presented at a 6-sec. rate. For each pair type, half of the cue words in the test trial were high in rated imagery, and the remaining half were low in rated imagery.

As a result, the HL and LH conditions may be defined in terms of the cue word used in a test trial. Since no effect was found due to location of the

cue word (top or bottom), no further mention of this variable will be made. Each *S* recorded his responses to the cue words on a separate sheet. In addition, each small group was given a different random order of the list in both the study and test phases, and the particular cue used during testing was balanced across *S*s.

Results and Discussion

For *S*s given interactive-imagery instructions, high-imagery cues led to .64 proportion correct recalls in contrast to .45 proportion for low-imagery cues. For *S*s given separation-imagery instructions, these proportions were .33 and .29 for high- and low-imagery cues, respectively. These results were subjected to an analysis of variance which revealed significant effects of instruction, $F\ (1, 38) = 16.30$, $p < .05$, rated imagery, $F\ (1, 38) = 18.44$, $p < .05$, and a significant interaction between these effects, $F\ (1, 38) = 8.46$, $p < .05$. Thus, interactive-imagery instructions led to a large difference in recall performance for high- in contrast to low-imagery cues, while separation-imagery instructions did not. Thus, we replicated the interaction between instructions and rated imagery found in Experiment I. However, in Experiment II, Group II was superior to Group SI for both HL and LH cues, although for Group II, performance was ordered HL > LH, while for Group SI, HL = LH.

Conclusion

The finding of an interaction between instructions (memorial strategy) and rated imagery values is precisely the interaction that would be expected by the conceptual-peg hypothesis (Paivio, 1971). In particular, it appears to be a confirmation of the interaction that Paivio (1971, p. 366) has predicted but has found to be elusive. It also appears to support the "integrated structure" notion of Begg (1972), as well as the "relational association" of Bower (1970, 1973), when taken together with a retrieval axiom, namely the conceptual-peg hypothesis.

EYELID CONDITIONING PERFORMANCE WHEN THE MODE OF REINFORCEMENT IS CHANGED FROM CLASSICAL TO INSTRUMENTAL AVOIDANCE AND VICE VERSA[1]

JOSEPH B. HELLIGE AND DAVID A. GRANT[2]

University of Wisconsin—Madison

Eyelid conditioning performance during Stage II instrumental avoidance reinforcement was examined after 0, 5, 10, or 20 Stage I classical reinforcements and eyelid conditioning performance during Stage II classical reinforcement was examined after 0, 5, 10, or 20 Stage I instrumental avoidance reinforcements. Response rate on the initial Stage II trial block of instrumental avoidance conditioning was a progressively increasing function of the number of Stage I classical reinforcements. Response rate on the initial Stage II trial block of classical conditioning was greater if 5, 10, or 20 Stage I instrumental avoidance reinforcements had been given than if no Stage I instrumental avoidance reinforcement had been given. Response efficiency on the initial trial block of Stage II also indicated positive response transfer from instrumental avoidance reinforcement to classical reinforcement. The results were discussed in terms of the complexities of the reinforcement and extinction processes involved in classical and instrumental avoidance conditioning of eyelid responses.

Some of the interrelationships among the responses learned under classical and instrumental avoidance reinforcement were investigated by shifting the mode of reinforcement from classical to instrumental avoidance and vice versa. As Kimble (1961, chap. 4) has pointed out, the experimental investigation of the interrelationships among the responses learned under different modes of reinforcement has proved to be extremely difficult. Distinguishing between paradigms in strictly operational terms is only an initial step in a scientific investigation of the various modes of reinforcement. Increasing attention must be given to the psychological processes involved. When note is taken of the positive and negative response transfer effects that may be observed in two-stage experiments in which the modes of reinforcement are shifted, more light may be shed on the similarities and differences of the psychological processes involved in each mode of reinforcement.

If a response learned under one mode of reinforcement can be transferred to another mode, then initial response frequency and efficiency after a shift in the mode of reinforcement should be a positive function of the number of preshift reinforcements. Grant, Kroll, Kantowitz, Zajano, and Solberg (1969) reviewed several studies which have demonstrated positive transfer from classical to instrumental conditioning and positive transfer of differential classical to differential instrumental conditioning but found no reports of positive transfer from instrumental to classical conditioning.

Grant et al. (1969) investigated transfer of responses from Stage I classical reinforcement to Stage II instrumental reward reinforcement and vice versa. They found that response rate during subsequent instrumental reward conditioning was a progressively increasing function of the number of Stage I classical reinforcements. In addition, the V or C classification of an S's eyelid responses using the Hartman–Ross (1961) criterion was usually the same in Stage I classical conditioning and Stage II instrumental reward conditioning. However, following Stage I instrumental reward training, the response rate during Stage II classical conditioning was not an increasing

[1] This research was supported in part by funds provided to the second author by the U.S. Public Health Service in Research Grant MH-06792.

monotonic function of the number of Stage I instrumental reward reinforcements. In fact, response rate during Stage II classical conditioning was slightly higher if no previous instrumental reward reinforcements had been given than if 20 had been given. Further, there was no significant tendency for the V or C classification of conditioned responses (CRs) in Stage II classical conditioning to correspond to the V or C classification of the responses in Stage I instrumental reward conditioning.

The classical conditioning reinforcement used by Grant et al. (1969) was a corneal airpuff—a mildly aversive unconditioned stimulus (UCS)—while the instrumental reinforcement was a symbolic reward. Before Stage I classical conditioning, their *S*s were given neutral instructions asking them to adopt a passive attitude, but before instrumental reward conditioning the *S*s were asked to adopt what amounted to an active, problem-solving attitude. The *S*s shifted from classical to instrumental reward conditioning were initially given neutral instructions and were later given the new set of instrumental reward instructions before the shift. However, the *S*s shifted from instrumental reward to classical conditioning received only the Stage I instrumental reward instructions and were not reinstructed before the shift. The asymmetry of response transfer found by Grant et al. may have been caused, at least in part, by (*a*) the asymmetry of response transfer from paradigms using aversive reinforcement to paradigms using reward reinforcement and (*b*) the asymmetry of preshift reinstruction.

Grant et al. (1969) suggested that another possible reason for the asymmetry of response transfer found by them was that the CR produced by classical conditioning was adequate to trigger the instrumental reward devices, but the response typically learned during their instrumental reward phase was of low amplitude and of a topography that would be ineffective in protecting the cornea in the subsequent classical conditioning. In one case, then, the initial classical conditioning made available a response which would be effective in the subsequent instrumental reward phase and positive, systematic transfer was obtained. In the opposite case, the initial instrumental reward training made available a response which would not be effective in the subsequent classical conditioning phase and nonsystematic, and perhaps negative, transfer performance was obtained.

Using the same transfer paradigm and avoiding some procedural problems encountered by Grant et al. (1969), the present experiment was designed to compare the transfer of responses conditioned by classical and instrumental avoidance reinforcement. The corneal airpuff can be used in both classical conditioning and instrumental avoidance training (e.g., Hansche & Grant, 1965; Kimble, Mann, & Dufort, 1955; Logan, 1951; Moore & Gormezano, 1961), so that the need for preshift reinstruction and problems with rewarding versus aversive stimuli can be eliminated. In addition, Massaro and Moore (1967) have examined the latency and recruitment of classically conditioned CRs and avoidance responses. Their analyses showed that the instrumental avoidance procedure produced a response topography similar to that of the classically conditioned CR. The implication is that the response learned during Stage I instrumental avoidance reinforcement should be effective in protecting the cornea during Stage II classical conditioning.

Method

Apparatus. The apparatus and laboratory were similar to those described by Grant et al. (1969). The *S* was placed in a soundproofed chamber. He sat in an ophthalmological examination chair facing a rectangular wooden enclosure painted flat white and illuminated to approximately 1 mL. At the back of the wooden enclosure were two ground-glass disks, approximately 10 cm. in diameter and separated from center to center by 66 cm. The disks were at eye level and approximately 120 cm. in front of the *S*. Between the ground-glass disks was a 45 × 30 cm. ground-glass screen which was not used in the experiment. The intertrial illumination of the two disks was approximately 1.5 mL. The *S* wore a plastic headset that was designed originally to support a welder's face mask. To it was attached a potentiometer to pick up the eyelid movement and a tubular jet from which the corneal airpuff could be delivered. The potentiometer was coupled

to the right eyelid of the *S* by means of a piano wire that was taped to the eyelid with plastic electrician's tape and inserted into a length of hypodermic tubing attached to the shaft of the potentiometer by a hinged coupling.

Procedure. The conditioned stimulus (CS) was the simultaneous illumination of the two ground-glass disks to a luminance of 1.9 mL. for a duration of 700 msec. The UCS, when given, was a 2 psi corneal airpuff lasting 200 msec. and delivered 500 msec. after CS onset. The intertrial interval varied from 15 to 35 sec., with a mean of 25 sec. During the instrumental avoidance training an eyelid response that produced a 1 mm. or greater deflection of the oscillograph first time-derivative pen between 200 and 500 msec. after CS onset was defined as an avoidance response (AR). An AR caused the airpuff to be omitted. A 1 mm. or greater deflection of the derivative pen corresponded to an eyelid closure of approximately 1 mm. Detection of an AR was accomplished by means of a Schmitt trigger and associated timing and logic circuitry. The puff was delivered on every trial during the classical conditioning sections of the experiment. The definition of a classically conditioned response (CR) was similar to the definition of an AR except that the scoring interval extended to 540 msec. after CS onset.

The *S*s were divided into eight experimental groups and were given neutral instructions in which they were asked not to aid or inhibit their natural eyelid responses. Four of the experimental groups (CL–AV groups) received, respectively, 0, 5, 10, or 20 classically reinforced pairings of the CS and UCS during Stage I of the experiment. They then received 60 instrumental avoidance conditioning trials during Stage II followed by 30 extinction trials with the CS alone. These four groups will be referred to as CL0-AV60, CL5-AV60, CL10-AV60, and CL20-AV60, respectively. The *S*s in the remaining four groups (AV-CL groups) received 0, 5, 10, or 20 instrumental avoidance conditioning reinforcements during Stage I of the experiment and then received 60 classical conditioning trials during Stage II followed by 30 extinction trials. These four groups will be referred to as AV0-CL60, AV5-CL60, AV10-CL60, and AV20-CL60, respectively.

A maximum of 60 trials was permitted during Stage I for *S*s in the AV-CL groups. To match groups, data from *S*s in the AV5-, AV10-, and AV20-CL60 groups were retained only if the *S* had made at least five ARs in 25 trials, because pilot experiments indicated that only *S*s who do so will typically go on to make 20 or more ARs in 60 trials. This criterion resulted in 38 rejections, approximately equally distributed among these three groups. Twelve additional *S*s were run in Group AV0-CL60 so that the data from the 12 *S*s with the lowest response rates could be rejected, resulting in an approximately equal number of rejections in each of the four AV-CL groups.

At the conclusion of the experimental session *S*s were given a questionnaire asking for their impressions of the experiment, how noxious they felt the airpuff to be, whether or not their responses were "voluntary," and whether they thought at any time that their behavior would cause the airpuff to be omitted.

Subjects. The *S*s were 80 men and 80 women student volunteers from introductory psychology courses at the University of Wisconsin—Madison. Assignment of 10 men and 10 women to each of the eight experimental groups was random until it became necessary to balance for sex.

Results

Summary of Stage I data. Table 1 gives (A) the average number of CRs or ARs, (B) the average number of trials, and (C) the average number of airpuff reinforcements during Stage I for each of the four CL-AV and the four AV-CL groups. During Stage I, the AV-CL groups received, on the average, more trials and gave more responses than the corresponding CL-AV groups. The differences between the four CL-AV groups in the mean number of Stage I airpuffs are larger than the corresponding differences between the four AV-CL groups.

Response form and transfer. All *S*s who gave one or more responses during Stage I were classified as V-form or C-form responders during Stage I, using the Hartman–Ross (1961) response-slope criterion, and were independently reclassified during Stage II. Of the 46 *S*s in the CL-AV groups who could be so classified 35 *S*s had the same V or C classification during both stages and 11 *S*s did not. Of the 60 *S*s in the AV-CL groups for whom the Stage I classification was available 50 *S*s had the same V or C classification during both stages and 10 *S*s did not. Two significant chi squares ($p < .001$), one for the CL-AV groups and one for the AV-CL groups, showed that in both cases there was a significant tendency for *S*s to have the same V or C classification in both Stage I and Stage II.

Stage II avoidance response frequency. Figure 1 shows the percent ARs given during each of the six 10-trial blocks of instrumental avoidance conditioning trials with the number of previous classical reinforcements as the parameter. The data of Vs and Cs are shown in the upper and lower panels, respectively. The final training point given for each group in Figure 1 is

the percent CRs for the final five trials of Stage I classical training. For Group CL0-AV60 the final training point is the percent ARs given on the first trial of instrumental avoidance conditioning. Since approximately 40% of the *S*s run in the AV-CL conditions were rejected on the basis of low response frequency, the 12 highest responders in the CL-AV groups are most likely to be similar to the AV-CL *S*s in terms of base response rate and conditionability. Although the results based on all CL-AV *S*s are presented, it is important to note that the pattern is identical when the data of only the high-frequency responders from the CL-AV groups are considered.

During the first 10-trial block of Stage II instrumental avoidance transfer response frequency was a progressively increasing function of the number of previous classical reinforcements, F (3, 76) = 4.95, $p < .005$. In general, during the first trial block, having had 5 or 10 previous classical reinforcements produced more responding than having had no previous classical reinforcement, and having had 20 previous classical reinforcements produced more responding than having had 5 or 10 previous classical reinforcements. Possible exceptions to this pattern are the Cs in Group CL5-AV60, but there were only four Cs in that group, so that the reliability of those data is questionable. The effect of the number of previous classical trials diminished quickly, and during the last three 10-trial blocks there was no significant effect of the number of previous classical reinforcements, F (3, 76) < 1.

Averaged over all AV trial blocks, the response rate of Vs was significantly higher than the response rate of Cs, F (1, 72) = 9.74, $p < .005$. In addition, although the initial effect of the number of previous classical reinforcements was greater for Vs than for Cs, the effect persisted longer for Cs, as indicated in a significant Number of Stage I Reinforcements × Response Form × Trial Blocks interaction, F (15, 360) = 1.75, $p < .05$.

Stage II classical conditioned response frequency. Figure 2 shows the percent CRs given during each of the six 10-trial blocks of classical conditioning with the number of previous instrumental avoidance reinforcements as the parameter. The data of Vs and Cs are shown in the upper and lower panels, respectively. The final training point is the percent ARs for the final five trials of Stage I, except for Group AV0-CL60 where the final training point is the percent CRs given on the first trial of Stage II.

The frequency of CRs during the first 10-trial block of Stage II was greater if 5, 10, or 20 ARs had been given during Stage I than if no ARs had been given, but there were no systematic differences in CR frequency between *S*s in the AV5-, AV10-, and AV20-CL60 groups during any of the 10-trial blocks. These observations were supported by a significant difference in the percent CRs on the first 10-trial block during Stage II as a function of the number of previous instrumental avoidance reinforcements, F (3, 76) = 29.26, $p < .001$, and the fact that the corresponding differences among the AV5-, AV10-, and AV20-CL60 groups were not statistically significant, F (2, 57) < 1. The response rate of the *S*s in Group AV0–CL60 reached an asymptotic level quickly, so that the number of previous instrumental avoidance reinforcements produced no significant differences in classical CR frequency during the final three 10-trial blocks of Stage II.

TABLE 1

STAGE I SUMMARY DATA

Group	A. Mean number of CRs or ARs	B. Mean number of trials	C. Mean number of airpuff reinforcements
CL0 -AV60	0	0	0
CL5 -AV60	.90	5	5
CL10-AV60	2.70	10	10
CL20-AV60	9.50	20	20
AV0 -CL60	0	0	0
AV5 -CL60	5	14.30	9.30
AV10-CL60	10	23.35	13.35
AV20-CL60	20	36.80	16.80

Note. Abbreviations: CR = conditioned response; AR = avoidance response. See text for explanation of group names.

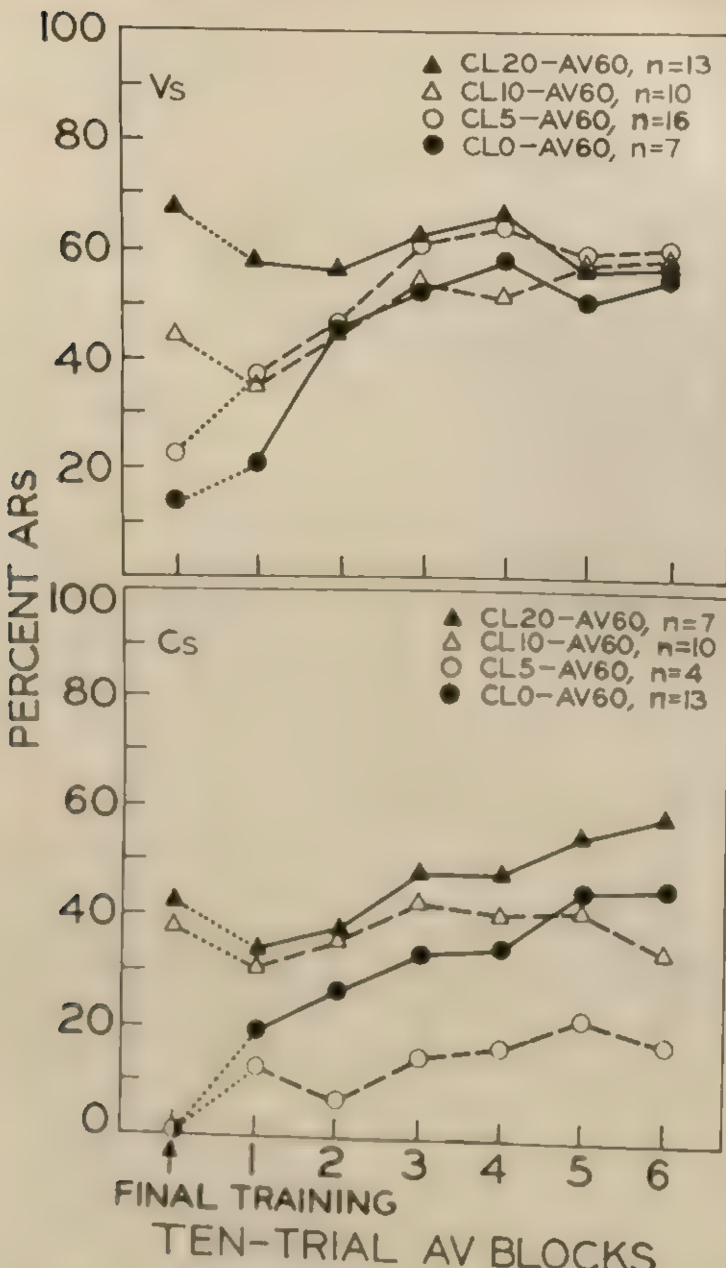

FIGURE 1. Percent avoidance re[illegible] six 10-trial blocks of Stage II [illegible] number of Stage I classi[illegible] with the [illegible] The data of [illegible] lower panel. The five trials of Stage [illegible] Group CL0-AV60 where the final training [illegible] Stage II.

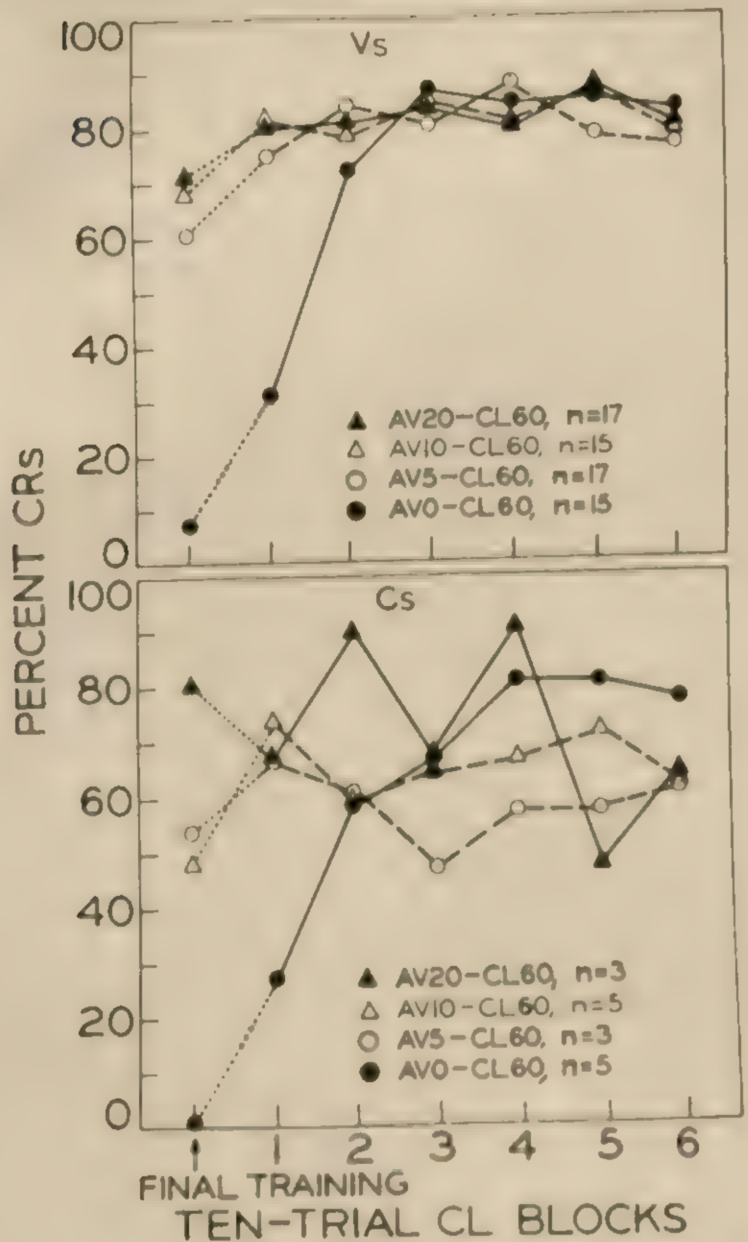

FIGURE 2. Percent conditioned [illegible] (CRs) given during each of the six 10-trial blocks of Stage II clas[illegible]itioning with the number of Stage I instrumental avoidance reinfor[illegible] the parameter. (The data of Vs are in the upper panel and the da[illegible] of Cs are in the lower panel. The final [illegible] percent CRs given on the first trial of Stage II.)

As Figure 2 shows, averaged over all Stage II trial blocks, Vs gave more CRs than Cs, $F\ (1, 72) = 12.38$, $p < .001$. In addition, the trend over Stage II trial blocks as a function of the number of Stage I avoidance reinforcements was different for Vs and Cs, as indicated by a significant Trial Blocks × Number of Stage I Reinforcements × Response Form interaction, $F\ (15, 360) = 1.75$, $p < .05$. Figure 2 also shows that only for the *S*s in Group AV0-CL60 did CR frequency increase over the successive trial blocks of classical conditioning. This is reflected in a significant Trial Blocks × Number of Stage I Reinforcements interaction, $F\ (15, 360) = 8.07$, $p < .001$.

Stage II response efficiency. Response Efficiency (PUFAMP/MAXAMP) was defined as the amplitude of eyelid closure at 500 msec. after CS onset (PUFAMP) divided by the maximum amplitude of eyelid closure between 200 and 700 msec. after CS onset (MAXAMP). During classical conditioning, MAXAMP typically occurred between 500 and 700 msec. after CS onset, making PUFAMP/MAXAMP similar to some of the efficiency measures used by Martin and Levey (1965; 1969, pp. 63–67). The mean PUFAMP/MAXAMP score was computed for each *S* on each 15-trial block of Stage II.

The mean PUFAMP/MAXAMP scores increased monotonically over the four 15-trial blocks of Stage II classical conditioning in the AV-CL groups, but did not increase over the 15-trial blocks of Stage II instrumental avoidance conditioning in the CL-AV groups. This difference between the linear trends of the AV-CL groups and the CL-AV groups was statistically significant, $F\ (1, 148) = 11.[illegible]2$, $p < .001$. Analysis of variance further indicated that the within-groups error variance of the PUFAMP/MAXAMP scores was significantly smaller during classical conditioning (AV-CL groups, error variance = .012) than during instrumental avoidance conditioning (CL-AV groups, error variance = .021), $p < .01$.

TABLE 2

MEAN PUFAMP/MAXAMP SCORES ON THE FIRST 15-TRIAL BLOCK OF STAGE II

Groups	Number of Stage I reinforcements			
	0	5	10	20
CL-AV				
Vs(n = 46)	.704	.813	.685	.796
Cs(n = 34)	.683	.838	.619	.749
AV-CL				
Vs(n = 64)	.571	.671	.747	.809
Cs(n = 16)	.444	.470	.475	.658

Note. Abbreviations: PUFAMP = amplitude of eyelid closure at 500 msec. after onset of conditioned stimulus (CS). MAXAMP = maximum amplitude of eyelid closure between 200 and 700 msec. after CS onset.

Table 2 presents the mean PUFAMP/MAXAMP scores on the first 15-trial block of Stage II for Vs and Cs in the CL-AV groups and the AV-CL groups. For the CL-AV groups the mean PUFAMP/MAXAMP scores on the first trial block of Stage II were not a monotonically increasing function of the number of Stage I reinforcements, but for the AV-CL groups the progressive increase in PUFAMP/MAXAMP scores was statistically significant, $F\ (3, 76) = 3.91$, $p < .025$.

An analysis of variance of the mean PUFAMP/MAXAMP scores for the AV-CL groups, with number of Stage I reinforcements (R), V or C response form (F) and trial blocks (B) as variables, yielded several interesting results. The Vs gave significantly higher PUFAMP/MAXAMP scores than the Cs, $F\ (1, 72) = 27.96$, $p < .001$, and their CRs showed an initially more rapid rate of PUFAMP/MAXAMP increase than the Cs, F × B interaction, $F\ (3, 216) = 3.59$, $p < .025$. The overall increase in PUFAMP/MAXAMP over trial blocks was also significant, $F\ (3, 216) = 7.57$, $p < .001$.

Extinction. In neither the CL-AV groups nor the AV-CL groups was response frequency during extinction a function of the number of Stage I reinforcements.

Questionnaire. The answers to the postexperimental questionnaire were astonishing in one respect. Of the 140 *S*s receiving some instrumental avoidance conditioning, not one reported that any of his responses would cause omission of the airpuff. The postexperimental inquiry thus confirms the reports of Massaro and Moore (1967).

Discussion

[illegible] mary results of the present study and [illegible] onship to the results of Grant et al. [illegible] 69) will be discussed in terms of their implica[illegible] regarding the nature of the processes [illegible] volved in classical and instrumental [illegible] conditioning.

[illegible] *ge II performance.* In the CL-AV [illegible] frequency during the first 10-trial [illegible] strumental avoidance conditioning [illegible] age II was a progressively increasing [illegible] ion of the number of previous classical [illegible] forcements. In addition, the *Ss* tended to retain the same V-C classification in Stage I and Stage II. These results essentially parallel the results on transfer from classical to instrumental reward reinforcement reported by Grant et al. (1969) and are consistent with the position that the exact CR learned under classical reinforcement is retained when the mode of reinforcement is changed.

Avoidance response efficiency, as defined by [illegible] IP/MAXAMP measure, was not a [illegible] ly increasing function of the number of Stage I classical reinforcements. The absence of an increasing PUFAMP/MAXAMP function at the beginning of Stage II is not [illegible] because, as Table 1 shows, the [illegible] ber of CRs given during Stage I [illegible] L0-, CL5-, and CL10-AV60 was 0, .9, [illegible] .7, respectively. When groups do not differ appreciably in the small number of CRs that have been given, systematic differences in topography measures should not be expected. Perhaps maximization of the PUFAMP/MAXAMP ratio depends upon the occurrence of enough CRs so that processes such as exteroceptive and proprioceptive feedback can influence response timing mechanisms (Grant, 1972), although Martin and Levey (1969, pp. 93–98) argue that the occurrence of overt responses may not be necessary for the development of response topography.

In the AV-CL groups, CR frequency during the first 10-trial block of Stage II was greater if 5, 10, or 20 instrumental avoidance responses had been given during Stage I than if no avoidance trials had been given, but CR frequency was approximately equal in the AV5-, AV10-, and AV20-CL60 groups during all six trial blocks of Stage II classical conditioning. Table 1 reveals a possible reason for these surprisingly equal response levels during Stage II. The CL-AV groups received 0, 5, 10, or 20 airpuff classical reinforcements during Stage I classical training. During Stage I, the AV-CL groups also received airpuffs which have long been regarded as intermittent classical reinforcement (Logan, 1951). In fact, several investigators have suggested that the occurrence of the airpuff is the primary reinforcing event in instrumental avoidance eyelid conditioning (e.g., Gormezano, 1965; Kimble, 1961, 1964; Logan, 1951). The AV0-, AV5-, AV10-, and AV20-CL60 groups received on the average 0, 9.3, 13.35, and 16.8 airpuff reinforcements, respectively, during their instrumental avoidance training. The differences in mean number of Stage I airpuffs among the AV5-, AV10-, and AV20-CL60 groups were, therefore, far smaller than the corresponding differences in the CL-AV groups. The smaller differences between the AV-CL groups in the number of such Stage I classical reinforcements could readily account for the smaller differences in the Stage II response frequencies of these groups.

The finding that *Ss* in the AV-CL groups tended to retain the same V-C classification when the mode of reinforcement was changed indicates that the same response learned during Stage I instrumental avoidance conditioning continued to be performed during Stage II classical conditioning. Positive response transfer was also indicated by the finding that the efficiency of CRs, as defined by the PUFAMP/MAXAMP measure, on the first trial block of Stage II classical conditioning was a monotonically increasing function of the number of Stage I ARs. This result also suggests that the response topography learned during instrumental avoidance training was very effective in attenuating the noxiousness of the airpuff on subsequent classical conditioning trials which may explain why the same response was retained.

In many important respects, the results in the AV-CL groups of the present experiment do not parallel the results on transfer from instrumental reward to classical reinforcement reported by Grant et al. (1969). In the Grant et al. experiment there was no indication that the response learned during instrumental reward reinforcement was the same as the CR that occurred during subsequent classical conditioning. Some or all of the differences noted in the introduction between the two experiments may account for this difference in results. The most important difference may be that the response topography learned during instrumental avoidance conditioning is effective in attenuating the noxiousness of the corneal airpuff in classical conditioning, whereas the

response topography learned during instrumental reward conditioning is less effective in this respect (Grant et al., 1969). The combined results of the present experiment and the experiments of Grant et al. suggest that when the response learned under one mode of reinforcement is "effective" under a second mode of reinforcement the response will continue to be given when the mode of reinforcement is changed from the first to the second.

Instrumental reward and avoidance reinforcement compared. In the present experiment, the AR frequency curves for the CL-AV groups converged to a common asymptote during the last three 10-trial blocks of instrumental avoidance conditioning. Grant et al. (1969) found that the instrumental response frequency curves for their four classical-to-instrumental reward groups remained parallel throughout the 60 trials of Stage II instrumental reward reinforcement and, therefore, reached different asymptotes. Differences between the relationship of Stage II reinforcement to the occurrence of a conditioned eyeblink in the two studies may account for the different patterns of results on the later Stage II trial blocks.

Grant (1973) has noted that opposing reinforcement processes occur during instrumental avoidance conditioning. The occurrence of the airpuff on no-response trials constitutes a classical reinforcement, which increases the probability of a CR on subsequent trials. The omission of the airpuff on the occurrence of an AR constitutes both an instrumental avoidance reinforcement, which increases response probability, and a classical extinction trial, which decreases response probability. Therefore, as the response rate increases, the number of classical extinction trials increases which should be expected to reduce the response rate. As a conditioning session progresses, these conditioning–extinction processes tend to produce a stable equilibrium in response rate. Therefore, even though the four CL-AV groups of the present experiment differed in initial Stage II response rate, the interaction of the processes just noted acted to produce convergence toward a common asymptote.

In instrumental reward conditioning, the number of reinforcements is a positive function of response rate. The higher the initial Stage II response rate, the higher the number of instrumental reward reinforcements. In general, higher proportions of reinforced trials should tend to produce higher asymptotic response rates (e.g., Moore & Gormezano, 1961). Therefore, the Stage II instrumental response frequency curves of Grant et al. (1969) increase in a more parallel fashion as a function of the reinforcements of the Stage II trial blocks. Thus, the differences between the results of the present experiment and that of Grant et al. can readily be understood in terms of differences between the reinforcement processes involved in instrumental reward and instrumental avoidance training of the two experiments.

Response efficiency changes over trial blocks. During Stage II the mean PUFAMP/MAXAMP ratio increased monotonically over the trial blocks of classical conditioning in the AV-CL groups. This increase is consistent with the reports of Martin and Levey (1969) and Hickok (1968), who found that CR efficiency, defined by various measures of puff avoidance, increased monotonically over trials in classical conditioning. However, during the Stage II instrumental avoidance conditioning trial blocks of the CL-AV groups, progressive increases in AR efficiency were not obtained. Maximizing the PUFAMP/MAXAMP ratio is biologically adaptive during classical conditioning. Nothing can be gained, however, during instrumental avoidance conditioning by synchronizing the point of maximum AR amplitude with the time that the airpuff would occur on a no-response trial. Therefore, one might expect that more individual variation in the CR topography would be found under instrumental avoidance training than under classical reinforcement. That the topography was actually more variable under instrumental avoidance reinforcement than under classical reinforcement was revealed by the fact that the error variance of the PUFAMP/MAXAMP measure was significantly greater with instrumental avoidance reinforcement than with classical reinforcement. The implications of the results on response efficiency can be summarized by stating that they are consistent with the suggestion of Martin and Levey (1965, 1969) that only those components of response topography that are biologically adaptive are likely to be maximized during the conditioning process.

Conclusion. Experimenters have traditionally been forced to distinguish among various forms of conditioning in terms of the experimenter's operations, rather than in terms of the *S*'s psychological processes, a very unsatisfactory situation (Grant, 1964). The findings of the present experiment and those of Grant et al. (1969), however, provide some evidence for *functional* differences as opposed to operationally defined differences among class-

ical conditioning and two forms of instrumental conditioning. Differences in response topography obtained under the different training procedures make it increasingly clear that it is inaccurate and misleading to speak of *the* eyelid CR becoming conditioned under these three modes of reinforcement. In addition, differences in the consequences of shifting from classical to instrumental avoidance or classical to instrumental reward reinforcement, etc., reveal some of the variety and complexity of the reinforcement processes that characterize these three modes of reinforcement. It is likely that further experiments using the transfer paradigm and further analyses of changes in response topography, as urged by Martin and Levey (1969), will provide a more incisive analysis of conditioning and will yield more precise specification of functional as opposed to operational differences among the various modes of reinforcement by which the eyelid response can be conditioned.

SHORT REPORTS

NONLEARNING: THE COMPLETENESS OF THE BLINDNESS[1]

PAUL FINGERMAN AND MARVIN LEVINE[2]

State University of New York at Stony Brook

College students fail to learn a simple discrimination (e.g., choosing A from the pair A–B), if they are set for a different type of solution. It is possible, however, that these *S*s learn enough to recognize the solution when stated. In the present study, therefore, *S*s who failed to learn this discrimination were given a multiple-choice test containing the statement of the solution as one of the alternatives. None of the *S*s selected this alternative.

Exploring one facet of his theory of learning, Levine (1971) derived conditions for the occurrence of *nonlearning*, the absence of learning, in the simplest of tasks. The conditions of failure were specified for even a well-motivated, intelligent adult who perceived all the relevant stimuli. Before reviewing the derivation, it is worth stressing that the task, simultaneous discrimination, is almost irreducible in its simplicity. Two letters, A and B, are both printed on each of a long series of cards, varying only in which of the letters is on the right (R) side of the card and which on the left (L). The *S* turns the cards 1 at a time and is instructed to state 1 of the 2 letters at each card. The *E* says *correct* whenever *S* says *A* and *incorrect* whenever *S* says *B*. The *S*s are instructed to try to be correct as often as possible. College students normally learn this task quickly, making their final error at about the second card.

The theory, which specifies the conditions under which the choice of A will not increase in frequency, may be summarized as follows: The *S* samples from a set of hypotheses in trying to solve this problem. If he samples from an incorrect set (one which does not contain the solution) he will not solve the problem. In such a circumstance, he will "learn," i.e., solve the problem, only by first exhausting the incorrect set. When it becomes empty he samples a new set, one which (hopefully) contains the solution. An *S*, then, who starts with an incorrect set of hypotheses can, nevertheless, solve the problem. The eventual emptying of this set serves as a signal to try something new.

Suppose, however, that this initial incorrect set of hypotheses is infinitely large—it never becomes empty, and *S* never receives a signal to try another set of hypotheses. For the specific task described above, suppose *S*'s initial hypothesis set is that the solution is a complex position sequence (e.g., it *double alternates* [LLRR] *for 4 trials, then single alternates* [LRLR] *for 4 trials, then repeats*). The set of such position sequences is virtually infinite, yet does not contain the hypothesis *say A*. According to the theory, *S* should learn nothing about the contingency between *A–B* and *correct–wrong*.

One can plausibly cause *S* to sample this incorrect but vast hypothesis set by presenting him first with preliminary problems having just such position-sequence solutions. Levine (1971) performed 2 experiments in which 6 preliminary problems with various position-sequence solutions preceded the critical problem with the *say-A* solution. He found 80% of the *S*s failed to solve the final problem in 100 trials, and were saying *A* about 50% of the time throughout all these trials. The prediction seemed confirmed, then, that *S* learns nothing about the simplest contingencies if the appropriate hypothesis is not in the set.

The question arises, however, whether *S* really learns *nothing* about the relationship between *A* and *correct*. The influence of this invariant repetition might be detected by some more sensitive probe. One possibility is that *S*, though unlikely to formulate the correct hypothesis, might recognize it when stated. If, for example, the correct rule statement were included among a small set of alternatives, *S* might be able to consult his memory of a few of the trials and recognize the existence of this invariant relationship. An *S*, therefore, responding *A* at chance level (i.e., failing by the normal criterion) might nevertheless select the correct alternative from a simple multiple-choice test. The following experiment was performed to investigate this possibility.

Method. Forty-one Stony Brook undergraduates served as *S*s. The data from 9 *S*s were discarded for reasons described below. Of the remaining 32 *S*s, half were fulfilling a requirement in the introductory psychology course, and half were paid volunteers.

Two decks of 110 3 × 5 in. cards each were developed. Every card had the letters A and B printed on the center horizontal line. Within each deck, half of the cards had A on the left and B on the right; the other half had the reverse. The 2 types of cards appeared randomly within each deck, and the 2 decks differed only in the sequence of these cards.

Four additional cards were prepared, each of which contained the following statement and 6

alternatives:

I said "correct" on this last problem:
(a) whenever you said "A".
(b) whenever you paused for more than two seconds before responding.
(c) whenever you responded according to the sequence LLRLRRLLRLLL.
(d) whenever you responded according to some other sequence.
(e) whenever you responded according to a sequence. The correct sequence, however, kept changing.
(f) None of the above.

The sequence of the alternatives was counterbalanced over the 4 cards, with the restriction that (using the above letter labels) Alternative d always followed c, and f was always last. Also, each of the 4 cards was replicated except that "B" appeared in Alternative a.

The *S*, seated across a table from *E*, was presented with a deck and instructed to go through the deck 1 card at a time, choosing on each card 1 of the 2 letters. He was further told that *E* would say *correct* or *wrong* according to some rule, and that he could be correct all of the time if he discovered the rule. This routine was then followed as *S* went through the deck. Seven problems were presented in this way. The first 6 problems had position-sequence solutions beginning with double alternation (RRLL) and ending with LLRLRRRLRR. The *S* was run in each of these 6 problems until he either made 15 successive correct responses or completed 95 trials. The *E* announced the solution at the end of each of these problems and then said, "Here is another problem," and presented the other deck. The final, critical problem also began in this style. For half of the *S*s, the solution rule was *say A*; for the other half, it was *say B*. If *S* made an error after Trial 60, *E* said: "You seem to be having some trouble with this problem. A lot of subjects seem to have trouble with it, so I've prepared a multiple-choice question I would like you to answer to help me to figure out why." He then presented the appropriate multiple-choice card and said, "What do you think is the best answer?" After *S*'s response, *E* said, "Now I'd like you to rank the answers from best to worst."

On the critical problem, 2 different decks and 2 solutions (*say A* or *say B*) defined 4 conditions. These, combined with the 2 conditions of payment and with the 4 multiple-choice sequences, produced 32 unique conditions. The *S*s were run until there was 1 *S* in each condition who (*a*) solved at least 1 of the first 6 problems, and (*b*) failed to solve the critical problem.

Results. Since the theory is best tested if *S* is motivated to be correct and if he is indeed sampling among sequence hypotheses, the protocols of any *S* who solved none of the 6 preliminary problems were eliminated from consideration. Five of the 41 *S*s were dropped for this reason. None of these 5 *S*s, incidentally, solved the critical problem.

There were, then, 36 *S*s who solved at least 1 sequence problem. Only 4 of these solved the final problem. This repeats the previous finding that the substantial majority of college students fail to learn this simple problem. For the 32 failing *S*s, the percentages of correct responses on each of the 6 successive blocks of 10 trials were 48%, 52%, 50%, 53%, 51%, and 47%.

The multiple-choice test was presented to these 32 *S*s in the search for the merest modicum of learning. The results were decisive. None of the *S*s selected the correct alternative as the solution. Twenty-seven *S*s picked 1 of the 3 sequence-solution alternatives. The remainder picked "none of the above." The *S*s had also been asked to rank order the alternatives. The mean rank of the correct alternative was 4.5. It tied for last place with the alternative concerning waiting for 2 sec. before responding, the alternative most irrelevant to the experiment. Several *S*s remarked on the unlikelihood of either of those 2 alternatives and said that they could not decide which to put last.

The conclusion seems clear. Although *S*s were forced, by stating the letter, to attend to the critical stimuli, and although the feedback was desirable, perceivable, and unambiguous, *S*s failed to register the simple invariant relationship between the two. We can assert with greater confidence that *S*s learn nothing about hypotheses not in their hypothesis set.

MEMORY SCANNING:

EFFECT OF UNATTENDED INPUT[1]

MARILYN CHAPNIK SMITH[2]

University of Toronto, Toronto, Ontario, Canada

DAVID BURROWS

State University of New York College at Brockport

To determine whether both attended and unattended items are held in a common short-term memory (STM) store, a Sternberg varied set reaction time (RT) paradigm was employed. Four word lists were presented either monaurally or with simultaneous dichotic presentation of a second 4-word list which *S*s were instructed to ignore. Fifty per cent of the negative probes consisted of nonlist items, while the remaining 50% were selected from the unattended channel. The error rate for the latter probe words, which required a *no* response, was 20%, indicating that there was some STM storage for the unattended items. The RT for the positive probes in the dichotic condition increased by 40 msec. These results were interpreted as suggesting that attended and unattended items are differentially tagged or in some other way kept separate in memory, but that random sampling of the unattended channel takes place.

While early investigators found no evidence of long-term memory (LTM) for verbal items which were not attended (Cherry, 1953; Moray, 1959), several recent studies have indicated that there is some short-term memory (STM) for such unattended inputs (Glucksberg & Cowen, 1970; Norman, 1969; Peterson & Kroener, 1964). As yet little is known about the storage properties of unattended materials. One question of interest is whether attended and unattended items are kept in a common memory store.

To study this problem, Davis and Smith (1972) examined the serial position curves for lists of attended words as a function of whether words that *S*s were instructed to ignore were presented in an unattended channel. It was argued that if all items are held in a common store, the presence of the unattended materials should result in an attenuation of the recency effect observed for attended materials, making it extend over fewer serial positions. No such change in serial position was found, suggesting that information from the 2 channels was not kept in common storage.

There were, however, 2 findings which suggested that despite the absence of a change in serial position there was some memory for unattended input. First, there was an overall decrease in accuracy when the unattended material consisted of words rather than nonsense syllables. Norman (1969) argued that, to be analyzed for meaning, items must make contact with LTM store. Second, when free recall was employed some intrusion errors were found from the unattended channel. When these intrusions were plotted as a function of their input serial position, a roughly inverse exponential decay of intrusions over serial position was found, suggesting an STM decay function for the unattended items. Further, in plotting these intrusions as a function of *output* serial position, it was found that they were offered only in the later output serial positions, i.e., after the recall of several other items. This latter finding suggested that attended and unattended inputs were differentially "tagged" (Yntema & Trask, 1963), and that unattended items were offered only after their "ear tag" had decayed. These results suggest that while there is some memory for unattended items, they appear either to be differentially tagged or in some other way stored separately from the attended materials.

A different paradigm for examining the storage of unattended verbal materials is presented here. Two lists of words, each 4 items in length, were presented dichotically. The *S*s were instructed to attend to one ear and to ignore the materials presented to the other. Following presentation of the lists, a probe word was presented. A *yes* response was required if the probe was one of the words in the previously presented attended list, and a *no* response if it was not. Sternberg (1966), using single list presentation, suggested that when such a procedure is employed, *S*s do a high-speed memory scan to determine if the probe was a member of the previously presented list.

In this study, to learn something about the storage of unattended materials, *S*s were occasionally presented with probe words that had in fact been presented to the unattended ear. A negative response to such probe words was required. If these words had no representation in STM, *S*s should treat them just as they would words which had not been presented at all—i.e., error rate and reaction time (RT) should be no greater than for other negative probes. If, on the other hand, all items from both attended and unattended lists are held in common store in an undifferentiated form, *S*s should always respond *yes*—i.e., there should be an error rate of 100%. Following Sternberg's (1966) as-

sumption that a serial scan of the memory set is made in order to reach a decision, twice as many items would have to be scanned in this condition. Consequently, RTs for both positive and negative probes should be considerably greater than RT in a control condition where only a single attended list is presented. A third possibility, suggested by the Davis and Smith (1972) study, is that the 2 lists may be tagged according to ear of arrival, or in some other way kept in a separate store in memory. If the tagging were perfect, and if *S*s were able to limit their scan only to the attended list, then even though the items were held in STM they should be handled in the same manner as regular negative probes. To the extent that the tagging was not perfect, however, or that there was a fading of tag information with time, some false positives would be expected, giving a greater error rate for negative probes from the unattended list. To test this possibility, word lists were presented at both fast and slow rates, with the expectation that there would be less fading of tag information, and hence fewer errors, under a fast presentation rate.

Method. The *S*s were 8 male secondary school students, all right-handed according to self-report. They were paid $2.00 per session for serving in the experiment.

The words used for each trial were sampled from a pool of 720 one-syllable words that had a rating of 45 or higher on the Thorndike–Lorge (1944) G count, and both began and ended with a spoken consonant. In cases where 2 or more words were homophones or syntactic variants of each other (e.g., give–gave), only one form of the word was retained in the pool. Only nouns, verbs, and adjectives were used.

The lists used in the experiment were generated by computer program and recorded by a male voice using a Sony TC-355 2-channel tape recorder. The *S*s heard the lists through Sharpe HA-10 headphones and responded by pressing one of 2 push buttons. The *S* held one button in each hand. The RT for each response was measured to the nearest millisecond by a Hunter Klockounter. Each *S* was run individually in a quiet room. A plywood partition separated *S* and *E*.

On each trial, *S* heard a warning tap, a list of 4 memory words, another warning tap, and a probe word. The *S* was required to decide whether or not the probe word was present in the list and to make a response as quickly as possible. In the monaural condition, *S* heard all stimuli through one ear only. For any given *S*, this was the same ear throughout the experiment, and was designated as the "relevant" ear for that *S*. In the dichotic condition, words were also presented to the irrelevant ear. Each irrelevant word was presented at approximately the same time as a memory word. Nothing was presented to the irrelevant ear during presentation of warning signals or probe word.

In the dichotic condition there were 3 types of probe words: (*a*) *Positive probes* were words that had been presented to the relevant ear as part of the memory set. The *S*s were instructed to press the *yes* button in response to positive probes. These probes were taken from each of the 4 serial positions equally often. Fifty per cent of all probes were positive. (*b*) *Negative intralist probes* were words that had been presented to the irrelevant ear while the memory set was being presented to the relevant ear. The *S*s were instructed to press the *no* button in response to these words. Twenty-five per cent of the probes were of this type. They were drawn from each serial position of the irrelevant word set equally often. (*c*) *Negative extralist probes* were words that had never been presented to either ear. They were always treated as *no* words. The *S*s were made fully aware of the nature of the *no* words and were especially encouraged to block out the irrelevant ear in the dichotic condition.

In the fast condition, the memory set, warning signals, and probe words were presented at the rate of 2 items per second. In the slow condition, the rate was 1 item per second. Each *S* served for 1 practice day and 4 test days. Each test day consisted of a monaural tape and a dichotic tape at one of the 2 rates. Each tape consisted of 4 practice trials followed by 80 test trials (40 *yes*, 40 *no*) presented in a random order. There were a total of 8 tapes, all dichotic. The monaural conditions were created by turning off the switch for the irrelevant channel. Half of the *S*s heard each tape as a monaural tape, and half heard each as a dichotic tape. Assignment of response type to button and order of serving in each Mode × Rate combination was balanced across *S*s.

Results. The error rates are shown in Figure 1. In the monaural condition, error rates for both *yes* and *no* responses are a relatively low 4% (Figure 1, Section a). In the dichotic condition, the error rate for the *yes* and external *no* responses does not differ from that found in the monaural condition. However, when the probe was a word that had been presented in the unattended ear (internal probe), the error rate was very high, jumping to 20%. Most of these errors were due to *S*'s failure to make a correct rejection—i.e., a false positive response was made (Figure 1, Section b). In Figure 1 Section c, these internal errors are plotted as a function of their serial position in the unattended ear. Most of the errors occurred at the middle 2 positions.

All RT analyses were based on correct responses only. Figure 2 shows mean RT for dichotic and monaural conditions as a function of serial position. Dichotic trials were on the average 42 msec. slower than monaural trials, $F\ (1,\ 7) = 5.79$, $p < .05$. There was also a significant effect of serial position, $F\ (3,\ 21) = 4.48$, $p < .05$. For both monaural and dichotic conditions, the serial position curve is bowed. The shortest RTs were for probes of the last position, followed by probes of the second-to-last position.

A repeated measures analysis for the RT data on negative trials revealed a significant effect of monaural vs. dichotic conditions, $F\ (1,\ 7) = 5.76$, $p < .05$, and no other significant effects.

Discussion. This study was conducted to determine whether unattended words are placed in the

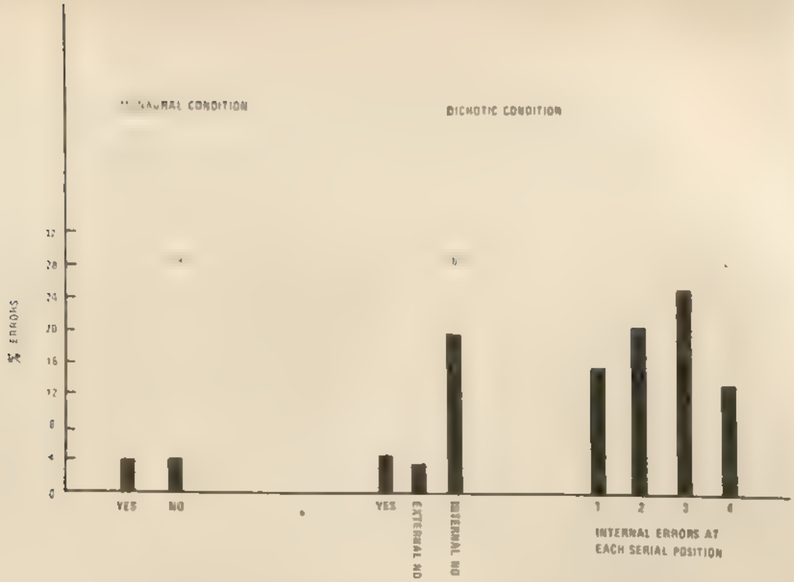

FIGURE 1. *Yes No* error rates for monaural and dichotic conditions.

same STM store as those to which *Ss* are paying attention. Clearly, there is some differentiation in STM between attended and unattended inputs. If both materials were simply placed in a common store, with *S* being required to scan all the items in order to reach a decision about the probe, all probes from the unattended channel would have been treated as positive items. This would have yielded an error rate of 100% for intralist negative probes. However, the error rate found was 20%. Second, given Sternberg's (1966) estimate of 38 msec. to scan an item in memory, adding 4 items in the dichotic condition would have increased RT by about 150 msec. Instead, an increase of approximately 40 msec. was found. Both the error and the latency data thus indicate a differentiation in memory between attended and unattended items.

Why, then, is there such a high error rate for intralist negative probes? One possibility is tha although the items in the 2 channels are differentiall tagged according to ear of input, there is a fadi of the tag information with time. Consequently, when a probe is presented which was an item in the unattended channel, *Ss* will respond *yes* if the item is still available in memory but the tag information has faded away. However, this hypothesis would have predicted fewer errors with a fast presentation rate, since there is less time for fading. Yet no effect

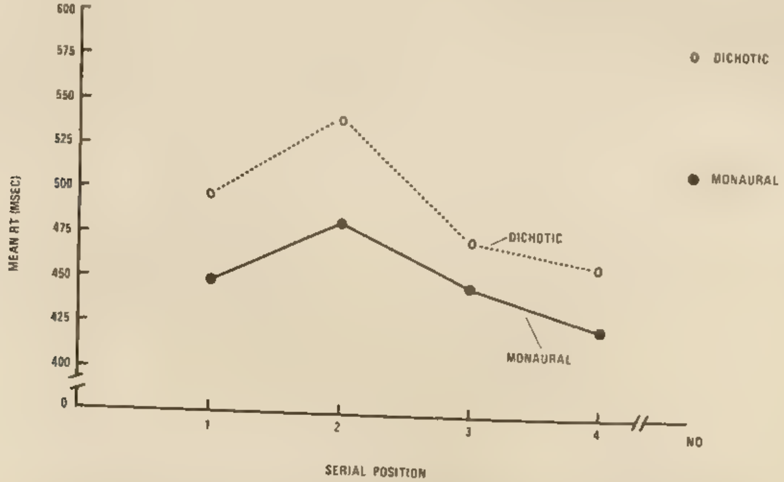

FIGURE 2. Mean reaction time (RT) for positive responses under monaural and dichotic conditions as a function of serial position. (Negative responses are shown on the right.)

of rate was found. Second, we would have expected the greatest number of errors when the probe was an item from the beginning of the list, with the number declining as the end of the list is approached. Instead, a bow-shaped serial position curve was found for errors, with the maximum number of errors occurring in the middle 2 positions.

A second possibility is that all presented items are placed in a common store, but that due to attenuation of the unattended input (Treisman, 1964), the trace strength of their memorial representations is very weak. We must, therefore, assume that the decision as to whether the probe was presented in the memory set is not based upon a serial scan but instead depends on trace strength. If the trace strength is not fixed, but varies about some mean, then on some trials it will be sufficiently high for *S*s to make a positive response to the probe. To account for the data, we must assume that trace strength for unattended materials does not vary greatly over serial position and is not sensitive to the different rate presentations employed here. This would account for the higher error rate for intralist than extralist negative probes. To explain the overall latency increase in the dichotic condition, we must postulate that the addition of these low-strength traces in memory adds noise, thereby causing a decrease in efficiency.

Finally, a different mechanism which could handle these data is one in which an attention switch to the unattended channel occurs during the list presentations, thereby allowing for one of the unattended items to be stored with the attended items. Time of occurrence for such a switch would be random, but would have increased likelihood of occurring in the middle of the list. If such a switch occurs once, permitting one additional item to enter the attended store, *S*s in the dichotic condition would have one more item to scan. The value of the increase in RT of 42 msec. found in the dichotic condition is just what would be expected for the scanning of an additional item. Further, if one item from the list of 4 does get tagged as an attended item, an error rate of 25% would be expected—a value which is very close to the 20% which was in fact found.

It is important to note that if this attention switching did take place, it must have occurred involuntarily, for *S*s were instructed to ignore the material in the irrelevant ear, and there was no reason for *S* to sample the unattended input in order to perform the task. On the contrary, his performance would be better if this switching did not occur at all.

Such an interpretation has several difficulties. It makes predictions opposite to the findings of Davis and Smith (1972), for such a mechanism must postulate a change in serial position data for the attended input. Second, it would bring into question the hypothesis of STM for unattended verbal items: it would suggest that items in the unattended channel reach STM only when an involuntary attention switch occurs, allowing them to pass into STM. This would seem unlikely, in view of the many recent studies in which evidence for STM for unattended materials has been found.

RETRIEVAL OF REPEATED ITEMS EMBEDDED IN CHANGING LISTS[1]

A set of target words from the same category, embedded in lists also containing other items, was repeated across all trials for free recall of all items presented on each trial. Retrieval of the repeated items from long-term storage was less when other items, from a different category, were new on each trial rather than also repeated across trials; and retrieval was still less when the other new items were from the same category as the repeated items. Long-term storage of the items in the repeated set was equivalent in all 3 conditions, confirming that retrieval of items within a list from long-term storage is affected by the context provided by the rest of the list.

It has been pointed out (e.g., Bower, 1972; Kintsch, 1970) that the properties of a list of items as a whole affect the learning of individual items in the list. This view can be examined by presenting a set of words as part of larger lists containing other words, so that the target words would be learned in different contexts, i.e., as parts of different lists. Accordingly, half of the items in a multitrial free-recall experiment were repeated from trial to trial, while the rest of the items were new on each trial. Since *S*s were required to recall all of the items presented on any given trial, their task was to learn the repeated items across trials, while also recalling the new items for only 1 trial.

The set of repeated items were all from the same category (BIRDS), the new items being drawn from the same category (BIRDS) for one group of *S*s and from a different category (TREES) for another group of *S*s. In addition, a third group of *S*s was given only repeated items, so that all items could be learned over trials; half of the items were the repeated BIRDS given to the other 2 groups and the rest were a set of TREES also repeated on all trials. The context in which the repeated subset of items (BIRDS) was presented to all 3 groups, therefore, was varied in 2 ways: (*a*) the balance of the items were from either the same or different categories, and (*b*) with same-category items, the context was nonrepeated, whereas with different-category items, the context was either repeated or nonrepeated. Finally, all 3 experimental groups were given an additional trial in which the repeated BIRDS were presented by themselves for free recall, and a control group was also given the repeated BIRDS alone, but without any previous trials.

Method. Eight successive lists of 16 items each were read aloud at the rate of 1 item/sec for free recall of each list immediately after presentation. There were 3 conditions, and the same 8 BIRDS were presented on all trials in each. On each trial, the repeated BIRDS were alternated with the other 8 items to distribute the 2 classes of items evenly over the list. From trial to trial, the order of the repeated BIRDS was randomized over their designated serial positions. In Condition B-b, the 8 repeated BIRDS alternated with the names of 8 BIRDS which were new on each trial. In Condition B-t, the repeated BIRDS alternated with a new set of TREES on each trial. In Condition B-T, the repeated BIRDS alternated with 8 TREES, which were repeated across trials. These repeated TREES were randomized within their designated serial positions across trials.

On each free-recall trial, *S*s wrote the items that were recalled on a separate sheet of paper. The *S*s were told about the structure and content of their lists, and were given 90 sec. for recall after each list was read. The 8 repeated BIRDS were presented alone on Trial 9 to all experimental *S*s and for only 1 trial to 20 control *S*s, who recalled them for the first time.

The *S*s were undergraduate students between the ages of 19 and 25 enrolled in psychology courses at Lehman and Brooklyn Colleges. A total of 80 *S*s participated in the experiment, 20 *S*s being randomly assigned to each of the 3 experimental conditions and to the control group.

The relative contributions of short-term storage (STS) and long-term storage (LTS) to total recall were estimated by the method of Tulving and Colotla (1970). Recall from short-term storage includes those items with 7 or less other items intervening between presentation and recall, counting both presented and recalled items. Retrieval from LTS includes those items with more than 7 intervening items between presentation and recall. The number of items retained in LTS is the cumulative number of items retrieved from LTS at least

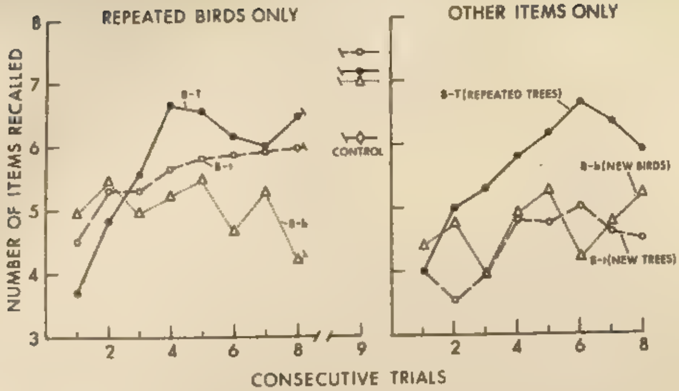

FIGURE 1. The left panel presents the number of repeated BIRDS recalled when presented for recall together with new BIRDS, new TREES, and repeated TREES, with results for Trial 9 representing recall of repeated BIRDS when presented by themselves; the right panel represents concurrent recall of new BIRDS, new TREES, and repeated TREES.

once, on the assumption that once an item has been retrieved from LTS, it remains in LTS. In support of this assumption, recent work has shown that when items on a list are no longer presented after they have been recalled just once (i.e., only items on the list never recalled are presented on subsequent trials), 85% will be spontaneously retrieved subsequently, even after several intervening trials where they have not been recalled (Buschke, in press).

Results. The left panel of Figure 1 shows the recall across trials of the repeated BIRDS embedded in the lists of the 3 conditions, and the right panel shows the recall of the rest of the items presented for recall on each trial in each of the 3 conditions. Recall of the repeated BIRDS increased most over trials (sum of Trials 1–4 vs. sum of Trials 5–8) in Condition B–T, t (19) = 4.98, $p < .001$; increased moderately in Condition B–t, t (19) = 3.52, $p < .01$; but did not increase at all in Condition B–b. There was a significant effect of conditions on the recall of the repeated BIRDS on Trial 8, F (2, 57) = 3.40, $p < .05$. The *S*s in Condition B–t had a greater overall recall of the repeated than of the new items, t (19) = 4.58, $p < .001$, whereas *S*s in Condition B–b did not differ in their overall recall of the repeated vs. the new items.

Evidence that the failure of the B–b group to increase in recall of the repeated BIRDS across trials was due to difficulty in retrieval from, rather than storage in, LTS was obtained on Trial 9, where the repeated BIRDS were presented alone to all groups. While there was no significant difference in recall among the 3 experimental conditions, recall by the control group, who were recalling the repeated BIRDS for the first time, was significantly lower, F (2, 76) = 8.54, $p < .01$. If the B–b group had not benefited from exposure to the repeated items during Trials 1–8, then they should not have done better on Trial 9 than the control group did on their single trial. Any benefit from previous trials presumably must be mediated by LTS.

To further substantiate the contention that the lower recall scores of the B–b group were due to less effective retrieval from LTS rather than less effective storage in LTS, estimates of retention in LTS, retrieval from LTS and recall from STS across trials are presented separately in Figure 2 for the repeated BIRDS for the 3 conditions. Recall from STS remained constant across trials in all 3 conditions, and analysis of variance indicated no significant differences among the conditions on Trial 8. Long-term storage clearly increased across trials for all 3 conditions, with no significant dif-

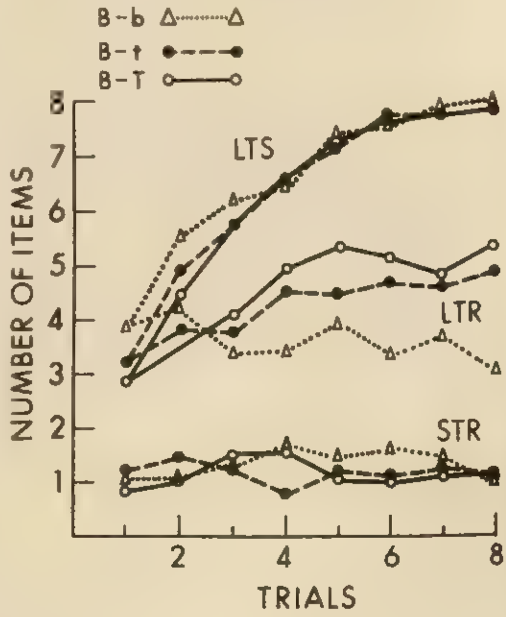

FIGURE 2. Retention in long-term storage (LTS), retrieval from long-term storage (LTR), and recall from short-term storage (STR) for the repeated BIRDS in Conditions B–b, B–t, and B–T.

ferences among the conditions on Trial 8. Retrieval from LTS, however, was significantly different among the conditions on Trial 8, $F(2, 57) = 3.82$, $p < .05$. This indicates that retrieval from LTS accounted for the differences in recall among the conditions shown in the right panel of Figure 1.

DISCUSSION

The results indicate that the context in which the repeated BIRDS were embedded affected their recall. When the rest of the items were from a different category (TREES), changing the TREES to be recalled on each trial resulted in somewhat poorer recall of the repeated BIRDS than when the TREES also were repeated across trials (Condition B–t vs. Condition B–T). Recall of the repeated BIRDS was markedly reduced when the balance of the items, which changed from trial to trial, were from the same category (Condition B–b). In contrast to the other 2 conditions, Condition B–b showed no increase at all across trials in the recall of the repeated BIRDS, even though the repeated BIRDS were presented an equal number of times to each group and in identical serial positions (Figure 1).

The analysis of LTS, retrieval from LTS, and recall from STS (Figure 2) yielded the surprising result that the differences in recall of the repeated BIRDS among the experimental conditions were not due to differences in recall from STS of the repeated BIRDS. We had expected that STS would have been needed for the new items in Conditions B–b and B–t compared to Condition B–T, where *S*s were not confronted with new items on each trial. Even though the new items could have been discriminated for preferential STS in Condition B–t on the basis of category membership, recall from STS of the repeated items was the same as in Condition B–b, where new items could not be distinguished on the basis of category membership. Long-term storage of the repeated BIRDS also was the same in all conditions. Since LTS and recall from STS of the repeated items were identical in all conditions, the differences in recall of these items must be accounted for solely on the basis of differences in retrieval from LTS.

The differences in retrieval from LTS of the repeated BIRDS among conditions reflect the differences in the total composition of the lists presented in the 3 conditions. In Condition B–T, where all of the items were the same from trial to trial, *S*s could learn the items as one coherent list. In Condition B–t, the items could not be treated as part of one coherent list, because half of the list changed on each trial. Vincent curves indicated that as the trials progressed, *S*s in Condition B–t reported an increasingly larger proportion of the new items in the first half of recall and the repeated items in the second half of recall. It appears that *S*s could treat the entire list (B–t) as 2 sublists of repeated (B) and new (t) items. The somewhat poorer retrieval of the repeated BIRDS from LTS in Condition B–t compared to Condition B–T may have been related to the extra processes involved in constructing 2 lists.

In Condition B–b, where the new items on each trial were from the same category as the repeated items, the possibility of constructing 2 lists was impeded by the difficulty in discriminating the repeated from the new items. The Vincent curves also indicated that *S*s in Condition B–b had difficulty in discriminating repeated and new items from the same category because, while they reported more new items in the first half of recall and more of the repeated items in the second half of recall, this was less successful and did occur not until later trials than for *S*s in Condition B–t. The items in Condition B–b could neither be treated as a single coherent list nor as 2 distinct sublists. The *S*s in Condition B–b in effect faced an entirely new list on each trial (even though half of the items were the same on each trial). This is reflected by the failure of the recall of the repeated items to increase across trials.

Taken together, the results of this experiment confirm that the context provided by a list as a whole has a significant effect on the recall of individual items in that list. Recall of the repeated items did not increase over trials when other items from the same category changed from trial to trial. These results also indicate that the differences in recall among the 3 conditions were due to differences in retrieval of the repeated items from LTS, rather than to differences in storage and retention of the repeated items in LTS. Retrieval from LTS appears to depend on the properties of the total list within which the items are presented.

THE EFFECT OF NUMBER OF STIMULI ON THE STEADY-STATE GENERALIZATION GRADIENT:

A TEST OF THE SUMMATION HYPOTHESIS [1]

JOHN C. MALONE, JR.[2]

University of Tennessee, Knoxville

The interacting-gradient model for discrimination learning predicts changes in the slope of the generalization gradient as a function of the number of stimuli comprising it. Attempts to verify this prediction, using the method of extinction testing after reinforced pretraining, have proven inconclusive. In this experiment, three pigeons produced steady-state generalization gradients over a prolonged training period. The number of stimuli forming the gradient was varied, while the temporal appearance of stimuli and the pattern of reinforcement availability remained constant. Variations in the number of stimuli present did not affect the slope of the gradient.

An intuitively reasonable way to view discrimination learning is in terms of excitatory and inhibitory response tendencies; such a position was taken by Pavlov (1927) and was adopted in various forms by others. Probably the clearest formulation of this view was that proposed by Spence (e.g., 1937). According to this interpretation, discrimination learning is a secondary process, dependent upon the formation and interaction of generalization gradients of excitation and inhibition. During the formation of a discrimination between two stimuli on the same dimension (e.g., size, hue), a gradient of excitatory response tendency is presumed generated around S+, as the result of reinforcement (e.g., food) received for responding in its presence, while lack of reinforcement for responding in S− results in an inhibitory gradient around it. The height of these gradients is presumed to decrease with distance from S+ and S−. A simple algebraic summation of such gradients determines the tendency to respond to S+, S−, and to other stimuli which lie within the range of generalization of either.

Despite a good deal of criticism, this model has remained the most popular general account for discrimination learning. In theory, it can account for the learning of a discrimination, for transposition and transposition reversal, and for most of the features of the shifted peak of the postdiscrimination generalization gradient (Hearst, 1968; Hilgard & Bower, 1966). The model has been limited in usefulness, however, due to difficulty in empirically verifying its predictions.

These difficulties must be due in large part to the extreme variability of empirical generalization gradients obtained with present methods, i.e., in the manner popularized by Guttman and Kalish (1956). Animals are usually trained in the presence of one or more stimuli, under conditions of intermittent reinforcement, so that resistance to extinction is developed. Transfer tests are then carried out in extinction; reinforcement is discontinued and the animal is presented a number of stimuli varying along some dimension of the training stimulus.

Two characteristics of empirical gradients which seem essential if they are to be used to explain the phenomena of discrimination learning are stability and recoverability. Gradients obtained in extinction are variable, both among and within subjects (cf. Blough, 1965). Such gradients are not recoverable if testing is repeated after additional single-stimulus training (Zeiler, 1969). The form of these gradients is influenced by a multitude of factors, such as the schedule of reinforcement used during training (Hearst, Koresko, & Poppen, 1964) and the length of the transfer test in extinction (e.g., Guttman & Kalish, 1956).

Several investigators (e.g., Blough, 1965; Zeiler, 1969) have suggested that gradients be obtained in the steady state, i.e., with reinforcement maintained in S+ and with presentation of S+ and "test" stimuli over many sessions. There are several advantages in following this procedure. Steady-state gradients reach quite stable asymptotes (e.g., Malone & Staddon, 1973); they are relatively independent (at asymptote) of the reinforcement schedule in force in S+ (Zeiler, 1969) and, perhaps most important, they are recoverable after interpolated training conditions (Zeiler, 1969).

The interacting-gradient model predicts summation of excitatory and inhibitory response tendencies which should affect the slope of the generalization gradient obtained during extinction testing, as well as during steady-state training. Excitatory gradients summating around reinforced stimuli should produce increased overall responding and a shallower gradient. The addition of nonreinforced stimuli should act to lower overall responding and to increase the slope of the gradient due to the addition

of inhibitory gradients around these stimuli. Evidence for summation of this sort is equivocal; Kalish and Guttman (e.g., 1957), using the method of extinction testing after reinforced pretraining, did not find convincing evidence for summation of excitatory gradients. Others, using the same method, have found evidence for excitatory-inhibitory summation following pretraining with reinforced and nonreinforced stimuli; the gradient obtained in extinction was shifted toward S+, as would be expected if an inhibitory gradient around S+ is subtracted from an excitatory gradient centered around S− (e.g., Hearst, 1968).

Changes in the number of test stimuli presented during extinction should similarly affect gradient form, due to the summation of inhibitory gradients around these stimuli; such effects have been reported (e.g., Marsh, 1967), but in other cases no effect appears (e.g., Guttman & Kalish, 1956). Others, using steady-state procedures, have varied the number of stimuli comprising the gradient (e.g., Pierrel & Sherman, 1962). However, these studies were not attempts to definitively test the interacting-gradient model; in addition, their procedures did not ensure that factors other than the number of stimuli comprising the gradient remained constant.

The interacting-gradient model is influential enough to warrant testing using the best means available; this experiment varies the number of stimuli comprising a steady-state gradient, while holding other factors constant.

Method. Three white Carneaux pigeons were maintained at 80% of their free-feeding weights throughout the experiment. One bird (119) was experimentally naive; the other two birds (48 and 72) were experienced with multiple fixed-interval schedules (in which key colors served as discriminative stimuli).

The experimental chamber was a 33 × 33 × 33 cm. Plexiglas box with a 1.9-cm. translucent key mounted on one wall. A line orientation produced by a Tektronix (Model 503) oscilloscope was focused onto the key by a small lens (focal length 1 in.) mounted between the oscilloscope face and the key. The image on the key was a line orientation approximately 1.3 × .5 cm., always presented on a blank background. A 24-v. battery connected to the horizontal input of the oscilloscope served to eradicate the trace left on the oscilloscope face between stimulus changes and during reinforcement. A 25-w. red lamp was mounted approximately 8 cm. behind the response key; when lit, the lamp transilluminated the key, providing a red stimulus which could be presented instead of the line-orientation stimuli provided by the oscilloscope. The animal chamber and ⅔ of the oscilloscope were enclosed by a larger box (51 × 51 × 122 cm.) comprised of hollow 5-cm. thick walls filled with soundproofing materials. Reinforcement (3-sec. access to mixed grain) was provided by a food magazine; the 5-cm.[2] aperture was located 5 cm. below the key. The key display was extinguished during reinforcement but the 15-w. fluorescent houselight remained lit. White noise and a ventilation fan masked extraneous noises; programming and recording equip[illegible]ent were located in an adjacent room.

A daily session comprised 90 1-m[illegible]timulus presentations; the sequence of presen[illegible]ns consisted of 10 blocks of nine present[illegible] each. Each block included three presentati[illegible] of S+ (90°; vertical line) and one presentation [illegible]ach of six other orientations (66°, 54°, 42°, 30[illegible]°, and 6° from the horizontal), randomized w[illegible]locks. During S+ (90°) a variable-interv[illegible] 1-min. reinforcement schedule was in effect; VI [illegible] was in effect at all other times. The selectio[illegible]nter-reinforcement intervals for both schedules [illegible]based on the progression suggested by Fleshler [illegible] Hoffman (1962); this was done to ensure steady [illegible]onse rates, by making reinforcement availability [illegible] unpredictable as possible.

The sequence of stimulus presentations was fixed throughout the experiment; although seven orientation stimuli were included in the sequence, a maximum of four appeared during any one cond[illegible]on. Orientations which were not scheduled to appear during a given condition were replaced by presentations of a red key light; VI 3-min. remained in effect during this stimulus. In this way, the temporal appearance of stimuli and the pattern of reinforcement availability during the session remained constant over conditions; *only* the presence or absence of orientation stimuli was varied.

To facilitate control by stimuli on the key, "no-stimulus" periods were inserted at the end of odd-numbered blocks of stimuli. During these periods no stimulus was present on the key and reinforcement was never obtained. The length of the period was determined by a timer which reset with each key peck, prolonging the period. The timer was initially set at 5 sec.; with improved performance (absence of key pecking), the setting was increased to 20 sec.

Each bird received preliminary magazine and key training in the presence of S+ (90°). This was followed by a period of initial training consisting of 11 sessions of 30 1-min. presentations of S+, reinforced according to VI 30 sec., alternated with 30 "no-stimulus" periods.

The experiment comprised the following three conditions: (*a*) S + (90°) vs. 6°; (*b*) S + (90°) vs. 30°, 6°; and (*c*) S + (90°) vs. 54°, 30°, 6°. Each bird was trained on each condition and returned to the original condition, as a test for recoverability. The order of conditions and number of sessions for each bird appear in Table 1.

Results. Within a week after the onset of training, virtually no responding occurred during "no-stimulus" periods. Extended training was carried out in order to assess any changes in gradient form due to length of training; little change occurred after the first few sessions.

There was no change in gradient form as a function of the number of orientation stimuli present. Table 2 shows average response rates per minute and standard deviations during the last four days of each condition for individual birds. Gradients were extremely stable over these periods, as they

TABLE 1

Sequence of Conditions and Number of Sessions of Training for Each Bird

a	31	*c*	36	*a*	38
b	22	*a*	37	*b*	27
c	16	*b*	5	*c*	11
a	15	*c*	5	*a*	5

were during the entire period of training. Bird 72's gradients were virtually indistinguishable over 69 sessions (Conditions *a*, *b*, and *c*), in spite of changes in the number of orientation stimuli present. Similarly, gradients for Bird 48 varied little across the first three conditions. However, attempts to recover the performance shown in the original condition led to an increase in absolute response rates in all stimuli for Bird 72, and an increase in 54° for Bird 48.

Bird 119 responded at extremely high rates throughout the experiment. During the first two conditions (65 sessions), 119's gradients remained approximately flat (Table 2), reflecting a lack of control by orientation stimuli. During Condition *c*, the gradient steepened, an effect which increased with the shift back to the initial Condition *a*. During a subsequent experiment, this animal showed a similar insensitivity to line-orientation stimuli; thus, the possibility that the lack of previous discrimination experience was responsible for his performance is unlikely. His data will not be discussed further.

The effect of alterations in the number of orientation stimuli on the slope of the gradients appears in Figure 1. The curves in this figure represent linear least squares approximations of the data in Table 1. Gradient slope remained virtually unchanged over conditions.

Discussion. The interacting-gradient model predicts that the slope of the steady-state generalization gradient will change with variation in the number of stimuli comprising it. However, the model may be interpreted to predict two outcomes for the present experiment.

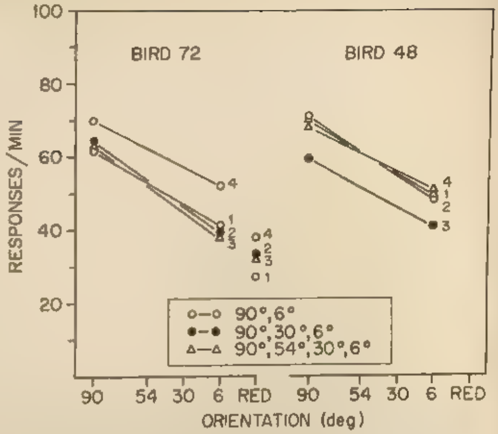

Figure 1. Least squares approximations of data averaged over the last four days of each condition for Birds 72 and 48 (see Table 1). (Gradients are labeled according to the order in which conditions appeared in training for each bird, rather than according to the number of stimuli appearing in that condition.)

Since responding was reinforced in *all* stimuli, though stimuli other than S+ were reinforced at a lower rate, the model would predict that excitatory gradients would be generated around all stimuli. Response rate to a particular stimulus depends upon the excitatory gradient associated with it, as well as upon summation of this gradient with gradients centered around other stimuli on the same dimension (cf. Spence, 1937). Thus, when the number of orientation stimuli forming the gradient is increased, the gradient should *flatten* and overall responding in all stimuli should *increase*, due to the summation of additional excitatory gradients.

An alternative prediction comes from Guttman's (1959) finding that a stimulus associated with

relatively less frequent reinforcement can become "functionally" inhibitory. Thus, the gradients centered around orientation stimuli other than S+ might be considered inhibitory, rather than excitatory. The summation of such gradients with an excitatory gradient centered around S+ predicts that an increase in the number of orientation stimuli should cause the gradient to *steepen* and response rates in all stimuli to *decrease*.

Neither of these effects occurred; an increase or decrease in the number of orientation stimuli produced no discernible change in gradient slope or in absolute response rates. The only major change in gradient slope during the experiment appeared in the data of Bird 119; this change cannot be attributed to changes in the number of stimuli forming the gradient.

The procedure used here seems optimal for testing the interacting-gradient model; predictions made by either interpretation of the model regarding changes in gradient slope as a function of variations in the number of stimuli present were not confirmed.

OVERHABITUATION AND SPONTANEOUS RECOVERY OF THE GALVANIC SKIN RESPONSE[1]

JAMES P. JAMES[2]
Fort Hays Kansas State College

KEN R. DANIELS
Brandon University

BRIAN HANSON
University of Manitoba, Winnipeg, Manitoba

The time course of recovery from 2 levels of habituation was examined. In a 2 × 4 completely randomized factorial design, with 24 *S*s per cell, the criteria of habituation were 2 or 5 successive trials without a response, and the recovery intervals were 1, 2, 4, or 6 min. Recovery of the orienting response was an increasing negatively accelerated function of the recovery interval. The 2 criteria of habituation did not produce significantly different curves of recovery. When both criterion groups were combined at each recovery interval, the median percentages of recovery for the 1-, 2-, 4-, and 6-min. intervals were 17%, 55%, 81%, and 84%, respectively.

The term *spontaneous recovery* refers to the response increment that occurs after a "rest" period which follows either extinction of a learned response or habituation of an orienting response (OR). Despite the fact that spontaneous recovery of a habituated OR is considered a major parametric feature of habituation (Thompson & Spencer, 1966), little systematic research with human *S*s has been reported.

[1] The results of this research were presented at the meeting of the Rocky Mountain Psychological Association, Albuquerque, May 1972.

[2] Requests for reprints should be sent to James P. James, who is now at the Department of Psychology, Western Illinois University, Macomb, Illinois 61455.

The purpose of the present study was to investigate the spontaneous recovery of the galvanic skin response (GSR) component of the OR. Specifically, an attempt was made to examine the time course of recovery from 2 levels of habituation.

Method. The *S*s were 192 male and female students enrolled in a general psychology course. Participation in the experiment partially fulfilled a course requirement.

The apparatus consisted of a Hunter GSR amplifier, modified to detect resistances from 0 to 150,000 ohms. Fels 20-mm.-diam. zinc electrode cups, filled with Fels electrode jelly, were used. Tones from a Grason–Stadler 950-D generator were presented through Roberts headphones. Stimulus durations were timed by a Hunter interval timer. The intertrial interval (ITI) was timed by *E* with a Standard timer, and the recovery interval was timed with a stopwatch.

The electrodes were attached to the palm and back of *S*'s right hand. The *S* was told that he/she would hear several short tones through the headphone and that he/she was to relax and remain as still as possible. The *E* next assigned each *S* randomly to 1 of 8 groups based on a completely randomized factorial arrangement of 2 habituation levels and 4 recovery intervals. The 2 habituation levels were 2 and 5 successive trials without a response, as defined later. The 4 recovery intervals were 1, 2, 4, and 6 min. following the final trial of habituation. These intervals were defined as the time between the onsets of the final habituation stimulus and the test stimulus.

After the baseline resistance became relatively stable, 1,000-Hz. tones of 2-sec. duration were presented at random intervals of 30, 40, or 50 sec. ($M = 40$ sec.). The tonal intensity was 62 db, measured at the headphone. Stimulus presentations continued until the appropriate criterion of habituation was met. On the test trial, the measure of recovery was the GSR magnitude elicited by the same standard stimulus.

A response was defined as a decrease in skin resistance of at least 200 ohms occurring 1–5 sec. after stimulus onset. These defined changes in skin resistance were transformed to log conductance change scores. A base-level resistance score was the skin resistance in ohms recorded at stimulus onset.

Results. On the first trial of habituation, the 8 groups did not differ in either mean GSR magnitude ($F < 1$) or base-level resistance ($F < 1$). On the final trial of habituation, the groups did not differ in base-level resistance, F (7, 184) = 1.16, $p > .20$.

Inter-*S* variability in rate of habituation was high. For the 2- and 5-trial groups, the ranges of trials required to meet the criterion of habituation were 3–30 and 6–27, respectively. The 2-trial groups averaged 7.29 trials to meet criterion; the 5-trial groups required a mean of 10.66 trials. Trials to criterion of habituation did not differ significantly within the 2-trial ($F < 1$) or the 5-trial, F (3, 92) = 1.58, $p > .10$, groups.

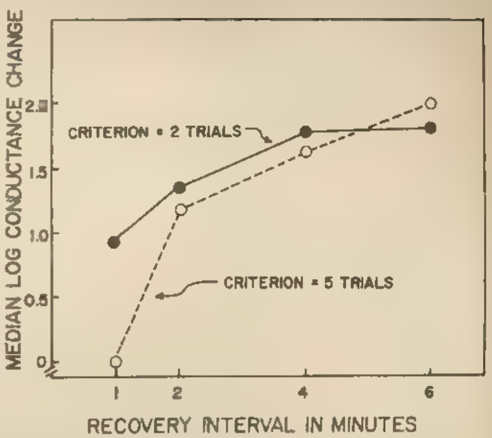

FIGURE 1. Median galvanic skin response magnitude across the recovery interval as a function of 2 criteria of habituation.

In Figure 1, median GSR magnitudes for the 2 criteria of habituation are plotted across the recovery intervals. Each data point represents a single group's median GSR magnitude. Because of several zero scores, with the resulting deviance from normality, nonparametric statistics were used for data analysis. By Kruskal-Wallis tests (corrected for ties), both 2-trial, H (3) = 9.88, $p < .02$, and 5-trial, H (3) = 29.31, $p < .001$, groups exhibited significant increases in response magnitude across the recovery interval. Although differential rates of recovery are suggested in Figure 1 by the apparent difference between the groups at the 1-min. interval, a Mann-Whitney U test did not yield an acceptable level of significance ($Z = 1.28$, $p = .10$, 1-tailed test).

The percentage recovery was calculated for each S by dividing the GSR magnitude of the recovery test trial by the equivalent score for the first habituation trial. When the 2 criterion groups were then combined at each recovery interval, the median percentages of recovery for the 1-, 2-, 4-, and 6-min. intervals were 17%, 55%, 81%, and 84%, respectively.

Discussion. The results suggest that the GSR component of the OR recovers a considerable portion of its prehabituation response magnitude. Fast recovery to the 2-min. posthabituation point was followed by slower recovery to 6 min. This increasing negatively accelerated curve also describes recovery from habituation of the withdrawal and hooking response in earthworms (Gardner, 1968), the head-shake response in rats (Leibrecht & Askew, 1969), and a variety of responses in several other species of vertebrates and invertebrates (cf. Hinde, 1966).

The 2 criteria of habituation used here did not produce significantly different curves of OR recovery, a finding consistent with those of Gardner (1968). However, it is clear that the present study and that of Gardner can be compared only in general terms, because of the differences in response systems and species investigated.

The present results raise the question of how many habituation trials beyond a certain point, a zero response being an arbitrary point, are necessary to produce differential recovery of the OR. If the ITI is thought of as one of the stimulus parameters, any lengthening of the ITI, such as occurs during the recovery interval, would represent a change in stimulus that may serve to evoke a generalized OR. Sokolov's (1960) neuronal model theory of habituation predicts that up to a point, the greater the number of habituation trials, the more completely established the model. A change in any stimulus parameter would then result in a greater mismatch between stimulus and model. Since overhabituation necessarily involves additional habituation trials, the increased stimulus novelty produced by the recovery interval may evoke a response increment that would tend to counteract the decremental effects of these additional habituation trials. This speculation predicts steeper recovery curves is a function [illegible] habituation trials, but may be limited to [illegible] where relatively few habituation trials are [illegible]tered. A steeper recovery curve for the group [illegible]eived the greater number of habituation trials [illegible]ested by the present data.

ASSOCIATIVE CONFUSIONS IN MENTAL ARITHMETIC [1]

JOHN H. WINKELMAN [2] AND JANET SCHMIDT

University of Oregon

The effects of associative interference between single-digit addition and multiplication problems were investigated. Associative confusions (e.g., 4 + 5 = 20) were about 50 msec. slower than comparable nonassociative confusions (e.g., 4 + 5 = 15), and produced many more errors. The result indicates the presence of associative processes in simple mental arithmetic and casts doubt on the counting theory of addition.

Previous work on single-digit addition problems has focused on reaction times for verifying sums as a function of the size of the addends (Parkman, 1971; Parkman & Groen, 1971). Parkman and Groen found a strong linear relationship between the size of the minimum of the two addends and the reaction time required for verifying the sum. They accounted for this finding by positing an unconscious counting process: first, the maximum of the addends is determined, and then it is incremented by ones for a number of times equal to the minimum addend. Since each increment presumably uses up the same amount of time, the decision time should be a linear function of the minimum of the two addends.

The counting model is not the only model consistent with the linear increase of reaction time with minimum addend. It is possible that addition is accomplished by an association between a digit pair (the addends) and the sum. As the size of the minimum digit increases, the strength of association between the digit pair and the sum decreases (because larger sums are practiced less often), and hence the verification reaction time increases. The associative model would predict a monotone increase of reaction time with minimum digit, rather than a linear increase; but most monotone functions can be fit fairly well by linear functions, so the Parkman and Groen (1971) result would be accounted for.

The present study will not argue that associative processes are the only ones involved in addition and multiplication, but it will attempt to establish that associative processes do occur in addition and multiplication. It is proposed that there exist associations between pairs of digits and both their sums and products; for example, the digit pair (3, 3) would have associations with both 6 and 9. The obvious prediction is that stimuli of the type 3 + 3 = 9 and 3 × 3 = 6 will produce a tendency to respond *yes* because of associative interference, and hence that stimuli of this type will produce longer

reaction times and more errors than comparable stimuli not exhibiting interfering associations.

Method. Six University of Oregon students served as *Ss*, each for 1 hr. on three separate days.

The stimuli were constructed from the pairs (3, 3), (4, 3), (3, 5), (4, 5), and (5, 5). Each pair could serve as part of an addition or a multiplication stimulus. The stimulus answer (the right-hand side of the equation) was one of the following four types: (*a*) associative confusion items (e.g., $3 + 5 = 15$; $3 \times 5 = 8$); (*b*) nonassociative confusion items, chosen from the set of possible answers to the other operation (e.g., $3 + 5 = 25$, because 25 is in the set of answers to multiplication problems); (*c*) confusion items, chosen from the set of possible answers for the actual operation (e.g., $3 + 5 = 10$, because 10 is the answer to one of the addition problems); or (*d*) the correct answer (e.g., $3 + 3 = 6$). The complete set of stimuli is given in Table 1. Each number which occurs on the right hand side of an equation is the correct answer for some problem in the set.

Subjects were run under three modes of presentation. In the blocked mode, *S*s received 30 addition problems, then a "ready" signal, and then 30 multiplication problems; the 60 problems together constituted one block in the design. In the triad mode, *S*s received three addition problems, then three multiplication problems, then three addition problems, etc., for 60 trials; the 60 problems constituted a block. In the random mode, *S*s received 30 addition problems and 30 multiplication problems in random order, so that *S*s did not know whether to expect an addition or a multiplication problem. In all three modes, the stimuli were selected by a random process, without replacement.

Within each block, half of the stimuli were correct and half were incorrect. Each stimulus of the three confusion types occurred exactly once per block, and each correct stimulus occurred exactly three times per block. Subjects were given a practice block, which was not recorded, and then eight blocks of trials under a single mode within a day. Mode of presentation was balanced against days in a Latin square design, so that each mode occurred an equal number of times on the first, second, and third days, and so that each *S* received each mode.

A visual warning signal preceded each test stimulus by 500 msec. Subjects were required to push the left of two keys if the stimulus was correct, and the right key if it was not correct; the test stimulus remained on until the *S* made a response. Feedback was given after each response.

The stimuli were exposed on a cathode ray tube, under control of the PDP-15 computer of the University of Oregon cognitive laboratory.

Results. Only data from the three confusion types were analyzed; the stimuli for which the correct answer was *yes* did not bear on the hypothesis.

The experimental design is given by SAMCB, where S = Subjects, A = Operation (addition or multiplication), M = Mode of presentation (blocked, triad, or random), C = Confusion type (associative,

TABLE 1

STIMULI USED IN THE EXPERIMENT

Operation	Associative confusions	Nonassociative confusions	Target confusions	Correct stimuli
$3 + 3 =$	9	12	7	6
$4 + 3 =$	12	9	6	7
$3 + 5 =$	15	25	10	8
$4 + 5 =$	20	15	8	9
$5 + 5 =$	25	20	9	10
$3 \times 3 =$	6	7	12	9
$4 \times 3 =$	7	6	9	12
$3 \times 5 =$	8	10	25	15
$4 \times 5 =$	9	8	15	20
$5 \times 5 =$	10	9	20	25

nonassociative, or target), and B = Block (eight levels).

For the reaction time data, medians were taken over the five stimuli occurring within a block, confusion type, and level of A. Thus, each block yielded six medians. An analysis of variance was performed on these medians.

There was a significant effect of Confusion type, $F\ (2, 10) = 12.96$, $p < .005$, and of Block, $F\ (7, 35) = 2.37$, $p < .05$. Two interactions were significant: the Operation $\times$ Confusion type interaction, $F\ (2, 10) = 18.27$, $p < .001$, and the Mode of Presentation $\times$ Confusion type interaction, $F\ (4, 20) = 4.20$, $p < .05$.

The Scheffé procedure (Meyers, 1966, p. 333) was used to test whether the differences between particular confusion types were significant. The comparison of chief interest was between associative and nonassociative confusions. An experiment-wide error rate of .10 was used, giving an F critical of 5.48. The associative–nonassociative comparison gave an F of 25.90; the associative–target comparison gave an F of 6.90; and the nonassociative–target comparison gave an F of 6.90.

Associative confusions are consistently about 50 msec. slower than nonassociative confusions, across both addition and multiplication, and in all three modes of presentation. Every *S* showed the effect. The error data show 221 errors for associative confusions, as opposed to 46 errors for the nonassociative confusions.

The main effect of Blocks was due to a fairly small but consistent decrease in reaction times over blocks, a practice effect. The difference between associative and nonassociative confusions did not show any consistent decrease over blocks.

The absence of a main effect for Mode of Presentation is surprising: one would have expected the Blocked mode to be faster than the Random mode. The cell means show a tendency in this direction, but the differences are not significant (due to a large Subject $\times$ Mode of Presentation error term, which includes variation arising from the differing orders in which *S*s received the Blocked, Triad, and Random conditions). The error data show the Blocked and Random modes to be approximately equal (mean errors = 3.06 and 3.17, respectively),

TABLE 2

TABLE OF MEAN REACTION TIMES (IN MSEC.)

Item	Confusion type			
	Associative	Nonassociative	Target	[illegible]
Operation				
Addition	749.5(5.2)	695.5(5.2)	691.5(5.2)	713.[illegible]
Multiplication	742.1(5.2)	685.3(5.2)	739.9(5.2)	722.4
M	745.5(7.7)	690.4(7.7)	712.2(7.7)	
Mode of presentation				
Blocked	709.1(4.3)	645.8(4.3)	698.2(4.3)	687[illegible]
Triad	766.7(4.3)	709.8(4.3)	732.3(4.3)	736.[illegible]
Random	761.6(4.3)	706.6(4.3)	721.1(4.3)	729.8
M	745.5(7.7)	690.4(7.7)	712.2(7.7)	

Note. Estimates of standard error derived from [illegible]

with the Triad mode producing somewhat more errors than either (4.03).

The interaction of Operation with Confusion type results solely from the different behavior of Target confusions under addition and multiplication. The weak interaction between Mode of Presentation and Confusion type is also due to the behavior of Target confusions under the three modes of presentation.

Discussion. The main result of interest is that associative confusions produce slower reaction times and more errors than nonassociative confusions. This result cannot be attributed solely to the readings by *S*s, because the effect occurs under all three modes of presentation: in both the blocked and triad modes the *S*s knew which operation to expect in the next problem.

TABLE 3

MEAN ERRORS PER SUBJECT

Item	Statistic	
	M	SE_m
Mode of presentation		
Blocked	3.06	.56
Triad	4.03	.59
Random	3.17	.60
Confusion type		
Associative	6.03	.71
Nonassociative	1.28	.24
Target	2.94	.38

The result forces us to reject an explanation of addition or multiplication based solely on internal computations since such a model would predict no difference between associative and nonassociative confusions. The result strongly suggests that the processes of addition and multiplication contain associative components, and is consistent with the theory that only associative processes are involved in addition and multiplication.

CUE EFFECTIVENESS IN CUED RECALL[1]

MARION QUINN LEWIS[2]

State University of New York College at Plattsburgh

Two experiments investigated effects of cues for categorized lists with both blocked and unblocked category presentation. Category labels and extralist category items were effective recall cues for both blocked and unblocked category lists. Cuing increased recall of categories but did not affect words recalled per category.

With categorized lists, providing the category labels or items from the categories as cues has been found to facilitate recall if category members were presented contiguously (blocked), but cuing has not been found to increase recall if category items were mixed (unblocked) in the lists (Dong, 1972; Lewis, 1971; Slamecka, 1968, 1972; Tulving & Pearlstone, 1966).

Facilitation of recall as a function of cuing has been interpreted as evidence that more information is available in memory than is immediately accessible for recall. Tulving and Pearlstone (1966) interpreted recall of categorized lists as a product of two independent processes, recall of "higher order memory units" (the categories) and the recall of items within the higher order units (category items). Category recall is seen as depending on the number of categories and retrieval cues, but recall of items within a category is apparently related only to whether the category itself is recalled and not to the experimental cues. Cuing increased the number of categories recalled, but did not affect the number of items recalled per category.

The failure of cuing to facilitate recall with unblocked category presentation is puzzling because it is not apparent that the two-level process described by Tulving and Pearlstone (1966) should be specific to blocked lists.

It should be noted that most investigators reporting no cued facilitation with unblocked lists used items from the list as cues (Lewis, 1971; Slamecka, 1968). List-item cues do not appear to be without effect, as Lewis (1971) reported such cues increased recall of blocked lists. However, when list items are used as cues, scoring of both cued and noncued conditions has been on the basis of "critical" words. That is, cue words are chosen before the list is presented, and the other list items are regarded as critical or target items. Thus, to the extent that *S*s recall noncritical items which are not scored, total recall may be underestimated. It may be possible to devise scoring procedures or experimental manipulations which are unbiased in this respect. For example, this bias would not occur if cues were category labels (e.g., Tulving & Pearlstone, 1966) or other extralist items.

In the present investigation of cuing effects with blocked and unblocked category presentation, two types of cues were used: category labels and category members which were not presented as list items.

Experiment I: Category Label Cues

Method. Eight categorized lists were prepared. Each 42-word list consisted of six Battig and Montague (1969) categories, with seven words per category. Category items were the words ranked 2–8 in the association norms, excluding obvious multiple-category items (for example, orange as color and fruit). Categories were assigned to lists at random. Both a blocked and an unblocked version of each list were prepared. For the blocked version, all category members were presented contiguously; category orders and within-category item orders were randomized. For the unblocked version, category items were mixed throughout the list with the restriction that no more than two items from the same category were presented contiguously.

There were thus four treatments representing lists and cuing conditions: blocked and unblocked list versions, and cued and noncued recall. Each treatment combination was presented twice; four list–treatment combinations and orders were prepared. For Cued conditions, the cue for each category was the category label.

Lists were presented on audio tape at a 2-sec. rate for written free recall. After the last word on each list, the *S*s heard a three-digit number. They wrote that number and subtracted from it for 6 sec., until signaled to begin recall. This procedure was used to equate cued and noncued recall in terms of possible forgetting from short-term memory while examining cues under cued recall (Lewis, 1971; Slamecka, 1968).

When the recall signal was given, the *E* turned over a card. For cued conditions, cues were printed on the card; for noncued recall, the card simply said to begin recall. For any given list, the *S*s did not know whether recall would be cued or noncued until they saw the card. The recall interval was 2 min. The *S*s were tested in small groups of two or three.

The *S*s were 40 students enrolled in psychology classes at the State University of New York College at Plattsburgh. They received extra course credit for participation.

TABLE 1

PERCENT TOTAL RECALL, CATEGORY RECALL, AND WORDS PER CATEGORY: EXPERIMENT I (CATEGORY LABEL CUES)

Recall condition	Presentation: Blocked			Presentation: Unblocked		
	Total recall	Categories	Words per category	Total recall	Categories	Words per category
Cued	53.4	95.8	55.7	48.4	97.1	49.3
Noncued	40.6	70.2	57.5	42.7	82.7	51.3

Total recall, number of categories recalled (defined as recall of at least one item from the category) and mean words per recalled category were examined by separate 2 × 2 × 40 (Presentation condition × Cuing condition × *Ss*) analyses of variance. Newman-Keuls comparisons among individual treatment combinations were made.

Results. Total recall, category recall and mean words per recalled category (WPC) are shown by percentages in Table 1.

Total recall was higher for cued recall (CR) than for Noncued recall (NCR), F (1, 39) = 50.48, $p < .005$. For both Blocked and Unblocked presentations, CR was higher than NCR, $p < .01$. The difference between Cuing conditions was larger for Blocked than for Unblocked presentation, F (1, 39) = 10.46, $p < .005$.

More categories were recalled with CR than NCR, F (1, 39) = 120.45, $p < .005$; and category recall was higher for Unblocked than for Blocked presentation, F (1, 39) = 22.22, $p < .005$. The effect was clear in the interaction, F (1, 39) = 10.49, $p < .005$. With CR there was no difference between Blocked and Unblocked presentation, both being nearly perfect; but with NCR, Unblocked category recall was higher than Blocked, $p < .01$.

More words per category (WPC) were recalled with Blocked than with Unblocked presentation, F (1, 39) = 30.50, $p < .005$. No other effects or interactions were significant.

The results are clear. Category label cues facilitate recall for both Blocked and Unblocked lists. The facilitation derives from higher category recall with cues. There is no difference between Cuing conditions in mean words per category.

It is perhaps possible that there is a qualitative difference between category items and category labels as cues. Intuitively, the label seems a more potent cue. In Experiment II, the cue for each category was an item which had not been presented on the list. That is, the cues were extralist members of list categories.

EXPERIMENT II: EXTRALIST CATEGORY ITEM CUES

Method. The lists prepared for Experiment I were used. For Cued conditions, cues were the highest ranking word in each category in the word association norms. The procedure was the same as for Experiment I.

The *Ss* were 26 students enrolled in psychology classes at the State University of New York College at Plattsburgh. They received extra course credit for participation.

Total recall, number of categories recalled, and mean words per recalled category were analyzed by separate 2 × 2 × 26 (Presentation condition × Cuing condition × *Ss*) analyses of variance. Newman-Keuls comparisons among individual treatment combinations were made.

Results. Total recall, category recall and mean words per recalled category (WPC) are shown by percentages in Table 2. Total Cued recall (CR) was higher than Noncued recall (NCR), F (1, 25) = 14.06, $p < .005$; and Blocked presentation was higher than Unblocked, F (1, 25) = 8.77, $p < .01$. The interaction was not significant.

Category recall was higher for CR than for NCR, F (1, 25) = 44.30, $p < .005$. Unblocked category recall was higher than Blocked, F (1, 25) = 7.08, $p < .025$, largely because of higher Unblocked NCR category recall; however, the interaction was not significant.

Mean words per recalled category (WPC) was higher for Blocked than for Unblocked presentation, F (1, 25) = 22.09, $p < .005$. There was no interaction or effect due to Cuing.

Overall, the results replicate those of Experiment I. Cuing facilitates recall by increasing category recall. Mean WPC is not affected.

Discussion. The cued facilitation with both Blocked and Unblocked category presentation using category labels and extralist category items as cues is consistent with Tulving and Pearlstone's (1966) formulation of recall as a process of (*a*) recalling higher order memory units, and (*b*) recalling contents of the higher order units. Cuing increased category recall (higher order units), but did not affect recall of items within a category.

Previous results (Lewis, 1971; Slamecka, 1968) showed no increase in recall for unblocked lists with list-item cues. Present findings indicate consistent facilitation with extralist cues, regardless of presentation condition. This suggests that critical-item scoring procedures used with list-item cues may

TABLE 2

PERCENT TOTAL RECALL, CATEGORY RECALL, AND WORDS PER CATEGORY: EXPERIMENT II (EXTRALIST CATEGORY ITEM CUES)

Recall condition	Presentation: Blocked			Presentation: Unblocked		
	Total recall	Categories	Words per category	Total recall	Categories	Words per category
Cued	50.9	94.9	53.5	45.0	96.2	46.8
Noncued	43.4	76.6	57.1	40.5	83.9	48.1

introduce sizable artifacts, which would account for the apparent discrepancy between previous and present findings.

Slamecka (1972) pointed out that cuing does not increase recall if unaided category recall is nearly perfect. In this context, the smaller differences between cuing conditions observed with Unblocked presentation is understandable. Noncued category recall is substantially higher for Unblocked than for Blocked presentation. There is less opportunity for cuing to add categories.

The higher Unblocked category recall might reflect differential Blocked–Unblocked memory organization. With Blocked presentation, it is most probable that *S*s will use *E*-defined categories to organize information for storage and retrieval. With Unblocked presentation, *S*s may develop somewhat different categories (for example, instead of a single "bird" category, *S* may use two, as "songbirds" and "birds of prey"). Moreover, serial position effects favor higher category recall with Unblocked presentation. Although the distractor task between list presentation and recall tends to reduce the characteristic free-recall recency peak, such a task has little effect on primacy (Glanzer & Cunitz, 1966). The first few words on an Unblocked list are from several categories, but the first few words on a Blocked list are all from the same category.

Taken overall, the results of the present experiments demonstrate that cuing can facilitate recall with both Blocked and Unblocked lists. As such, these findings appear inconsistent with those of Dong (1972), who reported no cued facilitation with category label cues on an unblocked list. Dong presented a given *S* with only one list; in the present experiments *S*s received several lists, both cued and noncued. Lewis (1971) noted that on every measure (total recall, category recall and WPC) differences between cuing conditions were greater for the last list of a series than for the first list. Although *S*s in the present experiments could not anticipate cues for any particular list, it may be speculated that they learned to use cues more effectively after having received cues several times. This speculation is consistent with both Lewis' (1971) findings and Dong's suggestion that cuing effects may reflect strategies and memory control processes.

RECALL OF ANTONYMS FROM SHORT-TERM MEMORY[1]

LAIRD S. CERMAK[2]

Psychology Service, Boston Veterans Administration Hospital

An experiment was designed to investigate the effect of introducing antonyms on adjacent trials of a short-term memory distractor task. It was discovered that recall of the antonyms increased when the trial on which they occurred was preceded by several trials each containing words that were antonyms of the final trial. However, recall did not increase when only the immediately preceding trial contained the antonyms. An interpretation based on the priming hypothesis is given.

Proactive facilitation (PF) has been used to describe instances in which retrieval of a particular word is facilitated by the fact that the word shares a feature in common with one or more previously presented words. Proactive facilitation has been demonstrated by Cermak (1970), who found, during the course of a distractor experiment, that when the to-be-remembered words in a particular triad are acoustically identical to words presented on the preceding trial (i.e., they are homonyms) their retrieval is facilitated. However, PF does not occur if the relationship between two adjacent trials is based upon the semantic features of the words. For example, synonyms, antonyms, and highly associated words all failed to produce facilitated retrieval of the second member of the relationship.

The failure of synonyms and associates to produce an increase in recall can be explained by the fact that these words also all belong to the same class of material and probably interfere with, rather than facilitate, one another's retrieval. However, interference between antonyms was unexpected since these words come from "opposite" categories and should be differentially encoded. One possible explanation for the antonym result might be that the procedure that was used, one in which only two words shared the critical relationship, may not have been sufficient to produce differential encoding. The usual procedure used to study differential encoding ability presents several instances of a particular relationship before testing for the ability to detect and utilize a differential relationship (Wickens, 1970). Perhaps a subject cannot encode antonyms as belonging to two separate categories unless a differential "relationship" has already been established. The present report investigates this possibility by preceding the introduction of an antonym relationship with either several unrelated word triads (Experiment I) or with several synonymous word triads (Experiment II).

EXPERIMENT I

Method. The *S*s were 48 introductory psychology students at Tufts University who chose to participate in the experiment as partial fulfillment of a course requirement. The *S*s were randomly assigned in order of their appearance to one of the two groups, with 24 in each group.

The short-term memory (STM) distractor technique was used. In this procedure a word triad was projected on a screen and the *S* repeated the words once; the *S* was then distracted from rehearsal until a signal for recall was presented. The distractor task consisted of counting backward by threes from a number flashed on a screen in time with a metronome beating at one beat per second. Four additional trials followed consisting of different word triads but using the same procedure.

The words used in this experiment were chosen in such a way that an antonym existed for each word. Five such word triads were used so that each triad could appear in each of the five positions in the series. In other words, five basic slides were counterbalanced with the fifth trial bearing an antonym relationship to the fourth trial for the subject in the Experimental (Antonym) Group, but no relationship at all for the subject in the Control Group.

The experiment consisted of five trials in which the material presented on Trial 5 bore one of the following relationships to the material presented on Trial 4: Antonym Group—antonymity; Control Group—no relationship. Trials 1–4 bore no relationship to one another for either group. In order to compare the Antonym Group's performance on the fifth trial with the Control Groups', both groups received the same stimulus material on that trial. The antonym or neutral relationship was established by presenting different material on Trial 4. In other words, the Antonym Group received antonyms of Trial 5 on Trial 4, whereas the Control Group received words unrelated to those of Trial 5 on Trial 4. Any differences in recall on Trial 5 could thus be attributed to the effects of the relationship that had been produced previously and not the difficulty level of Trial 5 material.

The *S* was seated facing a screen upon which the material was projected by means of a Kodak Carousel 800 projector. The projector was timed by a Gerbrands tape timer. The only other apparatus

in the room was a metronome used to pace *S*'s distractor task. After the instructions had been given, *S*s practiced on the counting task until approximation to the metronome was achieved. The timing and sequence of events were then initiated by the tape timer and the time intervals for one trial were as follows: asterisk (ready signal), 2 sec.; trial presentation, 2 sec.; retention interval, 15 sec.; recall interval, 10 sec.; rest interval, 6 sec. Recall was scored as the number of correct words given out loud during the 10-sec. recall interval. Following the end of the fifth trial, *S*s were asked whether they had noticed any similarities or differences among any of the word triads, and their responses were noted at that time.

Results. On Trial 5, the critical trial, the Antonym Group recalled 60% of the words correctly, while the Control Group recalled 57% correctly (Figure 1). There was no significant difference in recall between the group receiving an antonym triad on the previous trial and a group that did not. Furthermore, only two *S*s reported detecting the antonymity relationship. The buildup of proactive inhibition (PI) from Trial 1 to Trial 4 was significant ($p < .01$) for both groups and neither group showed any significant increase from trial 4 recall to trial 5 recall.

EXPERIMENT II

Method. The *S*s were 40 introductory psychology students at Tufts University who chose to participate in the experiment as partial fulfillment of a course requirement. The *S*s were randomly assigned in order of their appearance to one of the two groups with 20 in each group.

The distractor technique was used but, unlike Experiment I in which a relationship existed only between Trials 4 and 5, the present experiment presented word triads on Trials 1 through 4 that were synonymous with each other. In other words, the first word in each triad meant the same as the first word in each of the other triads and the second word meant the same as each other triad's second word, and so on. Trial 5 (the critical trial) contained words that were either antonyms of the preceding four triads, or were synonyms. Thus, the groups were differentiated on the basis of the type of relationship existing between the words presented on Trial 5 with those on Trials 1–4. It must be pointed out that the words appearing on Trial 5 were the same for both groups, and, in fact, were the same as those used in Experiment I. Trials 1–4 were all antonyms of Trial 5 for the Antonym Group, but they were synonymous with one another. For the Synonym Group the same word triad appeared on Trial 5, but all the preceding triads were synonyms of this triad and were synonymous with one another. Two sets of critical Trial 5 word triads were used in the experiment, both appearing under synonym and antonym conditions.

Results. On Trial 5, the Antonym Group recalled significantly more words than the Synonym Group, t (38) = 2.20 ($p < .05$). The Antonym Group recalled 82% of the words correctly while

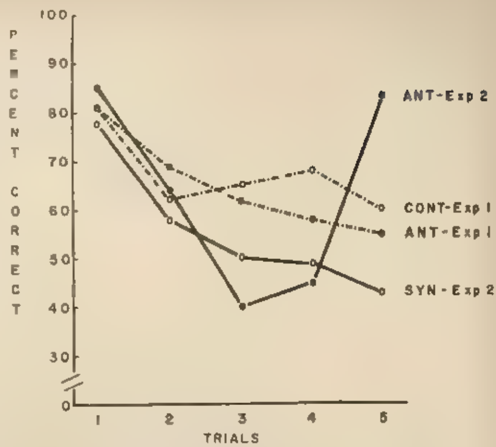

FIGURE 1. The percentage of words correctly recalled for the Antonym and Control Groups of Experiment I and the Antonym and Synonym Groups of Experiment II.

the Synonym Group recalled only 42% correctly (Figure 1). Both groups showed equivalent and significant ($p < .01$) reductions from Trial 1 recall to Trial 4 recall.

A comparison between the Antonym Group of this Experiment and the Antonym Group in Experiment I can be made since the same word triads were used on Trial 5 of both experiments. The only difference between the two groups was in the number of preceding trials that bore the antonym relationship with the word triad on Trial 5. In Experiment II four synonomous triads preceded the switch to antonyms and 82% of that critical trial was recalled correctly. In Experiment I only one such triad preceded and only 60% was recalled correctly on the critical trial. This difference was significant at the $p < .01$ level, t (98) = 2.95. Trial 4 recall performance in Experiment I was compared with the same performance in Experiment II in order to determine the difference in the extent of PI buildup in the two experiments. This difference was significant, t (98) = 2.53, $p < .05$, since *S*s in Experiment I averaged 63% (both groups combined) and *S*s in Experiment II averaged 46.5%. There were no differences between Experiments on Trial 1 performance.

DISCUSSION

The results of these two experiments, taken together, suggest that the presentation of more than one exemplar from a category may be necessary before the introduction of information from the opposite category will result in an increase in recall probability. This was shown by the fact that no increase in performance occurred when only Trials 4 and 5 contained antonyms of one another (Experiment I) but did occur when Trial 5 contained words that bore an antonym relationship with each of the preceding four trials (Experiment II). It could be that more than one instance of a relationship is needed before a subject can differentiate words that

do not participate in this particular relationship. This relationship could be established in one trial if all the words in that triad shared in the relationship, but more than one trial is needed in the present paradigm because no within triad relationships exist.

This finding poses a problem for theories that assume a word can be automatically encoded along several different dimensions immediately upon its presentation. If this were the case then the buildup of a relationship among the words should not be a necessary condition for release because differential encoding would occur as a result of automatically encoding several dimensions of each word. However, the present experiment suggests that encoding of specific features of a word may depend upon "priming" the subject for these features (Underwood, 1972). If this is true then an alternative to the automatic encoding hypothesis must be sought to explain the PI release effect.

SEMANTIC AND ASSOCIATIVE INTERACTIONS IN CHILDREN'S FALSE RECOGNITION[1]

PHEBE CRAMER[2] AND ANDREW P. SCHUYLER[3]

Williams College

Previous studies of memory encoding and false recognition in children have tended to focus *either* on associative relationships *or* on semantic attributes. The present study, based on the responses of third- and sixth-graders, indicated that associative and semantic factors interact to produce the false recognition effect. For Synonyms, associative strength determined the magnitude of false recognition, while for Antonyms, it was not important.

Both associative relationships and semantic features have been shown to be successful predictors of errors in children's recognition memory (e.g., Bach & Underwood, 1970; Cramer, 1972a). In general, however, those studies that have investigated the effect of associative relationships have not been concerned with the role of semantic features, while those that have investigated semantic features have not considered the possible role of associative relationships.

The influence of these two variables was investigated by Felzen and Anisfeld (1970), who compared the false-recognition errors made by third- and sixth-grade children to strongly and weakly associated synonyms and antonyms. On the basis of the finding that strong associates produced no more errors than did weak associates, they concluded that associative relationships among words played no significant role in determining such errors.

This conclusion, of course, was at variance with the results obtained in the studies cited above. Two possible reasons for the nonconfirmatory results are suggested. First, previous work with adults has indicated that there is an interaction between semantic category and associative relationship in determining recognition errors (Cramer, 1972b). If such an interaction were also a determinant of children's performance on a recognition memory task, it might mask the main effect of either variable. Second, the nonconfirmatory findings may be a function of the fact that words used to represent the various semantic and control categories were not mutually exclusive. On both lists, some of the words listed as Rhymes and nearly half of the words listed as Controls were in fact associates of the critical stimuli (based on Palermo & Jenkins, 1964, data for Grades 4–6). Considering this observed overlap, it seems likely that the other 28 filler words, interspersed throughout the continuous list presentation, might also be associatively related to the critical stimuli. Thus it is difficult to interpret the basis on which false recognition errors were being made.

The present study was designed to determine the extent to which these two factors—semantic × associative interaction and stimulus category over-

lap—were responsible for the failure to find strength of associative relationship as a significant factor in determining children's recognition memory. The general continuous presentation method of Felzen and Anisfeld (1970) was followed. However, great care was taken to eliminate associative overlap among the experimental, control, and filler word categories.

Method. The *S*s were 40 third-graders and 40 sixth-graders. An equal number of boys and girls was tested individually in each condition at each grade level. Following a practice list, consisting of numbers, each child was given the experimental test list. He was asked to indicate whether each item on the list was "old" or "new." The *S*s within each grade were assigned randomly within blocks of four (Weak/Strong associates $\times$ 2 test orders). Male and female *S*s were tested on alternating blocks.

In order to construct the test list, a group of 20 critical stimulus (CrS) words was selected such that half of the words elicited synonym word-association responses and half elicited antonym responses. An important criterion for the selection of these stimuli was that the associative responses should be of approximately equal strength for both third-graders (Palermo & Jenkins, 1966) and sixth-graders (Palermo & Jenkins, 1964). Of the 10 CrS–Synonym pairs, half were strongly associated (Third grade: $M = 40.0\%$; Sixth grade: $M = 47.6\%$) and half were weakly associated (Third grade: $M = 1.4\%$; Sixth grade: $M = 2.1\%$). Similarly, of the 10 CrS–Antonym pairs, half were strongly associated (Third grade: $M = 46.8\%$; Sixth grade: $M = 41.2\%$) and half were weakly associated (Third grade: $M = 1.2\%$; Sixth grade: $M = 1.2\%$). The Synonyms and Antonyms were equated approximately for Thorndike–Lorge (1944) familiarity.

From these materials, two lists were prepared. One list consisted of the 10 strongly associated CrS–Synonym and CrS–Antonym pairs; the other list consisted of the 10 weakly associated pairs. In addition, each list included 10 control words (words that had no associative relationship to any word previously presented) and 12 filler words. The words of each list were presented in two different orders, to control for possible sequence effects, making four test lists in all. Each of the four lists consisted of 59 items, and was constructed such that a word of the same class (CrS, Synonym or Antonym, Control, or Filler) was assigned the same item position on each list. Each CrS word appeared twice on the list, with 7 items intervening between the first and second presentation. Each Synonym or Antonym appeared 9 items following the second presentation of its respective CrS. A control word appeared either immediately prior to or directly after each Synonym or Antonym. The list positions not occupied by CrS, Synonyms or Antonyms, or Control words were assigned to filler words. Each list was recorded on magnetic tape at a 5-sec. rate.

Inasmuch as the study was concerned with the specific associative relationship between each CrS–Synonym or CrS–Antonym pair, it was important to make sure that no Synonym, Antonym, or Control word was associatively related to any other preceding word in the list. Thus care was taken that there was no associative relationship (associative strength = 0%) between any CrS, Synonym, Antonym, Control, or Filler word, and any subsequent experimental (Synonym, Antonym, or Control) word, other than the specific CrS–Synonym or CrS–Antonym associative relationship being investigated.

TABLE 1

MEAN NUMBER OF "OLD" RESPONSES TO SECOND PRESENTATION OF CRITICAL STIMULUS WORDS (CRS'), ASSOCIATE, AND CONTROL WORDS

	CrS's[a]	Associates[a,b]	Control[a]	Total *R*s
Third grade				
Weak list	9.0	1.6	.8	11.4
Strong list	9.1	1.5	.2	10.9
Sixth grade				
Weak list	9.1	1.2	.7	10.9
Strong list	9.3	1.6	.2	10.7

[a] Maximum value = 10.
[b] Includes Synonyms and Antonyms.

Results and discussion. The *S*s' responses were analyzed first in terms of the number of "old" responses made to CrS, Associate, and Control words. These results are presented in Table 1.

A three-way analysis of variance of these data was performed. A highly significant main effect for Word type was obtained, F (2, 152) = 1,898.45, $p < .001$. Application of the Neuman–Keuls test indicated significantly more "old" responses were given to CrS words than to Associates, and more to Associates than to Controls, all ps $< .01$. There were no other significant main effects.

A second analysis of variance, based on difference scores, considered responses to Synonym and Antonym associates only.[4] While there were no significant main effects, there was a significant Associate Strength $\times$ Semantic Category interaction, F (1, 76) = 18.40, $p < .001$. A Neuman–Keuls test indicated that significantly more responses were made to Strong Synonyms than to Weak Synonyms, to Strong Synonyms than to Strong Antonyms, and more responses were made to Strong Antonyms than to Weak Synonyms (all ps $< .01$) (see Table 2).

The results of the present experiment confirm the findings of earlier studies (e.g., Bach & Underwood, 1970; Cramer, 1972a), by demonstrating that associated words produced more false-recognition errors in children than did nonassociated words, and serve to extend those earlier findings. Contrary to the conclusions of Felzen and Anisfeld (1970), when stimulus materials were selected with adequate concern for the possibility of confounding relationships, synonyms that were strongly associated pro-

[4] Since there were twice as many opportunities to respond to Control words as there were to Synonyms or Antonyms, the difference scores for each *S* consisted of Synonym minus ½ Control and Antonym minus ½ Control.

TABLE 2

Mean Number of "Old" Responses to Synonyms and Antonyms, Corrected for Control Word Error

	Synonyms		Antonyms	
	Weak	Strong	Weak	Strong
Third grade[a]	.05	.80	.75	.55
Sixth grade[a]	.10	.70	.35	.25
Total	.15	1.50	1.10	.80

[a] Maximum value = 5.

duced more errors than did synonyms that were weakly associated.

This statement must be qualified by two further considerations. First, some other linguistic variables, not investigated in this study, may be contributing to the results. More important, from the authors' point of view, is the finding of a consistent pattern of interaction between semantic and associative factors in determining false-recognition errors. For both grades, significantly more responses were given to strong than to weak Synonyms; however, association strength was not important in determining responses to Antonyms.

Thus, the importance of association strength varies with the nature of the semantic relationship. More specifically, it may be that the semantic relationship of antonymity is particularly insensitive to associative strength. In a previous paper (Cramer, 1972b), it was pointed out that several recent studies have found associative variables to have a different, and counterpredicted effect on antonyms, as compared to other word types. Inspection of the published results of Felzen and Anisfeld (1970) reveals that the same Associative Strength × Semantic Category interaction appeared in their data.

SHORT-TERM MEMORY LIMITATIONS ON DECODING SELF-EMBEDDED SENTENCES[1]

MAIJA S. BLAUBERGS[2]
University of Georgia

MARTIN D. S. BRAINE
New York University

Previous studies on self-embedding have not isolated the contribution of a limited short-term memory span to the difficulty of processing self-embedded sentences. With the procedure used, auditory presentation of semantically neutral sentences and the use of a memory probe technique to measure processing at five levels of self-embedding, it was found that comprehension breaks down at three degrees of embedding. A control set of sentences, semantically equivalent, but with right-branching structure, were significantly better understood at three to five degrees of complexity, but not at one and two degrees. The results are predictable, given a seven-item short-term memory span, from some plausible assumptions about the manner of processing.

An automaton with limited short-term memory cannot process sentences with unlimited self-embedding (Chomsky, 1963). Although this result must apply to humans, laboratory confirmation has proved surprisingly difficult. Miller and Isard (1964) showed that sentences of equal length and equivalent word content are memorized with increasing difficulty from zero degrees through four degrees of self-embedding. However, Blumenthal (1966) criticized this study on the grounds that naive *S*s do not process multiply-self-embedded sentences correctly, but perceive them as ungrammatical sentences with a single embedding of conjoined relative clauses modifying the initial noun. Blumenthal's *S*s were unable to correctly rewrite three-degree self-embedded sentences in a more understandable form. Since *S*s do not perceive the structure, their poor performance cannot be due to difficulty in processing the structure.

Other experimenters have found that humans can decode self-embedded sentences under suitable conditions. Schlesinger (1968) and Stolz (1967) found that they can be decoded if each predicate is pragmatically appropriate to its subject, and inappropriate to the subjects of the other clauses. Self-embedded sentences with this property were called "semantically supported." To explain his results, Schlesinger proposed a "semantic-syntactic decoding process" in which the temporary memory store merely retains the nested parts (i.e., subjects and predicates), but no order information, and then the decoder matches up the parts with the help of the semantic cues. This decoding strategy cannot be used to decode semantically neutral sentences (i.e., sentences in which any of the predicates can pragmatically be predicated of any of the subjects) because such sentences cannot be interpreted unless the order of the subjects and predicates is registered. Stolz found that semantically neutral sentences can be decoded, but only after explicit training on the self-embedded structure. However, in Stolz's study the written form of the sentence was always available as an external memory aid for the *S*s to refer to, and thus the contribution of short-term memory to the difficulty of processing self-embedded sentences was again not examined.

Since none of the studies in the literature have shown that human short-term memory limitations actually interfere with the processing of self-embedded sentences, one purpose of the experiment reported here was to demonstrate and measure the extent of the interference. While the existence of a performance deficit is certain, the size of the deficit at various levels of self-embedding depends on how humans use their short-term memory in processing sentences. Measurement of the deficit therefore provides a basis for inferences about the manner of processing.

The literature reviewed makes clear that an adequate study must present material auditorily, must use semantically neutral content (to preclude *S*s from using Schlesinger's, 1968, semantically based decoding strategy described above), and must begin by training *S*s on the nature of self-embedded sentences (otherwise errors will reflect lack of competence, not difficulty of processing). Since increasing self-embedding inevitably increases sentence length, matching right-branching sentences were used to estimate errors due to sentence length alone.

Method. Forty introductory psychology students were assigned to one of two conditions with 8 males and 12 females in each condition. In both conditions, self-embedding (SE) and right-branching (RB) training in the understanding of the sentence structure used was given, followed by tests of comprehension. The sentences varied from one to five degrees of complexity (i.e., from one to five embedded or appended relative clauses). The word content of equivalent sentences in the two conditions was the same. All sentences used in the practice and test sessions were semantically neutral (i.e., any of the subjects can form a semantically sensible sentence with any of the predicates).

[1] This paper is based on part of the first author's MA thesis at the University of California, Santa Barbara, 1970, under the sponsorship of the second author.

Since the procedure was identical for the two conditions except for the use of SE sentences in one condition and RB sentences in the other, it will be described here only for the SE condition. The instructions read to the *S* by the *E* included an explanation of the grammatical structure of an SE sentence and an example illustrating how an SE sentence is composed of simple sentences. The explanation was accompanied by a visual display on cardboard strips of the examples used. The *S* was then given a series of practice SE sentences to read to himself. The series consisted of at least two sentences from each degree of embeddedness proceeding from one degree to five degrees. Comprehension of a sentence was tested by requiring the *S* to answer questions about the content, e.g., "Who was bickering with the Chinaman?" and "Who adored food?" were the questions for the SE sentence, "The Chinaman whom the Italian was bickering with adored food." The number of questions per sentence depended on the number of simple sentences it was composed of, i.e., there was one question per simple sentence. An exhaustive list of questions of the kind described involving all the constituent simple sentences was asked in a random order for each practice sentence. The criterion for proceeding to the next degree of complexity was that there be no more than one error in two consecutive practice sentences at each level. (This criterion was met at each level by all *S*s: SE *S*s never required more than four practice sentences to meet the criterion at any level, and RB *S*s never more than three.) The *S* was given an opportunity to correct his errors at the end of the questions for each practice sentence.

After the *S* had reached criterion at all levels of complexity, six test sentences for each level were presented by tape recorder. The order of presentation of the sentences of the differing degrees of complexity was randomized within the set of 30 sentences that each *S* heard. The *S*s were given as much time as they needed after each sentence to fill in a blank in a single simple sentence taken from the sentence they had just heard. Answers were written in an answer booklet that had separate pages for each blank. Examples of the blanks for the SE sentence given previously might be "——— adored food" and "The Italian was bickering with ———." (Only one of these sentences actually appeared in the answer booklet for this sentence.) The word to be filled in was always a noun but might be either the subject or object noun. Equal numbers of subject and object nouns (three each) were used at each level of SE, but they appeared randomly in the sequence of test sentences. The *S* was instructed not to turn the page for the next blank until after he had listened to the sentence for it, so that he did not know what information to listen for, but instead would try to comprehend the whole sentence. The *S* was allowed to hear each sentence only once and was not allowed to make any written notes about it. A practice sentence, which was reread if the *S* had any difficulty with it, was provided before the test session began. The *S* was allowed to guess when filling in the blanks for the test sentences but not told if his answers were correct or incorrect.

Results. The total number of correct responses at each level of complexity for each *S* was recorded. A correct response consisted of filling in the blank with the appropriate noun. The mean number of correct responses is plotted against the levels of complexity for both conditions (SE and RB) in Figure 1. (A chance level calculated on the assumption that the *S* would choose randomly from all nouns present in the sentence is included.)

A two-way, repeated measures, analysis of variance with *S*s nested within the two levels of the sentence-type factor (SE and RB) was used to analyze the data. The main effect of sentence type was significant, F (1, 38) = 37.4, $p < .01$, as was the main effect of sentence complexity, F (4, 152) = 134.1. The interaction between the two was also significant at the .01 level, F (4, 152) = 10.7. The significant sentence-type effect indicates that sentences with RB structure received significantly more correct responses than sentences with SE structure. The significant complexity factor indicates that level of complexity had a differential effect on the number of correct responses.

Since the interaction between the two factors was significant, the simple main effects of each factor were examined for significance at each level of the other factor. Significant differences were found for sentence type at the third, fourth, and fifth levels of complexity ($p < .01$ in all cases). Furthermore, significant differences were found for the complexity factor in each type of sentence ($p < .01$).

Scheffé tests were computed on all possible differences between pairs for the level-of-complexity factor for each sentence type. For the SE sentences, it was found that there were significant differences at the .01 level between each of the first and second levels of complexity and each of the third, fourth, and fifth levels of complexity. For the RB structure, significant differences at $p < .01$ were found between one degree and three, four, and five degrees; between two degrees and four and five degrees; and between three and five degrees.

Since the position of the test simple sentence within the longer sentence might have an effect on the number of errors, percentages of correct responses of the possible correct responses at each level of complexity for each position of a test simple sentence were calculated for the SE sentences. These percentages are as follows: 100% of responses to the first position, i.e., outermost simple sentence, and 100% of the responses to the last or innermost position, at one degree of complexity; 77.5% from the first position, 67.5% from the middle, and 95% from the innermost position at two degrees; 45% from the first, 30% from the middle, and 30% from the innermost position at three degrees; 50% from the first, 27.5% from the middle, and 40% from the innermost position at four degrees; 75% from the first, 21.3% from the middle, and 20% from the innermost posi-

tion at five degrees. The high percentages of correct responses to the outermost sentence presumably reflect combined primacy and recency effects, i.e., a tendency to remember the first subject and the last predicate. Thus, even when the entire sentence is not fully processed, the *S* may be able to correctly respond to probe items from the outermost simple sentence in the complex SE sentence. If these increased percentages of correct responses to the outermost test simple sentence at the higher levels of complexity are disregarded, it is clear that the scores at levels three, four, and five are even closer to chance level than the points in Figure 1 suggest. (A tendency for a larger percentage of correct responses to test sentences from the last or most recently presented clause in the RB sentences was also observed. Thus, the correct responses for RB sentences may also have included some responses that would not necessarily reflect processing of the complete complex RB sentence.)

The significant differences found for the complexity factor over both grammatical types support the hypothesis that comprehension decreases with degree of complexity. Furthermore, the finding of significant differences between SE and RB at the third, fourth, and fifth levels of complexity substantiates the hypothesis that the decrease in comprehension is greater in the SE condition.

Discussion. Results of the comparison between SE and RB conditions support the contention that it is complexity peculiar to SE and not merely sentence length that is causing the increased difficulty at the higher levels since there are no significant differences between SE and RB at levels one and two, but there are significant differences between SE and RB at levels three, four, and five. Length of sentence does contribute to increased errors since errors tended to increase with degree of complexity for both RB and SE sentences as shown by the downward curves in Figure 1. However, the sharp drop to near chance responses at level three for SE sentences, combined with the fact that the first significant difference between SE and RB appears at three degrees suggest that SE sentences become peculiarly difficult to comprehend at three degrees of complexity and remain so at higher degrees. Not understanding the structure has been ruled out by training the *Ss*. Length of sentence has been controlled by comparison with equivalently long RB sentences.

Thus, since the memory factor associated with length of sentence alone was constant for SE and RB sentences, the difference in errors between SE and RB sentences at each level is an unconfounded measure of increased difficulty in understanding sentences with SE structure. The reason for this difficulty is presumably the increasing demands on the short-term memory which, it is suggested here, exceed the available capacity. Thus, at three degrees of SE, in order to complete the simple sentences (i.e., recombine subjects with appropriate predicates), the decoder, hearing the predicates in reverse order to the subjects, must retain eight

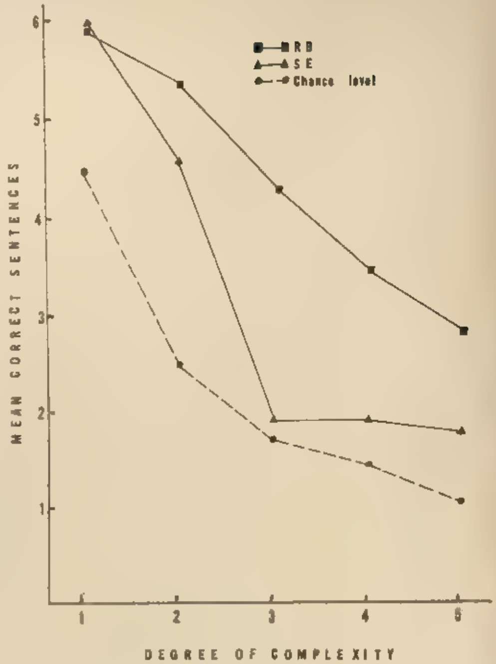

FIGURE 1. Mean number of test sentences correct as a function of complexity level. (Abbreviations: RB = right branching and SE = self-embedding.)

different items in order if recombination is done after hearing the complete sentence, or somewhere between four and eight items if recombination occurs starting with the first predicate heard. Only if the list of subjects were erased one by one as recombinations were completed before the next predicate was heard would there be only four items at a time present in the short-term memory. There is no reason to postulate such erasure. Thus if subjects and predicates are considered chunks or items of information, which seems reasonable since in the SE sentence they are presented discretely to the decoder, eight such items would have to be stored at the three-degree level. Accordingly, it is suggested that the breakdown of comprehension at the three-degree level can be accounted for by the assumption that the limitation of short-term memory to approximately seven items at a time (Miller, 1956) is first exceeded at this level of complexity. For RB sentences, the simple sentences conjoined by relative pronouns may reasonably be considered as the chunks of information to be retained. Thus, even at five degrees of complexity, a maximum of only six chunks need be retained. The results therefore support Miller's claim.

In conclusion, decoding beyond two degrees of SE for semantically neutral sentences is virtually

impossible, presumably due to structurally intrinsic short-term memory limitations.

FREE RECALL OF SENTENCES AS A FUNCTION OF IMAGERY AND PREDICTABILITY[1]

P. J. HOLMES AND D. J. MURRAY[2]

Queen's University, Kingston, Ontario, Canada

Four sentences were presented for immediate free recall: the sentences were varied in imagery and in predictability. It was found that these two variables predominantly affected recall from the secondary memory component of the serial position curve, but that they exercised enough of an effect in what was ostensibly the primary memory component to suggest that even when primary memory could be used for retention *Ss* will try to process sentences in depth. In general high imagery and high predictability improved recall, with the exception that predictable abstract sentences were better recalled than predictable concrete sentences for the last serial position only.

In studies of free recall of isolated words, it has been suggested that the last three or four words presented are recalled from a short-lasting type of storage known as primary memory, whereas the early and middle items are more likely to be recalled from secondary or long-term memory (see, e.g., Glanzer & Cunitz, 1966). As yet there seems to be no comparable evidence in respect of sentence retention. It is known that two variables likely to aid sentence retention are imagery (Paivio, 1971) and predictability (Rosenberg, 1968). These variables are, however, more likely to affect secondary memory: for example, Madigan, McCabe, and Itatani (1972) showed that the imagery value of isolated words presented for free recall mainly affected the secondary memory component of free recall. It would therefore be predicted that in the free recall of sentences only the recall of the early sentences would vary with imagery and predictability. Recall of the last sentence presented, which, according to current views, would probably be recalled from primary memory, should not be affected by these two variables. The present experiment was designed to discover whether this was the case.

Method. Four types of sentence were constructed: Predictable–Concrete (PC), Predictable–Abstract (PA), Unpredictable–Concrete (UC), and Unpredictable–Abstract (UA). Twelve examples were found of each, making a total of 48 sentences. All sentences were of the form, "The (adjective) (noun) (auxiliary plus verb) (preposition) (adjective) (noun)," with the variable of imagery being manipulated via the nouns. Using the Paivio, Yuille, and Madigan (1968) ratings of noun imagery, the mean imagery values for the nouns used in the PC and UC sentences were 6.5 (range, 5.73 to 6.86) and 6.45 (range, 5.87 to 6.86), respectively. For the PA and UA sentences the mean ratings were 2.77 (range, 1.93 to 3.37) and 2.85 (range, 1.63 to 3.37), respectively. All sentences were controlled for individual word frequency using the Thorndike Lorge (1944) ratings and all sentences had approximately the same number of syllables (mean, 15.31 syllables). Sentence predictability was defined in terms of the real world likelihood of occurrence of the situation described by the sentence. Typical

[1] This work was carried out as an Honours thesis project by P. J. Holmes under the supervision of D. J. Murray. Expenses were borne by National Research Council of Canada Grant A0-126.

[2] Requests for reprints should be sent to D. J. Murray, Department of Psychology, Queen's University, Kingston, Ontario, Canada.

examples of the four types of sentence are:

PC: The enraged alligator was chasing the small boy.
UC: The angry alligator was smoking his favorite claw.
PA: The serious casualty was caused by poor [illegible].
UA: The new casualty was lacking the re[illegible]d hypothesis.

[illegible] noted that the same individual word can [illegible] both in P conditions and in U conditions: [illegible] was deliberately done in order to keep the P [illegible] U conditions as similar as possible in respect of the individual words used.

The *S*s were divided into four groups: each group received just one of the four types of sentence. Within each group, the 12 sentences were divided into three sets of 4 each, with one set of 4 sentences constituting the material for a single trial. Each *S* thus received three trials. The sentences were presented by tape recorder at a rate such that each sentence took 4 sec. to present, followed by a 4-sec. interval before the next sentence. After each trial of 4 sentences, *S* had 3 min. in which to write down the 4 sentences in any order he preferred. After he had tried to recall the sentences, he was asked to [illegible] words he might still recall.

The sentences were scored both in terms of the number of complete correct sentences, and in terms of the number of critical words retained. There were five critical words per sentence (two adjec[illegible], two nouns, one verb). Since there were few [illegible]es between the two methods of scoring, only the critical word analysis will be presented here.

The *S*s were 40 students from Introductory Psychology classes at Queen's University, with 10 *S*s in each group.

Results. Figure 1 shows the percentage of correct critical words recalled for each of the sentence types as a function of the serial position of presentation. The last sentence was nearly always recalled first, and, following the convention used typically in studies of free recall of words, the retrieval of the elements from the last sentence was considered to be from primary memory. The recall of the first three sentences was considered to be from secondary memory. It is plain from Figure 1 that the differences between the four sentence types recalled from primary memory were less than those same differences as recalled from secondary memory. An analysis of variance on the data shown in Figure 1 revealed that concrete sentences were better recalled than abstract, F (1, 36) = 66.26, predictable sentences were better recalled than unpredictable, F (1, 36) = 18.79, and that there was a strong serial position effect, F (9, 324) = 17.66. All the above values are significant at $p < .001$. The only significant interaction (at the .01 level) was Concreteness × Serial Position, F (9, 324) = 5.19: Figure 1 suggests that this interaction was due to the steeper rise of the Abstract sentences on Serial Position 4

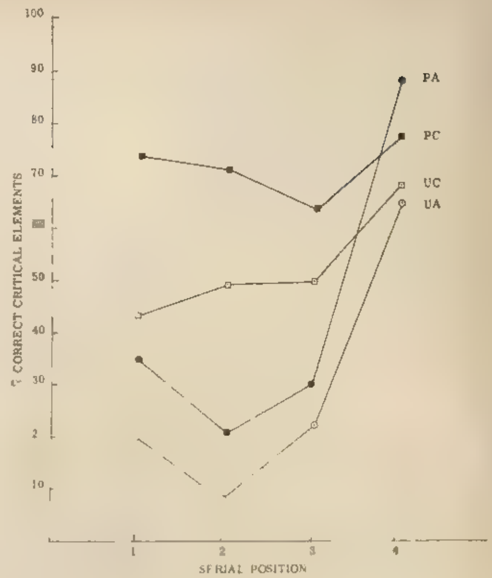

FIGURE 1. Recall as a function of imagery and predictability for the four sentences. (Abbreviations: PA = Predictable–Abstract, PC = Predictable–Concrete, UC = Unpredictable–Concrete, and UA = Unpredictable–Abstract.)

in comparison with that of the concrete sentences, and is consistent with the original hypothesis that the effects of imagery should be more marked in secondary memory than in primary memory. Nevertheless it should be noted that in primary memory the four data points shown in Figure 1 did differ significantly from each other at the .05 level as determined by Newman–Keuls tests.

A closer analysis showed that the reason the PA words were so well recalled from primary memory was that the second adjective and noun were particularly well recalled in comparison with the case for the other three groups. Since an analysis of recall by grammatical class showed that at nearly all serial positions the sentences were recalled in a "forward" manner, that is, with the first adjective and noun being better recalled than the second adjective and noun, it would seem that PA subjects paid more attention to the end of the sentences in primary memory than was normally the case. Incidentally, the fact of "forward" recall suggests that *S*s did indeed try to retain the sentences as units, rather than as collections of individual words: perhaps the first adjective–noun pair formed a "conceptual peg" on which to hook the second adjective–noun pair (Paivio, 1971). The more predictable and concrete the total sentence, the easier this would be to do.

Discussion. Imagery and predictability clearly affected recall from secondary memory, a finding consistent with the results of previous work. But in what was ostensibly retrieval from primary memory, there were two surprises: retrieval did vary

with imagery and predictability, and PA recall was best of all. Two choices are open to us: either we reject the primary–secondary memory dichotomy, at least insofar as sentence retention is concerned, or we assume that *S*s' strategies for dealing with sentences were such as to make it unlikely that the use of primary memory in sentence retention is the same as the use of primary memory for isolated words. Since Figure 1 shows that there was a clear serial position effect, we prefer to adopt the latter view. The fact that sentences were recalled in a forward manner at all serial positions suggests that, even though it was theoretically possible to store the last sentence as a collection of isolated words "echoing" for a few seconds, in fact *S*s preferred to process the last sentence in depth just as they had been doing for the earlier sentences. The advantage for the PA sentences may have resulted from an excessive concentration on the storage of the last sentence: the difficulty of the preceding three sentences may have led *S*s to compensate by storing the last PA sentence both in terms of meaning and at the same time relying on echoic memory to a greater extent than was necessary for the easier PC sentences. If this speculation is correct, it may be inferred that there is a flexibility in the use of primary memory which has perhaps been rather overlooked in the existing literature. In turn, this would suggest that some of the available evidence for primary versus secondary memory actually reflects differences in processing strategies rather than two types of storage (cf. Craik & Lockhart, 1972).

Journal of Experimental Psychology

CONTENTS

ARTICLES

(Continued on inside back cover)

American Psychological Association

Vol. 102, No. 5 May 1974

Beginning in 1975 the *Journal of Experimental Psychology* will appear as four independently edited and distributed sections:

The **Journal of Experimental Psychology: Human Learning and Memory** (Lyle E. Bourne, Jr., Editor) will publish experimental studies on fundamental acquisition, retention, and transfer processes in human behavior.

The **Journal of Experimental Psychology: Human Perception and Performance** (Michael I. Posner, Editor) will publish experimental studies designed to foster understanding of information-processing operations and their relation to experience and performance.

The **Journal of Experimental Psychology: Animal Behavior Processes** (Allan R. Wagner, Editor) will publish experimental studies concerning the basic mechanisms of perception, learning, motivation, and performance, especially as revealed in the behavior of infrahuman animals. The studies should make significant contributions to general behavior theory.

The **Journal of Experimental Psychology: General** (Gregory A. Kimble, Editor) will publish experimental articles in any of the three areas represented by the above sections, when the articles involve a longer, more integrative report leading to an advance in knowledge that is judged to be of interest to the entire community of experimental psychologists. The section will include but not be limited to articles such as those that have appeared as *Journal of Experimental Psychology* monographs and as chapters in contemporary books of "advances." Republication of a limited number of data may be permitted if necessary to make the article complete and definitive.

In some instances it may be difficult for the author to decide whether one of the above listed sections or the *Journal of Comparative and Physiological Psychology* is most appropriate for a given manuscript. The author should weigh the essential implications of the research rather than the specific techniques or subject population employed. Is the central message concerned with the issues and concepts of behavior theory (*JExP*) or with the biological substrates of behavior (*Journal of Comparative and Physiological Psychology*)? Is the study primarily addressed to theory of human behavior (*JExP: Human Learning and Memory* or *JExP: Human Perception and Performance*) or to theories equally or more relevant to infrahuman subjects (*JExP: Animal Behavior Processes*)? Is the major emphasis on the acquisition, retention, or transfer of new information, concepts, or problem-solving strategy (*JExP: Human Learning and Memory*) or on the organization or control of structures or mental operations, where the acquisition of new skills is only incidental (*JExP: Human Perception and Performance*)?

Manuscripts should be sent directly to the Editor of the relevant section at the address listed below. In cases where an Editor believes a manuscript is clearly more appropriate for an alternative journal of the American Psychological Association, he may redirect the manuscript with the approval of the author. A final action taken by one of the Editors will be final for all sections of *JExP*.

Manuscripts should be submitted in triplicate and according to the instructions contained in the *Publication Manual* of the American Psychological Association.

Authors should note that limitations on total pages make it necessary to restrict publication to those papers that in the opinion of the Editors make a notable contribution to the literature. Preference can be expected for sets of interrelated experiments that are definitive or provocative.

Addresses for the 1975 Editors-Elect are as follows: *JExP: Human Learning and Memory*, Lyle E. Bourne, Jr., Department of Psychology, University of Colorado, Boulder, Colorado 80302; *JExP: Human Perception and Performance*, Michael I. Posner, before June 1, 1974, same as Allan R. Wagner, after June 1, Department of Psychology, University of Oregon, Eugene, Oregon 97403; *JExP: Animal Behavior Processes*, Allan R. Wagner, Department of Psychology, Yale University, 333 Cedar Street, New Haven, Connecticut 06510; *JExP: General*, Gregory A. Kimble, Department of Psychology, University of Colorado, Boulder, Colorado 80302.

Subscriptions: **Subscriptions are available on a calendar year basis only** (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: **Authors may order reprints of their articles from the printer when they receive galley proofs.**

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: **For information regarding microform editions write to any of the following:** Johnson Associates, Inc., 175 Fifth Avenue, New York, New York 10010; University Microfilms, Ann Arbor, Michigan 48106, or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

Vol. 102, No. 5 — May 1974

ATTENUATION OF BLOCKING WITH SHIFTS IN REWARD: THE INVOLVEMENT OF SCHEDULE-GENERATED CONTEXTUAL CUES [1]

JAMES H. NEELY AND ALLAN R. WAGNER [2]

Yale University

Responding to an element, X, of a stimulus compound, AX, which signaled the availability of reward, was investigated in four discrete-trial bar-press experiments. "Blocking" of the acquisition of responding to X was produced in each case for some groups by separately training A alone as a signal for reward. The principle issue was whether or not blocking would be attenuated, i.e., whether or not there would be more responding to X if the reward conditions associated with AX were less favorable than those associated with A alone, as was reported by J. M. Feldman in apparent conflict with the R. A. Rescorla and A. R. Wagner model. Blocking was attenuated in Experiments I and II when the reward manipulation involved the percentage of rewarded trials and the magnitude of reward, respectively, and the A-alone training preceded AX training. Blocking was not attenuated in Experiments III and IV, which involved the same reward manipulations as Experiments I and II, respectively, but the A-alone training was intermingled with AX training. The results were interpreted as suggesting that contextual stimuli generated by the prevailing reward schedule may need to be taken into account in extension of the Rescorla Wagner model of Pavlovian conditioning to instrumental learning.

The so-called "blocking effect" occurs in Pavlovian conditioning (e.g., Kamin, 1969) when reinforced training to an elementary conditioned stimulus (CS) (e.g., A) is administered prior to reinforced training to a compound (e.g., AX) formed from that element and an added cue. The essential observation is that *S* will then be less likely to evidence conditioned responding to the added cue, X, than if *S* had received only the compound training: Pretraining to A somehow "blocks" the conditioning that would otherwise have occurred to X as a result of the compound trials. The same effect can be demonstrated when reinforced A trials are intermingled with, rather than entirely preceding, the reinforced AX trials. That is, *S* will again respond less to X alone than if training involves only the AX compound (Wagner, 1969).

To account for this effect, as well as a number of related observations, Wagner and Rescorla (e.g., 1972) have proposed

[1] This research was supported in part by National Science Foundation Grant GB-30299X to the second author and was conducted while the first author was a National Science Foundation predoctoral fellow.

that the change in signal value which accrues to any cue as a result of a Pavlovian training trial depends upon the aggregate signal value ($\bar{V}$) of all the CSs present on that trial, in relationship to the asymptotic signal value (λ) that can be maintained by the consequent reinforcement or nonreinforcement which occurs. Specifically, it is assumed that the change in signal value to the ith cue in a compound of n cues may be represented as

$$\Delta V_i = \alpha_i \beta_j (\lambda_j - \bar{V}),$$

where $\bar{V} = \Sigma V_i$.

In this formulation, the values of the two rate parameters α and β are restricted to the unit interval, the former being determined by the characteristics of the specific component cue involved, the latter, like the value of λ, being determined by the characteristics of the reinforcing event. Important for present consideration is the implication for the blocking paradigm that when cue A is reinforced alone it will serve to increase the value of V_A and hence $\bar{V}$ appropriate to subsequent AX trials, and thus decrease the discrepancy, $\lambda - \bar{V}$, determining the further increment in signal value that may be enjoyed by either A or X as a result of a compound trial.

In fact, the model leads to a richer set of deductions within the general blocking paradigm if one relaxes the condition that the unconditioned stimulus (UCS) magnitude or intensity be the same on A and AX trials. For example, if the UCS (and hence λ) is less on A than AX trials, V_A cannot as nearly approach the λ appropriate to the AX trials, so that greater increments will be allowed in V_X on such trials. That is, blocking should not be as complete. Alternatively, if the UCS is *greater* on A than AX trials, blocking should either be more complete than would be the case if the UCS were the same, or V_X should become negative so that X will act as an inhibitory cue. The latter case should result when the A-alone training is sufficient to make V_A greater than the λ appropriate to the AX trials. Then $\lambda - \bar{V}$ will be negative on such compound trials, resulting in a decrement in both V_A and V_X, necessarily driving V_X negative. (See Rescorla and Wagner, 1972, and Wagner and Rescorla, 1972, for more detailed derivations.)

There are now several studies relevant to these predictions. The majority have employed conditioned emotional response (CER) conditioning in rats, and these are generally supportive of the model. Kamin (1969), for example, first paired Cue A with a 1-ma. shock and then the compound, AX, with a 4-ma. shock. This treatment produced more conditioned suppression to X alone (less blocking) than comparison treatments in which A and AX training involved equivalent shock levels, either high or low. Kamin also reported an attenuation of blocking when A was trained with a single UCS pulse, whereas subsequent AX trials involved a double pulse.

Using the same general procedures, Kamin (personal communication, June 1973) has also investigated the blocking paradigm under conditions involving a shift in UCS intensity between the component and compound occasions, but when the shift involved a reduction in intensity, i.e., when A was paired with a more intense shock than was AX. Since the obtained blocking was nearly complete in the comparison condition without a shift in UCS intensity, the study was insensitive to the prediction of the model that *greater* blocking (or inhibitory learning) should occur under the shift conditions. Important, however, was the fact that no attenuation of blocking was detected as was seen in the previously cited study (Kamin, 1969) when A was paired with a less intense shock than was the AX compound.

Rescorla, in a CER experiment reported by Wagner and Rescorla (1972), followed each AX compound by a .5-sec. shock. Intermingled A presentations were either paired with the same .5-sec. shock, in a standard blocking procedure, or were paired with a longer and presumably more aversive 5.0-sec. UCS. Subsequent testing of X, which involved transfer to a conditioned-inhibition training schedule, revealed that X had acquired less of an excitatory tendency (or more of an inhibitory tendency) in the treatment in which A alone was

ed with the stronger UCS. Wagner Rescorla interpreted this finding as ing provisional support for their model proceeded to point out that the con- ional technique (e.g., Pavlov, 1927) aking a cue, X, a conditioned inhibi- viz., reinforcing A and nonreinforcing is but the limiting case of the generally uate condition specified by their model, is, the greater reinforcement of A than

In contrast to the relatively consistent utcomes of the available CER studies is n investigation by Feldman (1971) involving a discrete-trial food-rewarded bar-press situation. In brief, it appears that in such situations a change in reinforcement between A and AX occasions may uniformly attenuate blocking, whether A or AX is the more favorably reinforced. Although the Rescorla and Wagner (1972) model is cifically addressed to Pavlovian rather n instrumental learning situations, the eneral pattern of findings concerning overhadowing, blocking, inhibitory learning, , which the model was calculated to duce, have otherwise been indiscrimina- in the two situations (e.g., Wagner, 1969; Wagner, Logan, Haberlandt, & Price, 1968). Thus, it is important to attempt to reconcile the apparent conflicts that the Feldman data occasion both with respect to the Rescorla and Wagner model and the available CER studies.

The four experiments reported here were designed to comment upon the generality of Feldman's (1971) problematic finding that blocking is attenuated when A is *more* favorably reinforced than is AX. Experiment I was an attempt to replicate the finding using the same reinforcement parameter as did Feldman, viz., different percentages of reinforced trials. Experiment II was similarly designed but employed variations in reward amount rather than percentage. Experiments III and IV used the same reward parameters as Experiments I and II, respectively, but involved an intermingled presentation of A and AX trials as opposed to successive phases of training. As will be pointed out, the pattern of findings suggests a modification in application of the Rescorla and Wagner (1972) model to account for variation in the effects of shifting reward parameters in different situations.

Experiment I

Feldman (1971) ran six groups of rats in a bar-pressing situation in which reinforcement availability was announced by either an isolated cue, A, or a compound, AX. For three of the groups the AX compound was associated with 100% reinforcement (AX-100) while for the remaining three groups it was associated with 25% reinforcement (AX-25). In either condition one of the three groups was pretrained on A with 100% reinforcement (A-100), another with 25% reinforcement (A-25), while the third, control, group was not pretrained.

In test, the responding to X alone showed the usual blocking effect when the reinforcement percentage was the same on A and AX occasions, i.e., in spite of the equivalent reinforcement of X, the A-25/AX-25 group responded less to X than the group receiving only AX-25, while the A-100/AX-100 group responded less to X than the group receiving only AX-100. The novel observation, however, was that the two pretrained groups that experienced a shift in reinforcement percentage between A and AX occasions (A-25/AX-100 and A-100/AX-25) showed more responding to X (less blocking) than did the aforementioned blocking groups that received the equivalent reinforcement percentages on AX trials.

The Rescorla and Wagner (1972) model can account for the fact that more responding to X was observed in the A-25/AX-100 group than in the A-100/AX-100 group. It does not anticipate, however, that more responding to X would be observed in the A-100/AX-25 group than in the A-25/AX-25 group. As long as the λ associated with nonreinforcement is less than the λ associated with reinforcement, it should always be the case that after an equal number of trials the signal value of a continuously reinforced cue will be greater

than the signal value of a partially reinforced cue. Thus, on reinforced AX trials, V_X should have been incremented less in the group for which A was pretrained with 100% reinforcement than in the group for which A was pretrained with 25% reinforcement. Likewise, on nonreinforced AX trials, V_X should have been decremented more in the group for which A was pretrained with 100% reinforcement than in the group for which A was pretrained with 25% reinforcement. The overall effect predicted by the Rescorla and Wagner model is that there should have been *less*, rather than more, responding to X alone in the A-100/AX-25 group than in the A-25/AX-25 group.

Experiment I was designed to evaluate the reproducibility of those aspects of the Feldman (1971) data embarrassing to the Rescorla and Wagner model.

Method

Subjects. The *S*s were 18 experimentally naive male albino rats weighing 275–375 gm. at the start of the experiment. Each *S* was individually housed with free access to water and was maintained at 75%–80% of its original weight via limited feedings given immediately after each experimental session. Two *S*s died, and 1 *S* was discarded for failure to respond during shaping, leaving 15 *S*s from which data will be reported.

Apparatus. Experimental sessions were conducted in one of six identical 24.2 × 32.4 × 18.7 cm. operant chambers housed in sound-attenuated enclosures. A ventilation fan produced a continuous masking noise of 75 db. (General Radio sound-pressure meter, 20-kHz. scale), while a .143-w. jeweled house light located directly above the food well, in the center of an end wall, provided a low level of illumination. The manipulandum was a lever located 8.3 cm. above the floor and 2.0 cm. to the left of the food well.

A 1,000-Hz. 80-db. tonal cue was provided by a Foringer stimulus generator (Model 1166-4-M1) and was delivered through a 7.5 × 14.0 cm. speaker located under the level of the grid floor directly below the food well. A diffuse visual cue was provided by a shielded 3-w. lamp located at the ceiling. When appropriate to the reinforcement contingencies, a .045-gm. Noyes food pellet was delivered to the food well from a Davis Model PD-109A feeder. All experimental events were controlled by electromechanical equipment in an adjacent room.

Experimental design. Three conditions of training equivalent to those used by Feldman (1971) were employed to evaluate the effects of reducing reward percentage between the A and AX occasions. Group AX-25 was trained only with the AX compound, signaling reward on 25% of the trials. Groups A-25/AX-25 and A-100/AX-25 received an equivalent phase of AX training but were first pretrained with Cue A alone signaling reward on either 25% or 100% of the trials as indicated. Following *S* loss, five *S*s remained in each group. For all *S*s the auditory stimulus was designated as A and the visual stimulus as X.

Shaping. Over the first five days of the experiment, *S*s were trained to bar press for food reward and gradually adjusted to a trial regime. On each of Days 1–3, *S* was exposed to four cycles of a continuous reinforcement and extinction schedule consisting of 13 min. in which either A or AX was present (depending upon which cue was first scheduled in training) and each bar press was rewarded, followed by 2 min. in which no cue was present and bar pressing was not rewarded. On Days 4–5, a trial procedure was initiated wherein the appropriate cue was briefly presented at regular intervals during 1-hr. sessions, signaling the only occasions in which reward was available. If a response occurred, the stimulus was terminated with reinforcement. In the absence of a response, the stimulus was automatically turned off, initially after 15 sec., but with a gradual shortening to 6 sec. The intertrial interval, as measured from the onset of adjacent programmed trials, was originally 15 sec. and was gradually increased to 30 sec. by the end of Day 5. Finally, a pretrial period was prescribed, just prior to each scheduled cue presentation, such that a response in this interval would cancel the trial occurrence. The pretrial duration was initially .5 sec. and was gradually increased to 5.0 sec. Thus, by the end of shaping, the conditions were in effect which prevailed throughout training—a 5-sec. pretrial period, a 6-sec. (maximum) A or AX presentation, and a 30-sec. intertrial interval.

Element training. Groups A-25/AX-25 and A-100/AX-25 received six days of training with the A cue alone prior to compound training. Each daily session was scheduled to include 96 possible trial occasions. In Group A-100/AX-25, each A presentation announced the availability of reinforcement, whereas in Group A-25/AX-25, reinforcement was available on only 25% of the trials in a pseudorandom sequence.

Group AX-25 received no element training but had the shaping sessions delayed so that all three groups entered compound training at the same time in relationship to the initiation of deprivation.

Compound training. Reward training terminated for all groups with eight daily sessions with the AX compound scheduled to announce reinforcement on 25% of the trials. As in the element training, the schedule called for 96 trial occasions within each session.

Testing. Responding to X alone as well as to A and the AX compound was evaluated in a final experimental session. Following 20 AX trials with the reward contingencies still in effect, all *S*s were administered a series of 165 test trials in which a bar press terminated the stimulus but was not

rewarded. There were 55 test trials to each of A, X, and AX in a pseudorandom sequence having the restriction that successive blocks of 15 trials include 5 to each cue. In order to insure that all test trials were received, the pretrial, time-out contingency was omitted during testing.

Results and Discussion

All *S*s rapidly adopted discriminated bar pressing during the training sequence such that on the first postshaping day the percentages of trials presented (i.e., not prevented by a pretrial response) were 88.0, 85.0, and 89.0, while the percentages of those trials presented which were responded to were 90.0, 86.0, and 92.0 for each of Groups A-25/AX-25, A-100/AX-25, and AX-25, respectively. The only remarkable deviation from such performance was on the first day in which the X cue was introduced in the pretrained groups. On this day, percentage responding to the trial cue dropped for each of the 10 shifted *S*s ($p <$ .01, sign test) in comparison with the preceding day of element training, so that the mean percentage responding was 69.0 and 63.0 for Groups A-25/AX-25 and A-100 AX-25, respectively. With the exception of this transient evidence of "external inhibition," however, response levels were so uniformly high as to preclude the detection of any potential treatment differences during training.

Table 1 presents the percentage responses to each of the test stimuli for each of the three groups. Inspection of the data from Group AX-25 suggests that the visual X cue was more salient than the auditory A cue, the former being responded to on 50.2% of its test trials, the latter on only 19.6%, after equivalent compound training. In comparison, Group A-25/AX-25 responded considerably more frequently to the pretrained A cue and less to the X cue, so as to reverse the ordering of responding to the two cues. Group A-100/AX-25, in a similar comparison to Group AX-25, evidenced less of an advantage in responding to the pretrained A cue and no apparent decrease in responding to X.

Analyses of variance indicated that the differences among the three groups in responding to X were statistically reliable, F (2, 12) = 5.54, $p < .025$. Subsequent t tests, employing the overall within-groups variance as the error estimate, revealed that Group A-25/AX-25 responded significantly less to X than did either Group AX-25, t (12) = 2.91, $p < .05$; or Group A-100/AX-25, t (12) = 2.75, $p < .05$, while the latter two groups were not reliably different, $t < 1.0$.

TABLE 1

PERCENTAGE OF BAR-PRESS RESPONSES TO EACH TEST STIMULUS: EXPERIMENT 1

Group	Cue		
	X	A	AX
AX-25	50.2	19.6	73.1
A-25/AX-25	30.5	62.5	71.6
A-100/AX-25	49.1	41.4	64.0

Note. See text for explanation of group names.

Similar analyses of responding to the A cue indicated a statistically reliable difference among the three groups, F (2, 12) = 6.81, $p < .025$, with the responding of Group A-25/AX-25 being significantly greater than that of Group AX-25, t (12) = 3.69, $p < .01$. Although the responding of Group A-100/AX-25 was greater than that of Group AX-25 and less than that of Group A-25/AX-25, these differences did not reach conventional levels of statistical reliability in either case, t (12) = 1.88, $p < .10$; and t (12) = 1.81, $p < .10$, respectively. There were no reliable differences among the groups in responding to the AX compound (F = 1.09).

The major result of Experiment 1 was to replicate the Feldman (1971) finding: There was an attenuation of the blocking of responding to X when A was more favorably reinforced during pretraining (Group A-100/AX-25) as compared to a procedure involving the equivalent reinforcement of component and compound (Group A-25/AX-25).

While this finding is apparently inconsistent with the Rescorla and Wagner (1972) model, it should also be noted that a presumptive condition was not obviously met. That is, there was no evidence that pre-

training A with the higher percentage reinforcement resulted in greater signal value to A. Indeed, the test data showed somewhat less responding to A following 100% as compared to 25% reinforcement in pretraining. As testing involved an extinction series, the relative A responding of Groups A-100/AX-25 and A-25/AX-25 may of course be taken to reflect the ubiquitous "partial-reinforcement effect." But as far as the Rescorla and Wagner model is concerned, this only raises the question of how such an effect is to be explained and leaves unchanged the fact that there was no evidence that the cue with which X was trained in compound had been pretrained to a higher signal value in Group A-100/AX-25 than in Group A-25/AX-25.

Experiment II

Reduction in reward percentage on the occasion of shift between component and compound training appears to lead to a reproducible attenuation of blocking, at least in an instrumental bar-pressing situation such as that employed by Feldman (1971) and in Experiment I. The immediate question which this raises is how such an observation may be related to the contradictory evidence of Kamin (personal communication, June 1973) and Rescorla (cited in Rescorla & Wagner, 1972), obtained in a CER situation.

Other than the major paradigmatic differences between the two training situations, the one instrumental and appetitive, the other Pavlovian and aversive, there is the obvious difference in the reinforcement parameter manipulated, percentage of reinforced trials in the present situation as contrasted with the magnitude of a consistently occurring reinforcement in the Kamin (personal communication, June 1973) and Rescorla (cited in Rescorla & Wagner, 1972) studies. To evaluate this difference, Experiment II was designed with conditions analogous to those of Experiment I but with variation in the magnitude of food reward rather than percentage reinforcement.

Method

The apparatus, *S* population, and procedure, except as noted, were identical to those of Experiment I. Twelve *Ss* were randomly assigned to each of three experimental groups designated according to the number of pellets of reward consistently received for each discriminated bar press in the separate phases of element and compound training, i.e., Group AX-1, Group A-1/AX-1, and Group A-5/AX-1.

Shaping. Preliminary shaping was carried out in eight daily 30-min. sessions. On each of Days 1–4, *S* was exposed to two cycles of a continuous reinforcement and extinction schedule as in Experiment I. Over Days 5–8, *Ss* were gradually adjusted to the trial regime as in Experiment I, except that the intertrial interval was brought to 60 sec., and Group A-5/AX-1 received five pellets reward for each response to the trial cue.

Element training. Groups A-1/AX-1 and A-5/AX-1 received 20 days of training with the A cue alone prior to compound training. Each daily session was scheduled to include 16 possible trial occasions, and on Days 6, 8, 10, 12, 14, 16, and 18 the receipt of 16 trials was insured by terminating the session for each *S* only when this number had been completed. For *Ss* in Group A-1/AX-1, each trial response terminating the cue was reinforced with one .045-gm. Noyes pellet. For *Ss* in Group A-5/AX-1, each similar response was reinforced with five pellets delivered at 150-msec. intervals.

Compound training. For the final phase of training, all three groups received 20 daily sessions of 16 scheduled trials with the AX compound and one-pellet rewards.

Testing. Responding to the compound and component cues was evaluated over 4 test sessions. On Day 1, 4 rewarded AX trials were administered, then 18 nonreinforced test trials, in such an order that 2 A, 2 X, and 2 AX trials occurred in each successive block of 6 trials. On each of Days 2–4, the 18-trial test sequence was repeated to produce a total of 24 tests to each cue.

Results and Discussion

More pretrial responding occurred than in Experiment I, but again the groups did not differ reliably in this respect nor in percentage of trial responses within any phase of training. During the common compound phase, Groups A-1/AX-1, AX-1, and A-5/AX-1, respectively, received 91%, 88%, and 92% of the scheduled trials, ($F < 1$), and responded on 88%, 93%, and 92% of the occasions ($F = 1.26$).

Table 2 presents the percentage of responses to the two component cues and the compound over the test series for each of

the three groups. In general, the pattern of data repeats that of Experiment I. The X cue was more frequently responded to than A following equivalent joint training in Group AX-1. In comparison, Group A-1/AX-1 responded considerably more often to the pretrained A and less to X. Group A-5/AX-1 evidenced no greater, indeed slightly less, advantage over Group AX-1 in responding to the pretrained A cue than did Group A-1/AX-1, with no apparent comparative decrease in responding to X.

Analysis of variance indicated that the overall difference among the three groups in responding to X was statistically reliable, $F\ (2, 33) = 3.64$, $p < .05$, while subsequent contrasts revealed that Group A-1/AX-1 responded significantly less to X than did either Group AX-1, $t\ (33) = 2.54$, $p < .05$, or Group A-5/AX-1, $t\ (33) = 2.04$, $p = .05$, with the latter two groups not reliably different ($t < 1$). Similar analysis of responding to A indicated a statistically reliable difference among the three groups, $F\ (2, 33) = 12.88$, $p < .001$, with the responding of Group AX-1 being significantly less than that of either Group A-1/AX-1, $t\ (33) = 4.65$, $p < .01$, or Group A-5/AX-1, $t\ (33) = 4.06$, $p < .01$, which themselves did not differ ($t < 1$). There were no reliable differences among the groups in responding to AX ($F < 1$).

It appears that the attenuation of blocking reported by Feldman (1971) and in Experiment I, when the pretrained A cue was more favorably rewarded than the subsequent AX compound, is not peculiar to variation in reward percentage but extends as well to variation in reward magnitude.

TABLE 2

Percentage of Bar-Press Responses to Each Test Stimulus: Experiment II

Group	Cue		
	X	A	AX
AX-1	45.8	28.5	75.0
A-1/AX-1	26.8	66.7	67.7
A-5/AX-1	42.1	61.8	74.7

Note. See text for explanation of group names.

Experiment III

The results of Experiments I and II are apparently inconsistent with the results obtained by Kamin (personal communication, June 1973) and Rescorla (cited in Wagner & Rescorla, 1972) in CER conditioning and correspondingly at variance with the Wagner and Rescorla model which anticipates the CER data. In attempting to reconcile these differences, it may be helpful to recognize that there are other major effects of manipulating reinforcement percentage and magnitude that are more typical of instrumental than Pavlovian conditioning and also not obviously accounted for by the Wagner and Rescorla model. It is possible that a manner of application of the model that would embrace these major reinforcement effects would also accommodate the blocking data of present concern.

One of the most reproducible and robust phenomena in instrumental learning situations is the partial-reinforcement effect, i.e., the fact that reinforcing only a portion of the trial responses produces more persistent responding during an extinction series than does consistent reinforcement (e.g., Capaldi & Hart, 1962; Wagner, 1961). In comparison, in studies involving Pavlovian conditioning of infrahuman *S*s, the partial reinforcement effect has frequently not been obtained (e.g., Thomas & Wagner, 1964; Vardaris & Fitzgerald, 1969; Wagner, Siegel, & Fein, 1967) or has been relatively evanescent (e.g., Wagner, Siegel, Thomas, & Ellison, 1964). Likewise, whereas it is a common observation in instrumental-learning situations that small reward magnitudes during acquisition produce more persistent extinction responding than do large reward magnitudes (e.g., Hulse, 1958; Wagner, 1961), such an effect has not been observed in comparable Pavlovian investigations (e.g., Wagner et al., 1964).

Without added assumptions, the Rescorla and Wagner (1972) model would predict extinction performance more in line with that typically seen in Pavlovian conditioning as opposed to instrumental learning. Assuming that λ has a low (e.g., zero) value

on nonreinforced trials and increases with increasing magnitudes of reward (Wagner & Rescorla, 1972), the greater the percentage or magnitude of reward, the greater should be the effective limit toward which conditioning can proceed and hence the greater the signal value from which extinction is begun.

A common theoretical device for accounting for the partial-reinforcement effect and the slower extinction following smaller rewards is to assume that the reinforcement schedule, be it in acquisition or extinction, generates stimuli that function in compound with the nominal cues. Thus, for example, Capaldi (e.g., 1966) emphasizes the stimulus "aftereffects" of reward and nonreward, and Amsel (e.g., 1962) emphasizes the cue properties of "anticipatory reward" and "anticipatory frustration." Whatever the specific identification of the schedule-generated stimuli, the argument is commonly made that shifting from an aquisition schedule to an extinction schedule produces less of a change in stimulation for partially reinforced *S*s than continuously reinforced *S*s and less of a change for small-reward *S*s than for large-reward *S*s. Thus, for example, partially reinforced *S*s are assumed to be more resistant to extinction than continuously reinforced *S*s, not because of a "stronger" response tendency, but because they have presumably been trained to respond in the presence of cues that more closely approximate those that occur during extinction.

Such reasoning, of course, is perfectly compatible with the Wagner and Rescorla (1972) model. It simply leads to an enriched conceptualization of the stimuli that must potentially be taken into account in application of the model in any situation. Thus, for example, it might be assumed that when a nominal cue, A, is rewarded on a 25% schedule during acquisition, the functional stimulus should better be represented as AS, with the latter term standing for those stimuli generated by the particular partial reinforcement schedule.[3] Rescorla and Wagner (1972) in several applications of their model have made important appeal to "situational" cues acting in compound with the nominal CS. It apparently should further be acknowledged that certain of these situational cues are a consequence of the prevailing reward schedule. To handle the fact that such extinction phenomena as the partial-reinforcement effect, which are presumed to depend upon the influence of schedule-generated stimuli, are more prevalent in instrumental as compared to Pavlovian conditioning, it need only be assumed that the relative saliences (α values) of the nominal and schedule-generated cues are likely to differ in the two situations under conventional experimental arrangements such that the schedule-generated cues typically come to carry a greater relative signal value in instrumental as compared to Pavlovian conditioning.

This formulation has important implications for cases in which reward parameters are shifted in a blocking paradigm, as in Experiments I and II, if it is assumed that there are, in fact, salient schedule-produced cues that must be taken into account. That is, it must then be assumed that the reward shift produces not only a shift in λ but a change in the stimuli present during the pretraining and compound phases. Such stimulus change should consistently work to attenuate blocking of the added cue regardless of whether the reward shift is toward a higher or lower value. It may be seen that if *S* is pretrained with AS′ rewarded and then with ASX rewarded, the degree of blocking to X will be determined by the signal value which is held by AS as a result of AS′ training, and this will be limited by differences in S and S′ which make V_S less than $V_{S'}$. When AS′ is associated with a less favorable reward schedule than ASX, both the lower λ during pretraining and the change in cues between

[3] This notation is deliberately noncommital concerning the specific source and character of the schedule-generated stimuli since such is not important here. It would be anticipated, however, that in more precise treatment it would be necessary to acknowledge that the schedule-generated stimuli are not constant over a series of trials, but change systematically with each reinforcement and nonreinforcement occasion, with time since such occasions, and likely with other variables as well (see, e.g., Capaldi, 1966).

the former and latter occasions should work to minimize the signal value of AS and allow acquisition to X, i.e., to attenuate blocking. When AS′ is associated with a more favorable reward schedule than ASX, the greater λ during pretraining and the shift in stimuli should have opposing influences upon the subsequent acquisition to X: The greater λ should work to produce a greater signal value of AS so as to minimize acquisition to X (or produce inhibitory learning), while the shift in stimuli should serve to minimize the signal value of AS and allow acquisition to X. According to this treatment, it would be expected that increasing reinforcement between pretraining and compound training would consistently attenuate blocking, whether it be in CER conditioning (e.g., Kamin, 1969) or discriminated bar-press learning (Feldman, 1971), whereas the results of decreasing reinforcement would be expected to be more variable, depending upon the relative magnitude of the opposing λ and stimulus-change effects in different experimental situations. In this light, it is significant that when decreasing reinforcement has been found to attenuate blocking it has been in instrumental reward learning (Feldman, 1971; Experiments I and II above) where there is ample other reason for assuming that schedule-produced stimuli are important controllers of behavior, rather than in CER conditioning where such an assumption is less demanded, as has been pointed out above.

This set of arguments makes analysis of the blocking paradigm relatively complicated. One must be concerned, for example, with the schedule-produced stimuli that are present during testing as well as during training. That is, it must be assumed that responding during an extinction test session is not assessed to X alone but to XS″, where S″ represents those stimuli produced by the prevailing nonreinforcement condition. Then the relevant theoretical question is not simply the degree of acquisition to be expected to X under various blocking treatments, but the signal value to be expected to XS″, where S″ can be assumed to be more similar to the stimulation produced by partial reinforcement than by continuous reinforcement, and more similar to the stimulation produced by small rewards than by large rewards (e.g., Capaldi, 1966).

As unwieldy and indeterminate as this interpretation may be, it allows at least one clear prediction. It suggests that the only factor acting to attenuate blocking when A is more favorably reinforced than AX is the change in schedule-generated stimuli between the occasions of component and compound training. Thus, if A were more favorably reinforced than AX, but in the context of the *same* schedule-generated stimuli, there should be no attenuation of blocking. Indeed, the remaining factors, such as the greater λ on A than AX occasions, should then be allowed to produce enhanced blocking or the acquisition of inhibitory tendencies to X, as otherwise predicted by the Rescorla and Wagner (1972) model.

Experiments III and IV were designed to evaluate this possibility. It is known that blocking will occur when A and AX trials are intermingled, as well as in sequential phases of training (e.g., Wagner, 1969). In such an instance, the prevailing schedule-generated stimuli which may be in compound with the nominal cues can be assumed to be equivalent on the two kinds of trials. Thus, if A were to be preferentially rewarded in comparison with AX, both kinds of trials would still occur in the context of the same schedule-generated stimuli, resulting from the intermingling of the separate rewards. In this case, there should be no attenuation of blocking as was obtained in Experiments I and II, which employed separate phases of A and AX training. Experiment III repeated the blocking comparison of Experiment I, involving different percentages of reinforcement, but with an intermingling of A and AX trials. Experiment IV similarly repeated the blocking comparison of Experiment II, involving different magnitudes of reward.

Method

The apparatus, *S* population and procedures, except as noted, were identical to those of Experi-

ment I. Six *Ss* were randomly assigned to each of three experimental groups designated according to the percentage of reinforcement scheduled in the presence of the A element and AX compound. Group AX-25 was trained only with the AX compound signaling reward on 25% of the trials. Group A-25;AX-25 and Group A-100;AX-25 received equivalent training with AX but had intermingled trials with A alone signaling reward on either 25% or 100% of the trials, respectively.

Shaping. Over the first five days of the experiment, *Ss* were gradually adjusted to a trial regime in a manner identical to Experiment I except that the cue presentations in Group A-25;AX-25 and Group A-100;AX-25 were equally distributed between A and AX, while Group AX-25 received only AX.

Training. Element and/or compound training was carried out over 14 sessions, equivalent to the total number in Experiment I, but in this case, all *Ss* received 48 scheduled AX trials daily. Group AX-25 received no further trials, while Group A-25;AX-25 and Group A-100;AX-25 received 48 additional daily trials with the A cue alone interspersed among the AX trials according to an irregular sequence.

Testing. Following 20 trials with the reward contingencies still in effect, responding to the several cues was evaluated in a final nonreinforced test series identical to that in Experiment I.

Results

As in the previous experiments, all *Ss* rapidly adopted discriminated bar pressing during the training sequence, revealing no notable differences among the three groups or between the A and AX trials within the groups receiving both cues.

The final test data of major interest are presented in Table 3. Comparing the percentage responding to X of Group A-25;AX-25 with that of Group AX-25 reveals a blocking effect similar in magnitude to that observed in the comparable percentage groups of Experiment I. The major finding of Experiment III is to be seen in

TABLE 3

Mean Percentage of Bar-Press Responses to Each Test Stimulus: Experiment III

Group	Cue		
	X	A	AX
AX-25	57.8	26.1	89.8
A-25;AX-25	37.4	76.7	79.2
A-100;AX-25	30.9	62.1	61.0

Note. See text for explanation of group names.

the relative responding to X in Group A-100;AX-25. Rather than responding similarly to Group AX-25, as did the comparable Group in Experiment I, Group A-100;AX-25 evidenced no attentuation of blocking, indeed responded somewhat less to X than did Group A-25;AX-25. Analysis of variance indicated that the difference among the three groups in responding to X was statistically reliable, F (2, 15) = 5.80, $p < .05$, with Group A-100;AX-25 as well as Group A-25;AX-25 responding significantly less than Group AX-25, t (15) = 3.25, $p < .01$; and t (15) = 2.46, $p < .05$, respectively. The difference between the two groups trained with A alone was not reliable ($t < 1$).

The pattern of responding in test to A and AX was less radically different from that of Experiment I. Again, training A alone increased the test responding to this cue in Group A-25;AX-25 and Group A-100;AX-25 as compared to Group AX-25, and somewhat less in Group A-100;AX-25, in which A alone was consistently reinforced, than in Group A-25;AX-25, in which the cue was partially reinforced. Notable also was a tendency similar to that observed in Experiment I for the group in which A alone was consistently reinforced to respond less frequently to the AX compound than did the group trained only with the compound. Separate analyses of variance performed on the responding to A and to AX each revealed significant differences among the several groups, F (2, 15) = 10.37, $p < .01$; and F (2, 15) = 5.12, $p < .05$, respectively. However, in neither case was the contrast between the two groups trained with A alone reliable. Group A-25;AX-25 and Group A-100;AX-25 both responded significantly more to A than did Group AX-25, t (15) = 4.43, $p < .01$; and t (15) = 3.15, $p < .01$, respectively, while Group A-100;AX-25 also responded significantly less to the AX compound than did Group AX-25, t (15) = 3.17, $p < .01$.

Experiment IV

The results of Experiment III, in which A and AX training trials were intermingled,

stand in contrast to those of Experiment I, in which A and AX training trials were presented in sequential phases: In Experiment I, blocking was abolished when A was more consistently reinforced than was AX; in Experiment III, blocking was not attenuated under such circumstances. Experiment IV was consequently conducted as a modification of Experiment II, involving intermingled as opposed to phased training.

Method

The apparatus, *S* population and procedures, except as noted, were identical to those of Experiment II, and when different, were patterned after those of Experiment III. Twelve *S*s were randomly assigned to each of three experimental groups designated according to the number of pellets of reward scheduled for a discriminated bar press in the presence of the A element and the AX compound during training, i.e., Group AX-1, Group A-1;AX-1 and Group A-5;AX-1.

Shaping. Over the first eight days of the experiment, *S*s were gradually adjusted to a trial regime consisting of a 5-sec. pretrial period, a 6-sec. (maximum) CS, and a 60-sec. intertrial interval, identical to Experiment II. The only change in shaping from that in Experiment II was that A and AX were equally presented from the outset in Group A-1;AX-1 and Group A-5;AX-1, whereas only the AX compound was presented in Group AX-1. As in Experiment II, the five-pellet rewards to A were delivered beyond Day 5 in Group A-5;AX-1.

Training. Acquisition was distributed over 40 sessions equivalent to the total length of element and compound training in Experiment II. All *S*s had eight AX trials scheduled daily. Group A-1;AX-1 and Group A-5;AX-1 had an additional eight A trials scheduled daily, irregularly interspersed among the AX trials. To minimize the number of trials that could be missed as a result of any pretrial responding early in acquisition, occasional sessions within the first half of training were terminated for each *S* only after the scheduled number of A or AX trials was received, in a manner similar to Experiment II.

Testing. Responding to the compound and component cues was evaluated over four nonreinforced test sessions identical to those of Experiment II. Each session included six A, six X, and six AX test trials.

Results

Acquisition performance, as in the previous experiments, was generally so high as to obscure the detection of group differences. There was, however, evidence of the higher reward magnitude in Group A-5;AX-1 as compared to Group A-1;AX-1 in a reliably more frequent responding (90.5% vs. 73.9%) to A alone over the first eight sessions, t (22) = 3.27, $p < .05$, beyond which the groups did not differ.

The percentages of bar-press responding to the several cues during testing are presented in Table 4. As expected, blocking was observed in the X responding of Group A-1;AX-1 as compared to Group AX-1. The important observation is that an equivalent blocking was seen in the X responding of Group A-5;AX-1. This finding contrasts sharply with that from the comparable reward group of Experiment II involving sequential phases of A and AX training, but is consistent with the results of Experiment III when A was also more favorably reinforced than AX in an intermingled schedule. Analysis of variance indicated a significant difference among the three treatment groups in responding to X, F (2, 33) = 6.58, $p < .005$, attributable to the lower frequency of response in Group A-1;AX-1 and Group A-5;AX-1 in comparison to Group AX-1, t (33) = 3.16, $p < .01$; and t (33) = 3.11, $p < .01$, respectively.

The lower level of responding to X in Group A-1;AX-1 and Group A-5;AX-1 in comparison to Group AX-1 was accompanied by a higher level of responding to the separately trained A cue. Analysis of variance performed on the frequencies of responding to A indicated a reliable difference among the three treatment groups, F (2, 33) = 30.98, $p < .005$, with Group AX-1 responding less than either Group A-1;AX-1, t (33) = 6.72, $p < .01$, or Group A-5;AX-1, t (33) = 6.92, $p < .01$, and no

TABLE 4
MEAN PERCENTAGE OF BAR-PRESS RESPONSES TO EACH TEST STIMULUS: EXPERIMENT IV

Group	Cue		
	X	A	AX
AX-1	59.0	23.3	77.4
A-1;AX-1	35.1	69.3	74.7
A-5;AX-1	35.4	70.8	69.5

Note. See text for explanation of group names.

reliable difference between the latter two groups. None of the differences in responding to AX approached statistical reliability.

General Discussion

In an instrumental-learning situation in which responding to one cue, A, is pretrained prior to training on a compound, AX, blocking of the acquisition of responding to X is attenuated by reducing the percentage or magnitude of reward with the introduction of the compound (Feldman, 1971; Experiments I and II above). If, however, A and AX are contemporaneously trained in the same sessions, no similar attenuation of blocking results from less favorably rewarding responding to AX vs. A (Experiments III and IV above).

Any theoretical interpretation of this pattern must somehow discount the importance of the differential rewards per se as producing the attenuation of blocking seen in Experiments I and II. The view that has been presented here is that the reward schedule, at least in some situations, contributes important contextual stimuli which work in compound with the nominal cues to control *S*'s behavior and influence the learning which occurs. Changing contextual stimuli at the time of introduction of a new cue may then be assumed to decrease the likelihood that the new cue will be treated as redundant and increase the likelihood that its signaling relationship with reward will be learned about. Such reasoning is compatible with the Rescorla and Wagner (e.g., 1972) account of the blocking phenomenon as well as alternative attentional treatments (e.g., Sutherland & Mackintosh, 1971).

The implication of the Rescorla and Wagner (1972) model remains, however, that if the contribution of the schedule-generated stimuli could be ignored, preferentially rewarding A as compared to AX should either enhance blocking or make X a conditioned inhibitor, depending upon the degree of training involved. It thus remains problematic for the theory that Experiments III and IV, which sought to create equivalent schedule-generated contextual cues during the differential rewarding of A and AX, did not provide evidence of enhanced blocking in comparison with the cases in which A and AX were equivalently rewarded.

It is not clear how seriously this apparent failure of the model should be viewed. First of all, of course, it may simply represent a detection failure. With the relatively low levels of responding to X in Groups A-25 ; and A-1;AX-1 it may be difficult to demon yet less responding in Group A-100;AX-25 Group A-5;AX-1, respectively. Indeed comparison conditions were provided to co ment upon the degree to which the respondi to X observed in these blocking groups w greater than that which would have been see to an untrained cue. More importantly, one should recognize that the designs of Experiments III and IV were such as to insure that A and AX were trained in the presence of the same schedule-generated contextual stimuli *within* any blocking group. The designs did not insure that A or AX were trained in the presence of the same schedule-generated stimuli across the different blocking groups in either experiment, or therefore that the change in schedule-generated stimuli would be equivalent in the different blocking groups when the nonreinforced test sessions were introduced. Thus, one could argue that X was indeed more effectively blocked in Group A-5;AX-1 than in Group A-1;AX-1 of Experiment IV for example, but this tendency was obscured by the differential change in schedule-generated stimuli between training and testing in the two cases. Just as clearly, however, any such arguments would be a posteriori, with the issue better decided by further investigation in which potential differences in schedule-generated stimuli might be better specified and controlled.

Additional complexities are introduced into any theoretical analysis when one assumes that schedule-generated stimuli must be taken into account along with the nominal cues. Such an assumption has been extremely useful, however, in understanding the effects of reward manipulations in instrumental-learning situations (e.g., Amsel, 1962; Capaldi, 1966; Wagner, 1961) and is likely to be as fruitful in application of the Rescorla and Wagner (1972) model to such situations, whatever the ultimate resolution of the manner in which reward shifts influence blocking.

ANAGRAM SOLVING AS A FUNCTION OF WORD IMAGERY

KATHLEEN DEWING AND PAUL HETHERINGTON[1]

University of Western Australia, Nedlands, Western Australia, Australia

Two experiments are reported which examine the role of imagery in anagram solving. In Experiment I *S*s attempted 12 anagrams constructed from nouns of high or low imagery value, with either no information, structural information, or semantic information as aids to solution. All words had a Thorndike–Lorge frequency value of 20 or more words per million, and other variables known to influence anagram solution time were controlled (word length, number of possible solutions, frequency of successive letter pairs, and letter order). High imagery words were found significantly faster than low imagery words. Both structural and semantic clues facilitated performance, but structural information had a greater effect on the solution of low imagery words and semantic information had more effect on high imagery words. It was suggested that this might reflect the use of either letter manipulation or word production strategies under the different clue conditions. In Experiment II the main effect of imagery was replicated with different word lists and additional controls. The imagery effect was again highly significant and clearly independent of word frequency and associative meaningfulness.

The image-evoking (*I*) value of stimuli is now well established as an important variable in associative learning and memory (Paivio, 1969). Imagery value is coordinated to a concrete–abstract stimulus dimension, extending from objects to pictures to concrete nouns to abstract nouns, in decreasing order of concreteness. Item concreteness or *I* value has been shown to exert an effect on paired-associate learning, recognition memory, free recall, and, under some circumstances, serial learning.

The aim of the present study was to extend the findings relating to the role of imagery in verbal learning and retrieval to the solution of anagrams. There has been some recent research interest in this area (Jablonski & Mueller, 1972), but findings have been equivocal. The effect of word imagery, if present, must occur before the word is known, as in the case of the well-established effect of word frequency on anagram solving (Dominowski, 1966; Mayzner & Tresselt, 1966).

The frequency effect has been explained in terms of the "spew hypothesis" of Underwood and Schulz (1960), which says that the order of emission of verbal units is directly related to their frequency of occurrence in the language. When the *S* looks at the letters which when rearranged will make up the solution word, it is claimed that he makes implicit word responses similar to free recall (Safren, 1962) or to free association (Mayzner, Tresselt, & Helbock, 1964) and that if the word is of high frequency, it will be more likely to be among the responses the *S* makes. If noun imagery facilitates the availability of the words as units, it would follow that anagrams of high-*I* words would be easier to solve than those of low-*I* words.

In the first experiment an attempt was made to explore the anagram solving process in more detail by providing *S*s with partial information about the solution words. The interaction between *I* value and structural and semantic clues to the solution words was examined. The structural information provided was the initial and final letter of the solution word. The semantic information was the title of the category of which the word was a member, i.e., the word's superordinate. The aim here was to determine whether the types of clues would show any differential effect on anagram solution times depending on whether the solution words were of high or low *I* value. It may be argued that if a word is of low *I* value, the likelihood

[1] Kathleen Dewing passed away since this article was written. Requests for reprints should be sent to Paul Hetherington, University of Western Australia, Nedlands, Western Australia 6009, Australia.

of its appearing among words called to mind as suggested by the letters of the anagram is lessened. The *S*s then may tend to adopt the strategy of sorting out the letters more or less mechanically until they recognize the solution word. In such cases *S*s would be expected to find a clue giving the position of 2 of the letters of the solution word of more use than semantic information.

In the second experiment an attempt was made to replicate the main effect of solution-word imagery found in Experiment I using different word lists. By assigning an estimate of A = 50 and AA = 100 to the frequency value of items, it was possible to control frequency more precisely. In this experiment the effect of verbal associative meaningfulness, *m* (Noble, 1952), was also controlled.

Experiment I

Method. A 2 × 3 repeated-measures factorial design was employed. Every *S* was given 2 anagrams to solve under each of the experimental conditions making a total of 12 problems per *S*. The independent variables were (*a*) solution-word imagery, and (*b*) type of clue given, viz., no clue, first and last letter of solution word (structural clue), or the title of the category of which it is a member (semantic clue). For example, the semantic clues for high-*I* words CABIN and STORM were DWELLING and WEATHER CONDITION, and for low-*I* words SHAME and MERCY, clues were FEELING and MORAL SENTIMENT.

The degree of association between each solution word and its semantic clue was rated on a 5-point scale by 10 independent raters without any knowledge of the purpose of the study. There was no significant difference between ratings for low-*I* words ($M = 3.8$, $SD = .72$) and high-*I* words ($M = 4.0$, $SD = .52$).

Solution words were selected from Paivio, Yuille, and Madigan's (1968) word list. Low-*I* words had an *I* value of less than 4.20 and high-*I* words a value above 6.40. All were 5-letter common nouns, and no other 5-letter common nouns could be made by rearranging the letters. All words occurred with a frequency of 20 and above per million in the language by Thorndike and Lorge's (1944) tables. Since bigram frequency (BF)—total frequency of occurrence of successive letter pairs in solution word—may be a factor in anagram solving (Dominowski & Duncan, 1964), only solution words of similar BF were included. According to tables by Underwood and Schulz (1960), fairly extreme BF values are represented by ZEBRA (1,780) and EATER (11,812). Words used in the study were all in the BF range, 3,500–8,500. The words selected were EVENT, FOLLY, MERCY, TRUTH, ARRAY, and SHAME (low-*I* words), and ANKLE, PIANO, STORM, CABIN, CHAIR, and SUGAR (high-*I* words).

Three anagrams for each solution word were constructed by 3 times randomly ordering the letters of each of the 12 words. This procedure was adopted to minimize any interfering effects arising from anagram letter order or anagram BF. The 3 sets of anagrams resulting from 3 times randomly rearranging the letters of each of the 12 words were combined factorially with the 3 clue conditions to give 9 resulting lists of anagrams, each of the treatment conditions being assigned to each anagram.

Seventy-two male and female students enrolled in first-year psychology at the University of Western Australia served as *S*s. The *S*s were randomly assigned to each of the 9 anagram lists. The nature of the task was explained, and examples given of both clue types.

The *S*s were given 3 practice trials, one with each type of clue and one with no clue. The practice trials were followed by the 12 experimental cards presented one at a time in a random order. The time taken by *S* to solve each anagram problem was recorded by *E*. To control for *E* bias, cards were placed face downward and presented to *S*s without *E* seeing the anagram until after solution times had been recorded. No provision was made to control for trial effects since it has generally been found (Mayzner & Tresselt, 1962) that *S*s do not show any great deal of improvement on such tasks until after at least several weeks' practice.

Results. Subjects were required to solve 2 anagrams under each of the 6 experimental conditions, and the *S*s' scores for each set of 2 problems were averaged. Since the distribution of response times was highly skewed, a logarithmic transformation of the form $X = \log(X_i + 1)$ was applied to the resulting data prior to within-*S* analysis of variance. The log mean solution times for word *I* values and clue conditions are shown in Table 1.

Anagrams of high-*I* words were solved faster than anagrams of low-*I* words to a highly significant degree, $F\ (1, 71) = 64.864$, $p < .001$. The variance under the 3 clue conditions was also highly significant, $F\ (2, 142) = 94.154$, $p < .001$. Interaction between *I* value and clue type was significant, $F\ (2, 142) = 5.306$, $p < .01$. This interaction includes the no-clue condition. The Semantic vs. Structural clue × *I* Value interaction was also

TABLE 1

Log Mean Solution Times for High- and Low-Imagery Words under Structural, Semantic, and No Clue Conditions

Clue condition	High imagery	Low imagery	M
No clue	1.358	1.566	1.462
Structural clue	.902	1.078	.990
Semantic clue	.704	1.182	.943
M	.988	1.275	Grand Mean = 1.132

significant, $F(1, 71) = 8.212$, $p < .01$, and the No Clue vs. Average Clue × I Value interaction was not significant, $F(1, 71) = 1.897$. Structural clues had a greater effect on the solution of low-I words and semantic information on high-I words.

Experiment II

Method. The second experiment replicated the main effect found for I in Experiment I using different words and additional controls for solution word attributes. As in Experiment I the number of letters, bigram frequency of the solution word, and number of possible solutions for each anagram were controlled. In addition, the number of redundant letters in each anagram and frequency and meaningfulness of the solution words were equated for high- and low-I lists. The words selected were POWER, CHASM, GRIEF, VENOM, CHAOS, and DRAMA (low-I words) and TRUCK, SPRAY, HOTEL, PLANK, FLASK, and DRESS (high-I words); m values used were calculated according to Paivio et al. (1968), following Noble's (1952) production method for obtaining m data. The procedure for constructing and presenting the anagrams was the same as for Experiment I, except that no clues were given. Twenty-four male and female second-year psychology students served as *S*s.

Results. Mean response time for high-I words was 32.0 sec. ($SD = 46.6$) and for low-I words 50.6 sec. ($SD = 42.4$). Anagrams constructed from high-I nouns were solved significantly faster than anagrams constructed from low-I nouns ($t = 3.5$, $p < .001$).

Discussion

The results of this study clearly demonstrate that solution-word imagery has a strong effect on anagram solving, and that this effect is independent of word frequency or associative verbal meaningfulness. Imagery must exert its influence *before* the identification of the word and in this sense displays much the same effect as frequency. The explanation that suggests itself is in similar t[illegible].

When *S*s are presented with a set of jumbled letters they at least in part recall words to match these letters (Safren, 1962). High-frequency words are more likely to be recalled by S since they are towards the top of S's hierarchy of available words. Numerous studies have found such results. The present findings suggest that the image-arousing potential of nouns also affects the availability of nouns as units. This view would predict that high-I words, because of their more ready availability, have a greater probability of being among those words suggested by the letters of the anagram. Word identification is expedited and the anagram solved more easily.

Reviews of anagram solving research indicate that both parts and wholes contribute to the solution of the problem (Johnson, 1966). Studies carried out within an S-R mediational model (e.g., Mayzner & Tresselt, 1966) have tended to restrict themselves to only one aspect of the processes involved, i.e., letter arrangement. Anagrams are treated as stimuli which evoke a variety of implicit responses in S based on successive rearrangements of the letters into new combinations, and little attention is paid to the characteristics of the word as a whole.

However, some evidence suggests that anagram difficulty in general is more [illegible] on the characteristics of the solution word than of the anagram (Dominowski, 1967). The S's solution attempt is often a word which has more, less, or other letters than does the anagram. The S jumps to his goal (word), then returns to match it against the anagram; the progression is from the word to the anagram rather than from the anagram to the word (Johnson, 1966). The availability of the solution word appears to be very important in the anagram task, and the present study provides further support for this view.

The interaction between solution-word imagery and clue type may throw some light on the strategies employed by *S*s in the solution process. Rearranging letters and producing words are different types of responses, but they are likely to occur simultaneously in anagram solving when no clues are provided, and need not be independent of each other (Dominowski, 1966). The present study showed that both semantic and struc-

tural information improved performance, but semantic clues facilitated the solution of high-*I* words more than low-*I* words and vice versa for structural clues. This may indicate that word production and letter arrangement are used differentially as strategies under those clue conditions. However, it is possible that the concrete and abstract category titles may not have been equally informative as solution clues, either because of differences in category set size or in the strength of the associative link between the word and its superordinate. An attempt was made to measure the degree of this association; the associative bond was judged by independent raters to be slightly stronger for high-*I* words, but the difference was not statistically significant. Further work is needed to clarify the issue, and the present findings should be interpreted with caution.

The results of both experiments show that imagery exerts an influence on availability of items per se and does not act purely as a mediator between stimulus and response. Experimental investigations of concreteness and the image-arousing value of stimuli have so far tended to concentrate on paired-associate learning, and have led to a rather narrow view that the effect of imagery is chiefly to cement associative relationships (e.g., Bower, 1972). The findings of the study reported here, taken in conjunction with investigations of the effects of imagery on free recall and recognition memory, suggest that imagery is much more than a mediator and may prove to be an effective variable in a wide range of cognitive tasks.

TRANSFER OF INFORMATION FROM SHORT TO LONG-TERM MEMORY[1]

VITO MODIGLIANI[2] AND JOHN G. SEAMON

Wesleyan University

The present study examined current hypotheses concerning information t[illegible] fer from short-term memory (STM) to long-term memory (LTM) us[illegible] Peterson STM task with word triplets presented over retention intervals o[illegible] 3, 6, 9, and 18 sec. One-third of the *S*s counted backward during the inter[illegible] one-third employed a relational imagery code, and the last third were [illegible] tracted and uninstructed in coding. The STM trials were followed by [illegible] LTM recall test of all stimuli. Half of the *S*s in each condition were forewa[illegible] of the subsequent testing. Results showed that neither warning nor dur[illegible] of information in STM had an effect on recall. Coding, however, had [illegible] nificant effect. These data were discussed in terms of the conditions whic[illegible] sufficient for storage of information in LTM.

The present study examines the conditions of information transfer from short-term memory (STM) to long-term memory (LTM) in light of current theories of memory (Atkinson & Shiffrin, 1968; Waugh & Norman, 1965). Such theories assume that information put into STM is quickly lost unless maintained by a process of rehearsal. Rehearsal may have other functions aside from maintaining information in STM. Atkinson and Shiffrin hypothesize that rehearsal "serves the purpose of increasing the strength built up in a long-term store, both by increasing the length of stay in STS (during which time a trace is built up in LTS) and by giving coding and other storage processes time to operate [p. 111]." Hence, the longer the duration of information in STM, the higher the probability of its transfer to LTM. Rehearsal thus enables information to be automatically transferred into LTM and allows time for control processes, such as coding, to be applied.

The present research is an attempt to examine the above issues within the context of the Peterson and Peterson (1959) paradigm and the extension of it by Meunier, Ritz, and Meunier (1972). Peterson and Peterson plotted the temporal course of forgetting in STM when a rehearsal-preventing distractor task was employed for 0–18 sec. Meunier et al. (1972) extended this by comparing STM performance between groups which differed by the presence or absence of a distractor task. Forgetting in STM was observed only in the group engaging in the distractor task. However, a subsequent unexpected free-recall test of all items at the end of the experimen[illegible] yielded identically poor performanc[illegible] both groups. This is consisten[illegible] view that rehearsal can ma[illegible] tion in STM, but does n[illegible] [illegible] result in transfer to LTM.

The present study [illegible] of Meunier et al. (1972) by [illegible] STM and LTM performance of [illegible] with different instructional sets in the Peterson and Peterson (1959) paradigm. The *S*s were instructed to employ a relational imagery coding strategy or a rehearsal-preventing distractor task, or were not instructed to engage in any particular activity during the retention interval of 0–18 sec. Moreover, half of the *S*s in each condition were warned of a retention test on all items at the end of the experiment.

It was hypothesized that only *S*s in the distractor group would show forgetting in the STM trials. Short-term memory performance in the coding and free groups

would be essentially perfect over all STM retention intervals. With regard to the more important LTM performance, it was expected that *S*s engaged in imagery coding during the STM task would show significantly better LTM performance than all other *S*s, and that *S*s warned of subsequent testing should perform somewhat better than *S*s not so warned, because of the possibility of spontaneous coding.

Method

Design. The experiment consisted of 2 phases. The first was an STM task, in which *S*s were presented with 3 word triplets to be recalled after a time interval of 0, 3, 6, 9, or 18 sec. This was followed by a recall phase, in which each *S* was asked to write down all the words he could remember.

The STM retention interval was a within-*S*s variable, while warning information and STM instructional set were both between *S*s. The experiment, therefore, can be considered a $5 \times 2 \times 3$ factorial.

Subjects. There were 10 *S*s in each of the 6 groups. They were Wesleyan University students who signed up voluntarily for the experiment and were paid $2 for their services. No attempt was made to control for sex, and *S*s were randomly assigned to experimental conditions as they showed up for the experiment.

Materials. The words used in this experiment consisted of concrete nouns with a frequency count of A or AA in the Thorndike-Lorge (1944) G count. Only nouns of 3-5 letters in length were selected to constitute the initial pool from which all successive selections were made. From this pool, 150 nouns were chosen to constitute the experimental words. They were then randomly grouped into 50 triplets with the restriction that no words in a triplet begin with the same letter and that they not be obvious associates of one another.

Each triplet was typed in capital letters on the same row, and approximately in the middle of a 12.7×20.4 cm. white index card. At the bottom of each card, a 3-digit number was also typed. The distance between the words and the number was approximately 6 cm. The 50 cards so obtained were thoroughly shuffled to yield one random order of presentation. A second order of stimuli was obtained in the same fashion. In addition to the 50 experimental cards, there were 5 warm-up cards, constructed in the same manner. The numbers on the bottom of all cards were taken from a table of random numbers.

Other materials consisted of an electric auditory clicker set at 3 clicks/sec and a screen which was put on top of a desk shielding *S* from *E*. There was an opening in the screen, slightly smaller than the cards being used, through which *E* presented all stimuli.

Procedure. Four different sequences of the STM retention intervals were used, each of which consisted of 10 blocks of 5 trials each. Each block contained a random permutation of the 5 retention intervals being used. Thus, over the 50 trials, each retention interval appeared 10 times.

Each of the 2 stimulus sequences was combined with each of the 4 STM retention interval sequences to yield 8 different sequences. Each of these was used with the first 8 *S*s in each group, with the remaining 2 *S*s given 2 of the 8 sequences selected at random.

During each trial, *S* was to read orally each of the 3 words followed by each of the digits, one at a time and in time with the auditory clicks. Reading time, determined by click frequency, took 2 sec.—1 sec. for the words and 1 sec. for the number. The *S* was explicitly asked not to pause between the words and the number, so as to minimize the opportunity for rehearsal at that point. As soon as *S* read the last digit of the number, *E* started a timer set at 0, 3, 6, 9, or 18 sec. At the end of the retention interval, *E* said "recall." The *S* was given approximately 10 sec. to respond. As soon as he responded, *E* recorded the response and then, after saying "ready," proceeded to the next presentation. The minimum time from the cue for recall to the next presentation was about 5 sec.

In the distractor condition, *S* was instructed to count backward by 3's beginning with the number he had just read. He was to count by pronouncing each digit of each number in time with the clicks until *E* gave a signal to recall the words. He was also told to avoid rehearsing the triplet and to concentrate on the counting task.

In the free condition, *S* was told that after he had read the last digit of the number there would be a period of time, varying in length from trial to trial, at the end of which *E* would give a signal for him to recall the words.

In the code condition, *S* was instructed to form an imaginary scene of the referents of the words he had just seen during the time between the presentation of the triplet and the signal for recall. The relational imagery instructions were the same as those used in a previous study (see Seamon, 1972). It was stressed that the visual scene should be one in which the single images touched each other and interacted to form meaningful, if not always realistic, units. An example of an appropriate construction, such as a car sitting in a tree with a belt around the tree, was provided to insure that *S* understood the task. No *S* reported any difficulty.

Within each of the above conditions, half of the *S*s were told that after the completion of the present task there would follow another session, in which they would be asked to recall all the words they had previously studied. For the other half of the *S*s, no mention was made of the subsequent task. Irrespective of initial instructions, all *S*s, after completing the STM phase, were given a sheet of paper and asked to write down as many of the words they had studied in the preceding trials as they could remember. They were allowed approximately 7 min. for recall, and guessing was discouraged.

Results

Responses in the STM and recall phases were scored in terms of correct triplets and correct words recalled. The latter measure was thought to be more sensitive to possible differences than the former. Triplets were scored correct regardless of word order.

In all analyses, none of the main or interaction effects associated with foreknowledge of the recall test approached significance (all ps > .10). The warning variable, therefore, was not considered further, and groups which differed only in this factor were combined.

Short-term memory retention data. Mean percentage of correct triplets and words recalled in this phase of the experiment are shown in Table 1. There was little variability associated with the code or free conditions, recall being uniformly high at all STM intervals. Recall in the distractor condition, however, whether scored for words or triplets, showed the decay function typical of this paradigm. As expected, the retention function for triplets showed a greater decrement over time than that for words, since the scoring criterion was more stringent for triplets.

Long-term memory recall data. Mean percentages of correct words and triplets recalled after the completion of the STM trials are shown in the top and bottom sections of Figure 1, respectively. Since a floor effect for the distractor and free conditions was evident when recall was scored for triplets, only recall for words was analyzed statistically. An overall analysis of variance showed that STM retention interval had a significant effect on the subsequent LTM recall of words, F (4, 216) = 14.58, $p < .01$, with Neuman–Keuls comparisons showing recall to be better at 3 sec. than at 0 sec. ($p < .01$) and at 18 sec. than at 3 sec. ($p < .05$). A significant STM Interval × Group interaction was also found, F (8, 216) = 7.27, $p < .01$, indicating that relative recall performance between groups was not constant over all STM retention intervals. The code condition was poorest at the shorter intervals, but best at the longer intervals. The main effect of group was not significant.[3]

Analyses of simple main effects followed by Neuman–Keuls comparisons for each experimental group found no significant comparisons between intervals for the free condition, significantly better recall at 3 sec. than at 0 sec. for the distractor condition ($p < .05$), and significantly better

TABLE 1

Mean Percentage of Short-Term Memory Recall for Triplets and Words

Experimental condition	Retention interval (in sec.)				
	0	3	6	9	18
Code					
Triplets	98.5	98.5	98.0	98.5	99.0
Words	99.5	99.3	99.0	99.3	99.7
Free					
Triplets	99.5	98.5	98.5	97.5	96.0
Words	99.8	99.7	99.5	99.2	98.8
Distractor					
Triplets	95.5	52.5	35.5	24.5	17.5
Words	98.8	74.2	64.5	51.5	37.5

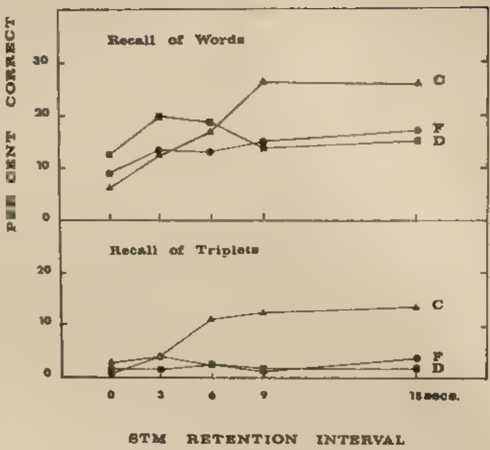

Figure. 1. Mean percentage of correct recall of individual words and triplets for the Code (C), Free (F), and Distractor (D) conditions as a function of the short-term memory retention interval.

[3] Essentially the same findings were obtained in a recognition test given to all *S*s after the recall test. Recognition performance was similar and did not increase with STM interval length for the free and distractor conditions, while the performance for the code condition was initially poorer than that of the other conditions, but improved through the 9-sec. interval to surpass them. These data do not, however, provide independent information.

recall at 3 sec. than at 0 sec. ($p < .05$) and at 9 sec. than at 6 sec. ($p < .01$) for the code condition. Comparisons of groups as a function of STM interval found significant differences at 3, 9, and 18 sec., with the distractor condition better than the code condition at 3 sec. ($p < .05$), and the reverse true at 9 and 18 sec. (both ps $< .01$). Other differences were not significant, although the distractor–code comparison approached significance at 0 sec. ($p < .10$).

The mean number of false recalls, i.e., words not from either the warm-up or experimental trials, was 2.0 across all groups, as compared to an overall mean number of experimental words recalled of 23.4.

Serial position data. The STM phase of the experiment lasted approximately 15 min. In the second phase of the experiment, therefore, some of the to-be-recalled words had been studied as long ago as 15 min. and some as recently as 2–4 min. before recall. It was desirable to examine, albeit informally, whether serial position in the STM list had an effect on recall. For this purpose, the STM list, consisting of 10 blocks of 5 triplets each, was divided into 3 groups, viz., Blocks 1–3, 4–7, and 8–10, covering the initial, middle, and end portions of the list, respectively. Two overall trends were noted. First, regardless of list position, words studied at 0 and 3 sec. were always recalled more poorly in the code condition than in the distractor condition, with the free condition intermediate. The reverse was true for words studied at 9 and 18 sec. This indicates that the recall pattern shown in Figure 1 was fairly constant over the range of possible list positions. Second, a strong recency effect was present, with much better recall from Blocks 8–10 than from Blocks 1–3 or 4–7.

Discussion

The major focus of this study was on the mechanisms of information transfer from STM to LTM. Such mechanisms will be discussed with reference to the following 4 propositions, which summarize the major tenets of current theories of memory on this subject. (*a*) Amount of information transfer is an increasing function of the time an item remains in STM (Atkinson & Shiffrin, 1968; Waugh & Norman, 1965). (*b*) Rehearsal strengthens LTM traces (Bjork, 1970). To the extent that rehearsal keeps an item in STM, this proposition is a corollary of the first. However, since rehearsal per se is currently receiving a great deal of attention, we prefer to keep these 2 propositions separate. (*c*) Rehearsal provides more time for coding processes to operate, and (*d*) memory traces in LTM can be strengthened by such coding processes.

Consistent with earlier data (Jacoby & Bartz, 1972; Meunier et al., 1972), the present findings offer no support for the proposition that prolonged stay (up to 18 sec.) in STM increases an item's probability of transfer to LTM. This is shown both by an analysis of the free condition itself, and by a comparison with the distractor condition. First, the finding of essentially perfect retention in the free condition over all intervals in the STM trials indicates that triplets were held in STM for varying intervals up to 18 sec. However, no increase in LTM retention was observed as a function of STM interval length, a result clearly at odds with the proposition being discussed. Second, while the distractor and free conditions were qualitatively and quantitatively different in STM recall, they were alike in LTM retention. The STM decay function found in the distractor condition means that items were lost from STM very rapidly. In spite of this, they were remembered as well as items which, in the free condition, had been kept in STM for longer periods of time, again at odds with the proposition in question.

With respect to the proposition that rehearsal, directly or indirectly, increases an item's strength in LTM, the situation is more ambiguous. The present data rule out the possibility that rehearsal, by virtue of simply keeping items in STM, automatically transfers them to LTM. Further, if it is assumed that *S*s engaged in rehearsal to maintain the items in STM over the retention intervals, the LTM performance of the free and distractor conditions would suggest that either rehearsal does not strengthen LTM traces, or the amount of rehearsal was the same for both conditions and over all intervals. This follows from the fact that there was more opportunity for rehearsal in the longer STM intervals than the shorter intervals and in the free condition than in the distractor condition.

Does rehearsal provide time for coding processes to operate? A comparison of the free and code conditions would suggest that spontaneous coding strategies, if employed, were not very effective in engendering LTM retention, or that *S*s simply did not engage in coding processes when given the opportunity in this task. It is still possible, of course, that under different conditions, effects of spontaneous coding would be evidenced.

We shall now consider the fourth of the propositions under scrutiny, the one concerning coding processes. As Figure 1 shows, LTM performance of the code group was poorest for words shown at 0-sec. STM intervals and increased up to asymptotic level as the STM interval increased. At 9- and 18-sec. STM intervals, this group showed better LTM performance than either the free or distractor groups. The monotonic increase in LTM retention as a function of STM interval in the code group suggests that it takes time to apply the imagery code to words, a time that can be estimated to be within 3–9 sec., judging from the recall function. This parameter may actually be expected to vary with the number and concreteness of the words employed. Moreover, it can also be expected to vary with practice. This can be inferred from the fact that the highest relative increase, as a function of trial blocks in the STM list, occurred for items shown at 0-sec. STM intervals, while the smallest relative increase occurred for items shown at 9 and 18 sec. The indication is, therefore, that *S*s became better at imagery coding with practice, and this increased efficiency was most beneficial at very short STM intervals.

The finding that the code condition, given sufficient time, produced superior LTM retention as compared to the free and distractor conditions is consistent with previous findings (Bower, 1972) indicating the superiority of the mnemonic device over other methods and with the view that organization enhances LTM retention. Thus, imagery coding is cl... sufficient condition for storage of infor... in LTM and, as judged by the lack of a w... effect, intent to remember may be superfl...

GOOD CONTINUATION REVISITED [1]

LUBOMIR S. PRYTULAK [2]

University of Western Ontario, London, Ontario, Canada

Twenty female *S*s inspected patterns of three lines of dots radiating from a common dot, in which one line (the shaft) was longer than the other two lines (the arms). Which arm the shaft appeared to group with, and which of two arms in different patterns the shaft grouped with more strongly, were predicted from three predictors: (*a*) rectilinearity—grouping is stronger with the arm closer to forming a 180° angle with the shaft, the function between strength of grouping and angle being nonlinear; (*b*) orientation—grouping is stronger with an arm on the vertical-horizontal rather than an oblique arm; and (*c*) enclosure—grouping is stronger when the arm closer to rectilinearity is ipsilateral with the other arm than when it is contralateral. Computer-generated predictions were correct 16/16 times when predicting grouping within individual patterns and were correct 103/109 times when predicting inequalities of grouping between patterns.

The principle of good continuation was introduced into the psychological literature in 1923 by Max Wertheimer (1958). In several demonstration displays (Figures 1–5, pp. 126–127), he showed that when three straight lines of dots radiate from a common point, the two lines forming a 180° angle appear to group more with each other than either appears to group with the third line. This is the fundamental good continuation effect which the present paper attempts to elaborate. More particularly, using three-line patterns similar to Wertheimer's, three questions are explored. First, what are the grouping effects at various angle juxtapositions, including ones that do not contain 180°? Second, does the orientation of the lines with respect to the vertical-horizontal affect grouping? Third, does ipsilateral vs. contralateral juxtaposition of two lines at constant angles to a third line affect grouping?

Method

Stimuli. Each stimulus was made up of 2-mm.-diam. circular black dots on a 21.6 × 27.9 cm. white card. The dots were arranged in three lines radiating from a single shared dot, as in Figure 1. Within each line, dots were placed at 5-mm. intervals. A line could appear at any of eight orientations—four on the vertical and horizontal and four 45° off the vertical or horizontal. One of the three lines (the *shaft*) was longer than the others—it contained four dots, counting the shared dot. The remaining two lines (the *arms*) contained three dots, again counting the shared dot. As the shaft appeared at eight orientations, and for each of these the two arms assumed $\binom{7}{2} = 21$ pairs of orientations, the number of stimuli was 168. When one of the arms came closer to forming a 180° angle with the shaft, it was referred to as Arm a and the other arm as Arm b; when the arms were symmetrical about the shaft, however, this labeling could not be used. Figure 1 shows a stimulus in which Arm a is at 90° to the shaft and Arm b is at 45° to the shaft—the "angle of an arm" always refers to the smaller angle between that arm and the shaft.

Subjects. Twenty female students at the University of Western Ontario were paid to participate in a series of experiments on grouping and visual illusions, of which the present experiment was one. At no time, however, did *E* discuss with *S* the nature of the experiments, or apprise her of data from earlier experiments or of hypotheses relevant to the current experiment.

Procedure. The *S* placed a stimulus card on a stand tilted back 15° from the vertical (where its illuminance was .088 cd/cm²), rested her chin in a chin rest (which gave a viewing distance of 45 cm.), pushed a button which turned a quietly-sounding buzzer off for 5 sec., and fixated the shared dot

during the 5 sec. of silence. During fixation, she decided which of the two arms appeared to group with, or belong to, the shaft. She indicated her experience of grouping by writing an integer from −3 to +3 excluding 0. Positive values indicated that the shaft appeared to group with Arm a and negative values, with Arm b (a small replica of the stimulus drawn in the upper-left corner of the stimulus card labeled Arms a and b). The integers 1, 2, and 3 indicated that grouping was weak, moderate, or strong. After recording her rating, *S* found the stimulus number on the back of the card and wrote it beside her rating. Before running each *S*, the deck of cards was rearranged by shuffling as well as by dealing the cards into separate piles in haphazard order, then picking the piles up in haphazard order.

Data simplification. In order to reduce the task of data presentation and data interpretation to manageable proportions, 144 of the 168 stimuli were sorted into 18 *patterns* of 8 stimuli each. (The remaining 24 stimuli were ones in which the arms were symmetrical about the shaft and will be discussed below.) The 8 stimuli that were considered to be instances of a single pattern were stimuli in which the two arms bore the same relation to the shaft and in which the shaft was either always on the vertical-horizontal or always oblique. Below the abscissa in Figure 2, for example, Pattern 1 stands for 8 stimuli, 4 of which can be generated by rotating Pattern 1 in 90° steps, and the other 4, by rotating a mirror image of Pattern 1 in 90° steps. Similarly, Pattern 10 stands for 8 stimuli whose arms bear the same relation to the shaft as in Pattern 1, but now with the shaft oblique. The data in Figure 2 were produced by averaging together each *S*'s ratings to the 8 stimuli within 1 pattern, then calculating the means and standard errors of the means across *S*s.

What is predicted. Two sorts of predictions are made. The first is which arm within a pattern will group more strongly with the shaft. These predictions are called *within-pattern* predictions and consist merely of specifying the sign of the mean ratings.

The second sort of prediction specifies inequalities between means. These predictions are called *between-pattern* predictions. Between-pattern predictions, however, were attempted only for pairs of means originating from *comparable* patterns. Comparable patterns are pairs of patterns in which one of the arms in the first pattern is at the same angle to the shaft as one of the arms in the second pattern. These two arms are called *common* arms, and the remaining two arms are called *target* arms. Thus, 1b–2b are common arms and 1a–2a are target arms; 1a–15b are common arms and 1b–15a are target arms; and so on. In between-pattern comparisons in which the angles of the arms in one pattern are the same as the angles of the arms in another pattern (1–5, 2–4, and others), the a arms will be considered to be the target arms.

The between-pattern predictions generated below will be for the target arms of comparable displays. Thus, no prediction will be ventured for Patterns 1–9 or 1–18 because they contain no common arms and, therefore, no target arms for which predictions can be made. Of the $\binom{18}{2} = 153$ combinations of patterns, 129 proved to be comparable.

Three predictors. Three predictors were used: *rectilinearity*, *orientation*, and *enclosure*. These are described below.

The first predictor, rectilinearity, states that a shaft groups more strongly with the arm with which it comes closer to forming a 180° angle. The increase in the grouping of an arm to the shaft, however, is considered to be a nonlinear function of angle. If we start off by imagining a linear function, we can say that at every 45° increase in angle, the increase in strength of grouping is "moderate," in comparison with which any larger increase would be "large." If we now imagine that the point in the function above 135° is pulled down so as to be on a level with the point above 90°, the 90°–135° increment will be zero, and the 135°–180° increment will be large. By inference, the 45°–135° increment will be moderate, and the 45°–180° and 90°–180° increments will each be large. In short, all comparisons in which one arm is at 180° imply a strong rectilinearity effect, all comparisons in which the two arms are at 90° and 135° imply no rectilinearity effect, and all other comparisons imply a moderate rectilinearity effect.

For an example of a within-pattern prediction, we see that in Pattern 1, Arm 1a is at 90° and Arm 1b is at 45°—grouping, therefore, is predicted to be with 1a so that the sign of the mean rating should be positive. In between-pattern prediction, we might compare the two target arms 1a and 3a—3a is at 180° and is, therefore, predicted to receive a higher rating than 1a which is at 90°. (Whenever a target arm is a b arm, the sign of the mean rating for that pattern must be reversed. In predicting 1b < 15a, for example, the data are considered to show $-1.27 < -.14$.) Rectilinearity, however, is unable to generate a prediction in every instance. Thus, it generates no within-pattern prediction for Patterns 6, 8, 15, and 17 (because within each pattern the two arms are at 90° and 135°) and generates no between-pattern prediction for Patterns 1–5 or 1–10, for example (because the target arms are at equal angles to the shaft), or in the case of 1–2 or 9–16, for example (because the target arms are at 90° and 135°).

The second predictor, orientation, states that a shaft groups more strongly with an arm on the vertical or horizontal than with an oblique arm. Within Pattern 1, for example, 1a is horizontal and 1b is oblique—thus, orientation joins rectilinearity in predicting 1a > 1b. In the case of Pattern 10, however, orientation works against rectilinearity—whereas rectilinearity predicts 10a > 10b, orientation predicts that 10a < 10b. (The resolution of contradictory predictions is discussed in the next section.) In cases where both arms are oblique (like Pattern 2) or both vertical–horizontal (like Pattern 11), orientation makes no prediction.

In between-pattern comparisons, the orientation

prediction is more complex to derive. First, each target arm is assigned a value of +1, 0, or −1 depending on whether the within-pattern prediction is that the target arm is helped, unaffected, or hurt by orientation. Second, the values assigned the target arms within each pattern are compared—a shaft is predicted to group more strongly with the target arm which has the higher value, otherwise no prediction is made. For example, 1a gets +1 and 10a gets −1—therefore, orientation predicts 1a > 10a; 1a(+1) − 2a(0)—therefore, orientation predicts 1a > 2a; and 2a(0) − 11a(0)—therefore, orientation makes no prediction.

The third predictor, enclosure, is used only in between-pattern comparisons and only when the target arms in comparable displays are at the same angle to the shaft. Enclosure specifies that the shaft groups more strongly with the target arm when the target arm is ipsilateral with, and thus encloses, the common arm. Illustrative predictions are 1a > 5a and 2a > 4a.

Contradictory predictions. When only one predictor was applicable, or when two predictors were applicable and both predicted the same thing, the prediction was said to be unequivocal. (In no comparison were all three predictors applicable.) In the case of equivocal predictions, however (when two predictors were applicable and made opposite predictions), a simple tie-breaking rule was invoked —when rectilinearity contradicted orientation, rectilinearity was expected to dominate when the rectilinearity effect was large (one target arm was at 180°) and orientation was expected to dominate when the rectilinearity effect was zero (the target arms were at 90° and 135°)—although the latter case could have been classed as unequivocal, it was classed as equivocal so as to distinguish it from cases in which rectilinearity differences did not exist and rectilinearity was totally inapplicable. In all other cases of contradiction, no prediction was made—the antagonistic predictors were considered to be equivalent in strength so that no overall prediction could be ventured with safety.

Stimuli with symmetrical arms. Data from 24 stimuli will not be discussed—these are stimuli in which the arms were symmetrical about the shaft so as to form a Y, a T, or an arrowhead. They will not be discussed for four reasons: (*a*) no predictor was able to generate a prediction on the sign of the mean rating within a given stimulus; (*b*) in between-stimulus comparisons, there was no basis for deciding which arms to call common arms and which to call target arms, and thus there was no way of knowing which arm a prediction should be made for; (*c*) four, rather than eight, stimuli existed per pattern; and (*d*) no systematic tendency in the ratings given these stimuli was apparent.

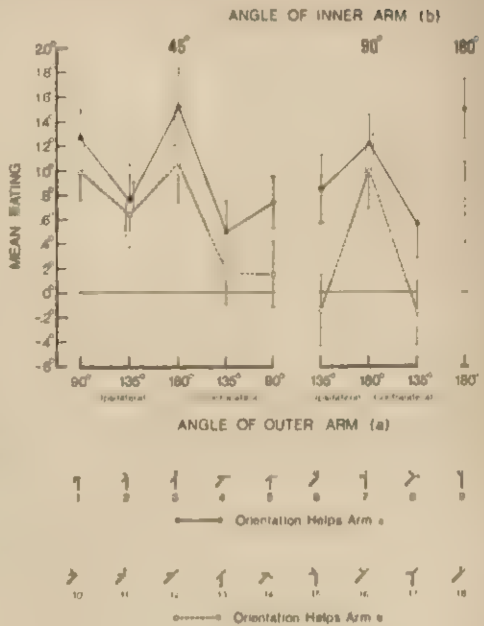

FIGURE 2. Means with ±1 standard error of each mean for 18 stimulus patterns. (An instance of one of the 8 stimuli in each pattern is shown below the abscissa in schematized form, with Arm a dashed. Positive ratings indicate that the shaft grouped with Arm a; negative ratings, with Arm b.)

RESULTS

Figure 2 is organized as follows. The two functions on the left present data from patterns in which Arm b is at 45°, with Arm a rotating from 90° ipsilateral with Arm b, to 90° contralateral to Arm b. The two middle functions present data from patterns in which Arm b is at 90°, with Arm a rotating from 135° ipsilateral to 135° contralateral. The two right-hand data points are from patterns in which Arm b is at 135° and Arm a at 180°. Finally, with the exceptions noted below, the solid functions present data from patterns in which orientation promotes grouping toward Arm a, and the dashed functions present data from patterns in which orientation promotes grouping toward Arm b.

Within-pattern predictions. Rectilinearity and orientation both predicted grouping toward Arm a in Patterns 1, 3, 5, and 9. Rectilinearity alone predicted grouping toward Arm a in Patterns 2, 4, 7, 11, 13, and 16. Orientation alone predicted grouping toward Arm a in Patterns 6 and 8 and toward Arm b in Patterns 15 and 17 (in

these four patterns, the rectilinearity difference was the impotent 90°–135°). Orientation favoring Arm b opposed rectilinearity favoring Arm a in Patterns 12 and 18, but rectilinearity was predicted to dominate because of the presence of a 180° arm. Finally, no prediction was made for Patterns 10 and 14 where orientation favoring Arm b was opposed by a moderate rectilinearity effect (arms at 45° and 90°) favoring Arm a.

Overall, then, the algorithm made predictions on the sign of the mean rating given 16 of the 18 patterns, and was correct 16/16 times, $p < .001$ in the binomial distribution $n = 16$, $p = .5$. (The binomial distribution was used to calculate all probabilities reported below.)

Between-pattern predictions. As noted above, the algorithm for generating between-pattern predictions showed that 129 of the 153 pattern combinations were comparable. In 20 of the 129, however, the algorithm generated no prediction for the following reasons. In 3 comparisons (2–11, 4–13, and 7–16), no predictor applied. As the orientation predictor was among those that failed, it was unable to determine which member in each of the three pairs should go in the solid "Orientation Helps Arm a" functions and which in the dashed "Orientation Helps Arm b" functions. Accordingly, Patterns 2, 4, and 7 were placed in the solid functions in order to keep the solid and dashed functions from crossing. In 17 more comparisons, two predictors made contradictory predictions which the algorithm was not programmed to resolve—in 2 comparisons (8–15 and 5–10), orientation opposed enclosure and in 15 comparisons, rectilinearity opposed orientation with target arms at 45° and 90° (2–6, 8; 4–6, 8; 6–11, 13; 7–12; 8–11, 13; and 12–16) or at 45° and 135° (9–12; 10–15, 17; and 14–15, 17).

Of the 109 comparisons that remain, predictions were generated and were correct 103/109 times ($p < .001$). These may be broken down into 75/79 correct ($p < .001$) when predictions were unequivocal and 28/30 correct ($p < .001$) when predictions were equivocal.

A further breakdown of the 79 unequivocal predictions shows: (*a*) 41/45 correct ($p < .001$) when rectilinearity and orientation made compatible predictions (prediction confirmed: 1–6, 7, 8, 16; 2–3, 9, 14, 15, 17; 3–4, 7, 10, 11, 13, 14, 16, 18; 4–9, 14, 15, 17; 5–6, 7, 8, 16; 6–9; 7–15, 17, 18; 8–9; 9–11, 13; 11–14, 15, 17; 13–14, 15, 17; 15–16; and 16–17, 18; prediction disconfirmed: 2–10; 4–10; 10–11, 13)—the 4 incorrect predictions, it will be noted, all involve Pattern 10, whose mean was expected to be lower, even lower than the mean of Pattern 13; (*b*) 18/18 correct ($p < .001$) in comparisons in which rectilinearity was the only applicable predictor (1–3, 15, 17; 3–5, 9; 5–15, 17; 6–10, 14, 18; 8–10, 14, 18; 9–15, 17; 10–12; and 12–14, 18); (*c*) 8/8 correct ($p < .01$) in comparisons in which enclosure was the only [illegible]plicable predictor (1–5; 2–4, 13; 4–11; 6–8; 10–14; 11–13; and 15–17); (*d*) 6/6 correct ($p < .05$) in comparisons in which orientation was the only applicable predictor (1–10; 3–12; 5–14; 6–15; 8–17; and 9–18); and (*e*) 2/2 correct ($p > .05$) in comparisons in which orientation and enclosure made compatible predictions (1–14 and 6–17).

A further breakdown of the 30 equivocal predictions shows (*a*) 19/20 correct (p [illegible] .001) when rectilinearity contradicted [illegible]tation but when rectilinearity domi[illegible] because one of the target arms was at 180° (prediction confirmed: 2–12, 18; 4–12, 18; 5–12; 6–7, 16; 7–8, 10, 14; 8–16; 10–16; 11–12, 18; 12–13; 13–18; 14–16; 15–18; and 17–18; prediction disconfirmed: 1–12); (*b*) 9/10 correct ($p < .01$) when orientation dominated the impotent 90°–135° rectilinearity difference (prediction confirmed: 1–2, 4, 11, 13; 4–5; 5–11, 13; 7–9; and 9–16; prediction disconfirmed: 2–5).

Although the above listing of predictions gives a precise and complete account of what the algorithm does and does not accomplish, it may be helpful to note a few of the key effects as they appear in Figure 2. First, the difference between solid and dashed functions reflects the effect of orientation helping Arm a in the first case and helping Arm b in the second (with the

exception of Patterns 2–11, 4–13, and 7–16, as discussed above). Second, enclosure accounts for the means to the left of the two 180° positions on the abscissa being higher than the corresponding means to the right. Thus, 1 > 5, 2 > 4, 10 > 14, 11 > 13, 6 > 8, and 15 > 17. Third, if Arm a's approach to rectilinearity facilitates grouping, why is there a drop in the function from Pattern 1 to 2 or from 5 to 4? The answer is that the 90°–135° step toward rectilinearity is the one that fails to enhance grouping, and that 2a and 4a lose the help of orientation that boosted 1a and 5a. Fourth, the rise from 14 to 13 and the incorrectly predicted rise from 10 to 11 were based on Arm a's gaining strength from orientation, the rectilinearity difference again being impotent. Fifth, the ordering 7b > 9b >3b (recall that when a target arm is a b arm, the sign of the mean rating must be reversed) can be explained as follows: 7b > 9b (orientation, rectilinearity impotent); 9b > 3b (rectilinearity); and 7b > 3b (rectilinearity and orientation). Sixth, the ordering 18b > 16b > 12b can be partially explained as follows: 18b > 16b (orientation, rectilinearity impotent); 18b > 12b (rectilinearity); 16b–12b, however, generates no prediction (a moderate rectilinearity effect favors 16b but orientation favors 12b). Seventh, 15b > 11b and 17b > 13b (rectilinearity and orientation). These, then, are a few of the bigger effects that catch the eye in scanning Figure 2.

Discussion

Overall, the simple algorithm employed above made 16/16 correct within-pattern predictions and 103/109 correct between-pattern predictions. It does not seem too much to say, then, that the algorithm generates an unprecedented bounty of predictions and that these turn out to be mostly correct.

The success of the algorithm suggests that Max Wertheimer's (1958) original observation that juxtaposition at 180° produces stronger grouping than at other angles needs to be elaborated in two ways. First, the function relating strength of grouping to angle of juxtaposition appears to be nonlinear—compared to the slope between 45° and 90°, the slope is relatively shallow between 90° and 135° and is relatively steep between 135° and 180°. Second, good continuation is not a function merely of the degree of rectilinearity; it is a compound of three phenomena—rectilinearity, orientation, and enclosure. As one of these can enhance or cancel another, any attempt to examine one must be guided by an awareness of all three.

RECALL AND RECOGNITION OF SEMANTICALLY ENCODED WORDS [1]

ENDEL TULVING [2]

Yale University
and
University of Toronto, Toronto, Ontario, Canada

The hypothesis was tested that the phenomenon of recognition failure of recallable words is attributable to the discrepancy between semantic properties of encoded target words and the semantic interpretation of corresponding recognition test words. Target words were presented for study and encoding in the presence of specific list cues, and subsequently tested with strong associates of target words serving as extralist cues. In one critical encoding condition, the list cues were semantically congruous with target words; in another, they were identical with target words. Results showed that congruous encoding rendered extralist cues only slightly less ineffective than incongruous encoding, and that under the conditions of "identical" encoding extralist cues were least effective. The results thus provided little support for the hypothesis, suggesting instead that specificity of encoding of word events in episodic memory transcends the semantic meaning of words.

This article describes two experiments designed to explore the phenomenon of recognition failure of recallable words recently reported by Tulving and Thomson (1973). In the Tulving and Thomson experiments, target words T (e.g., CHAIR) were presented at input in the company of cue words C (e.g., *glue*). Subjects expected to be tested for recall of T with C as a cue. When, instead of presenting C as a cue, the experimenter provided another word X (e.g., *table*)—which was a close semantic associate of the target word T but which had not appeared anywhere in the list—as an extralist retrieval cue, subjects could not readily use it as an aid in recall of T. Retrieval of the target word T was rather poor even in a subject-generated recognition test. In this test, subjects were instructed to write down free-association responses to the cue X, and then were asked to identify the generated responses as copies of target words from the studied list. Subjects had no difficulty generating copies of target words, but they did have difficulty recognizing them as "old" words from the studied list. In one experiment, for instance, only 24% of generated target words were correctly recognized in such a subject-generated recognition test, although 63% of all target words were subsequently recalled when the word C that had been paired with T at input was presented as cue.

The effectiveness of extralist retrieval cues consisting of strong associates of target words is a well-established phenomenon, under a variety of experimental conditions (e.g., Bahrick, 1969; Light, 1972; McLeod, Williams, & Broadbent, 1971; Thomson & Tulving, 1970), and hence the lack of their potency under the conditions of the Tulving and Thomson (1973) experiments is of some interest. What renders extralist cues ineffective? Why cannot certain recallable words be recognized?

A general interpretation of all acts of successful and unsuccessful retrieval of information from episodic memory is given by the encoding specificity principle (Tulving & Thomson, 1973). It states that the properties of the memory trace of a word event are determined by specific encoding

operations performed on the input stimuli, and that it is these properties, rather than the properties of the word in semantic memory, that determine the effectiveness of any given stimulus as a retrieval cue for the event. The principle suggests that if a stimulus in the retrieval environment renders possible or facilitates recall of the target word T, the retrieval information was appropriate to or compatible with the information contained in the episodic trace of T. Conversely, if a particular stimulus is ineffective in retrieving a particular trace, the conclusion follows that the appropriate relation was lacking. It is not yet known exactly what constitutes the "appropriate" relation between information contained in the trace and information present in the general retrieval environment or in a specific cue. Nor is the nature of the retrieval process as such clear. In absence of such knowledge, we assume that the unknown relation is one of "similarity" or "informational overlap," and that the retrieval process consists of some sort of combining of information from the two sources.

The failure of recognition of recallable target words in the Tulving and Thomson (1973) experiments thus can be interpreted as a special case of encoding specificity. It can be assumed that the trace of the target word T that had been encoded in relation to a particular list cue C did not possess sufficient overlap with the copy of the target word that was generated as a semantic associate of the extralist cue X. This is why X failed to bring about recovery of information in the trace of the target T. The encoding specificity principle, however, says nothing further about conditions or mechanisms responsible for inadequate overlap or complementarity between the trace of the C–T complex and the copy of T. But, if one accepts the reasoning so far, it is possible to ask the next question: Why do the encoding operations performed by the system on the target word T sometimes create a trace whose informational content cannot be matched by that of cue X, a strong semantic associate of T? Thus, for instance, why does the trace of the target word CHAIR, when presented as a part of the *glue*–CHAIR compound, differ from the trace of the target word CHAIR presented by itself, so that in the former case cues *table* and *chair* are relatively ineffective, although they both are quite effective under different experimental conditions (Bahrick, 1969; Light, 1972; McLeod et al., 1971; Thomson & Tulving, 1970; Tulving & Thomson, 1973)?

One hypothetical answer to this question was studied and evaluated in two experiments reported in this article. The answer consists of two parts: (*a*) what is stored, or at least what is retained after an interval, about a target word in a typical list-item memory experiment is the "meaning" of the word, and (*b*) pairing of the target word T with a certain list cue C at input produces a specific meaning of T that differs from the meaning of the same lexical unit perceived or produced in a different context, such as in a free-association test in which some other word X elicits T. Thus, CHAIR presented in a to-be-remembered list of words as a part of the *glue*–CHAIR compound is assumed to have a different semantic representation in memory than CHAIR generated as a semantic associate to the word *table*. The failure of recognition of recallable target words, the argument goes, then comes about for the same reason as the decrement in recognition of a homographic target word when the semantic interpretation of its copy at the time of the test is changed through changes in its verbal context (e.g., Light & Carter-Sobell, 1970; Winograd & Conn, 1971).

This semantic explanation of encoding specificity manifested in the phenomenon of recognition failure of recallable words was tested in the experiments described here. The experimental paradigm used was one in which the lexical identity of the target words was held constant and in which the effectiveness of various retrieval cues was examined as a function of semantic overlap between encoding context of the target word and the retrieval cue. Thus, retrieval of target word T was tested with extralist cue X following the presentation of the target word in one of three input contexts: (*a*) in the company of cue

words whose dominant semantic meaning was relatively incongruous with that of the target word T and the extralist cue X; (*b*) with cue words whose meaning was congruous with that of the semantic target word and the extralist cue; and (*c*) with cue words that were identical with target words. Thus, for instance, with the word CHAIR serving as target, the Incongruous encoding context or condition was represented by the pair *glue*–CHAIR, the Congruous condition by the pair *furnish*–CHAIR, and the Identical condition by *chair*–CHAIR. The extralist retrieval cue was *table*. It was assumed that the semantic information contained in the retrieval cue *table* would be most compatible with the stored information about the target word CHAIR presented in the *chair*–CHAIR compound (Identical encoding), somewhat less compatible with CHAIR presented in the *furnish*–CHAIR compound (Congruous encoding), and least compatible with information about CHAIR that had appeared as a part of the *glue*–CHAIR compound (Incongruous encoding). In keeping with the semantic encoding hypothesis it was expected that the effectiveness of the extralist cue would be directly related to the semantic similarity or compatibility between the cue and the target word.

Experiment I

Method

Materials and design. Target words presented in three different encoding contexts were recalled in three successive tests. The three encoding conditions were all represented within a single list that contained 24 target words. Each target word was accompanied at presentation by another word, a list, or input cue. Three types of list cues defined the three encoding conditions: (*a*) incongruous, (*b*) congruous, and (*c*) identical. The designations refer to the semantic relations between target words or subsequently presented extralist cues on the one hand and the list cues on the other. Each type of list cue appeared with 8 target words in the list.

Three successive retention tests were those used in previous experiments by Tulving and Thomson (1973): (*a*) a test in which strong extralist associates of target words served as retrieval cues, (*b*) a recognition test in which copies of target words were generated by *S*s as free associations to strong extralist associates of target words, and (*c*) a test in which list cues served as retrieval cues.

The basic set of materials used in the construction of experimental lists is presented in Table 1. Each of the 24 target words is shown together with its extralist associate which was used in the first cued recall test, and with both the Congruous and the Incongruous input cue. The 24 target words were specifically selected from the materials used in earlier experiments described by Tulving and Thomson (1973) to yield low recognition scores. Extralist cues and the incongruous input cues of these 24 target words were the same as those used in earlier experiments. The identical list cues are not shown in Table 1, for obvious reasons. Extralist and incongruous cues had been selected in the earlier experiments (Thomson & Tulving, 1970) from two sets of free-association norms. In these norms target words were primary associates of extralist cues; they were given as responses to incongruous cues 1% of the time, and extralist and incongruous cues were not related. The congruous input cues were generated by *E*, for the purpose of the present experiment, to represent words closely related semantically to both the target words and their extralist associates. By perusing the listing of the experimental materials displayed in Table 1, the reader can convince himself that the congruous list cues are more closely related to the target word and the corresponding extralist cue words than are the incongruous cues.

For the purpose of balancing of specific words and their encoding conditions, three different lists were constructed of the materials that appear in Table 1. The 24 target words were divided into three subsets of 8, each subset being used with a different set of input cues (incongruous, congruous, and identical) in one of the three lists. The lists were used with equal frequency in the experiment (specifically, since there were 50 *S*s, with 17, 17, and 16 *S*s respectively, in each group). Half of the target words in each subset of 8 were tested in the first retention test (with extralist associates of targets as cues), while the other half was tested in the second test (subject-generated recognition test), with the two halves counterbalanced across the two tests. Thus, each of the 24 target words was represented with equal frequency in all conditions of the experiment.

Prior to the presentation of the critical experimental list, *S*s were given a single practice and set-establishing list. It consisted of 24 target words, half of which were accompanied by input cues identical with target words and half accompanied by incongruous cue words comparable to those used in the critical experimental lists.

Subjects and procedure. Fifty *S*s, undergraduate students at Yale University and the Southern Connecticut State College, served in Experiment I, either in fulfillment of course requirements or for pay. They were tested in small groups of from 2 to 4 persons, in a session lasting approximately 40 min.

The initial instructions, given prior to the presentation of the set-establishing list, informed *S*s of the general nature of their task and the type of materials to be presented. They were told that they

would see pairs of words presented on the screen in front of the room, that their task was to remember the capitalized target words, but that they should also pay attention to the cue word accompanying each target word and notice the relation between them, since these cue words would help them to remember the target words. No special mention was made of the fact that some of the pairs would consist of identical words, nor were *S*s told anything particular about the retention tests.

The cue–target pairs from the set-establishing list were presented by means of a slide projector, at the rate of 3 sec/pair. At the end of the presentation *S*s were asked to open their recall booklets that had been handed out to them at the beginning of the session, turn to page 3 in the booklet, read the instructions, and proceed with the retention test. On this recall sheet the 24 input cues from the list were presented in an order unrelated to the input order. The instructions at the top of the recall sheet told *S*s to write down the capitalized words that had accompanied the given word cues in the list. Subjects were given 3 min. for the completion of this test.

Next, *S*s were told that they would be shown a new list of pairs of words, and that their task was the same as before—to remember each capitalized target word, noting the relation between it and its cue word. The nature of the relation between target and cue words was not specified or further commented upon.

The 24 pairs of the experimental list were then presented, again at the rate of 3 sec/pair. At the end of the presentation *S*s were asked to turn to page 6 of the recall booklet, read the instructions on the top of the page, and then proceed. (The pages for recall tests in the recall booklet were always separated by two numbered blank pages, hence this numbering system.) The recall instructions informed *S*s that their task was to try to recall the capitalized words they had seen in the list, but that this time the cues presented on the page were different from those they had seen in the input list. The *S*s were told to look at each cue word given on the recall sheet, see whether it reminded them of any target words they had just seen, and, if so, write it down beside the cue word. Twelve extralist cues, corresponding to four target words from each of the three encoding conditions, appeared on the recall sheet. Subjects were given 3 min. for this task.

Next, *S*s were asked to turn to page 9 in the recall booklet, which contained 12 extralist cues corresponding to the target words that had not yet been tested. Extralist cues, each followed by four spaces for free-association responses, were listed in a column on the left-hand side of the page. The instructions at the top of the page told *S*s that their task now was to produce free associations to the presented cue words. They were to write down four words in response to each of the cue words they saw on the page, words that the cue word "made them think of." This was an unpaced task, and *S*s were given as much time as they needed to complete it. When all *S*s in the group had finished writing, they were told to look at each word they had written down, decide whether or not it had occurred as one of the target (capitalized) words on the preceding study list, and, if they thought it had, draw a circle around the word. Four minutes were given for the completion of this task.

Finally, *S*s were asked to turn to page 12 of the recall booklet, read the instructions on the top of it, and proceed as instructed. This page contained all 24 input cues, in a scrambled order with respect to the order of their original appearance in the study list. The instructions informed *S*s that these were the input cues from the list, and that their task was to write down as many target (capitalized) words from the study list as they could, each one beside its corresponding cue word. Four minutes were allowed for this task.

The experimental session concluded with *E* explaining the purpose of the experiment to *S*s and answering any questions they had.

EXPERIMENT II

The *S*s in Experiment I seemed to do considerably better in the first retention test (cuing with extralist associates) than in the second (subject-generated recognition test). Since these data suggested that the order of the two tests may have been an important source of variance in the retention scores, Experiment II was con-

ducted to replicate Experiment I in every respect, with the sole exception of the order of the two tests. In Experiment II, the first of three tests was the subject-generated recognition test, while the second one was the cued recall test with extralist associates as cues. Otherwise the procedure was identical with that used in Experiment I in all details. The same materials were used both in the set-establishing list and the experimental list, the same counterbalancing procedure was followed, and the same final test with input cues was given. Thirty-six new *S*s from the same sources as in Experiment I served in this experiment.

Results

Set-establishing lists. The mean number of words recalled from the first set-establishing list was 16.7 in Experiment I, and 17.8 in Experiment II. In both experiments slightly more target words were recalled to identical than to incongruous cues (M = 8.8 and 9.5 in the two experiments, respectively). The mean number of intrusion errors was 1.34 and 1.83 per S in Experiments I and II, respectively. Of these intrusion errors in the two experiments, 44% and 58%, respectively, were "identical" intrusions: S gave a response identical with the cue although in the input list the cue had been paired with another word. It is possible that the higher recall of target words to identical cues was at least partly a consequence of inflation of recall scores by unidentifiable intrusions, but since it is not entirely clear what would constitute an appropriate correction, no attempt was made to assess the possible guessing bias.

Scoring and analysis. Analysis of the cued recall data, in all tests in which extralist or input cues were used, was straightforward. Each S's recall score was the number of target words recalled, from a maximum of four or a maximum of eight per condition in the two tests, respectively. A stringent scoring criterion was used: S received credit for every target word only if it was correctly paired with its cue. (The inclusion in the data of target words recalled to incorrect cues, or to no particular cues, would not have changed the conclusions.)

Intrusion errors were ignored in all analyses. It is not immediately obvious how their inclusion in the results would change the overall conclusions drawn from the experiments.

In scoring the protocols from the subject-generated recognition tests, *S*s were given credit only for those copies of target words generated and recognized that belonged to the half of the input list being tested in the recognition test. In Experiment I there was a total of 33 cases in the protocols of the 50 *S*s where a copy of the target word had been generated as a part of the free-association procedure and correctly recognized even though these words nominally belonged to the other half of the list that had been tested in the immediately preceding cued recall test using extralist retrieval cues. Since it was impossible to rule out the possibility that the words from the other half of the list constituted importations from the immediately preceding test rather than representing *S*s' memory for the material seen in the input list (particularly since most of these generated and recognized words had been in fact recalled by *S*s in the immediately preceding test), they were excluded from the analysis.

The data from the subject-generated recognition tests required a special treatment inasmuch as the maximum possible score of correct identification of target items depended upon the number of copies of target items any particular S had generated in the free-association test. There were three essential steps in the analysis of these data.

First, the number of copies of target items correctly generated in the free-association test were tabulated for each S, separately for target words from each of the three encoding contexts. The means of these scores were 2.84, 2.76, and 2.91 for the incongruous, congruous, and identical encoding conditions, respectively, in Experiment I, and 2.98, 3.11, and 2.44, for the same three encoding conditions in Experiment II. There is no obvious explana-

tion for the lower value of this statistic in the identical encoding condition in Experiment II, and since the same decrement was not observed in Experiment I, whatever implications this finding might have will be ignored in what follows.

The second step consisted of the calculation of proportions of copies of target words that were recognized by each *S* in each encoding context. Thus, for instance, if a given *S* generated three copies of the target item in a particular encoding condition, and recognized one of these, his recognition score (hit rate) was $\frac{1}{3}$ or .33. The means of these proportions are provided as summary statistics for the subject-generated recognition test in Table 2. In a small number of cases, when *S* did not generate any copies of target words for a particular encoding condition in the free-association test, and hence could not possibly have recognized any, his score was considered indeterminate and was not entered into any analyses.

The third step in the analysis of the recognition scores was necessary for the purposes of the statistical evaluation of the data. Since the distributions of the recognition hit rates from individual *S*s in different encoding conditions in most cases were not distributed normally, statistical tests involving these measures were deemed inappropriate. Another measure of recognition performance was used instead. For each *S* in each encoding condition a right minus wrong (R − W) score was calculated.[3] Each target word whose copy had been generated and correctly recognized was considered R while each generated copy of a target word that was not recognized was considered W. For instance, an *S* who generated three copies of targets in a particular encoding condition, and recognized one of these, received an R − W score of $1 - 2 = -1$. The *differences* of these R − W scores for all three comparisons (incongruous vs. congruous, incongruous vs. identical, and congruous vs. identical) were distributed normally, thus permitting the use of *t* tests for related measures. Thus, while the data in Table 2 are summarized as mean hit rates, the corresponding analyses were conducted on the R − W scores as explained. There was, of course, a high although not a perfect correlation, within each of the encoding conditions, between individual *S*s' hit rates and R − W scores, the coefficient exceeding .90 in all cases.

Retrieval data. Table 2 presents a summary of the data on retrieval of target words from three different encoding conditions in three different tests.

Consider first the mean proportions of target words retrieved in various tests, with data pooled over the three encoding conditions in each test. Two observations are of interest. First, the order of the first two tests, both involving extralist cues, appears to have exerted considerable effect on the level of retrieval: *S*s' performance was higher in the first test (cued recall with extralist cues in Experiment I, and subject-generated recognition test in Experiment II) than in the second test. To evaluate test-order effects, a *t* test for unrelated measures was done comparing the differences between *S*s' scores on the cued recall and recognition tests in Experiment I with the same difference scores in Experiment II. The obtained value for t (84) was 4.57, $p < .01$. It appears, therefore, that some general test interference was produced in the course of the first test that suppressed the level of performance in the second. The proportions of copies of target items generated in the recognition test were identical at 71% in both experiments, suggesting that it is only the episodic and not the semantic (Tulving, 1972) component of the task that reflects interference, but given the design of the experiments, it is difficult to say anything more about the nature and sources of the test interference.

The second point with respect to retrieval scores pooled over different encoding conditions concerns the superiority of the performance in the final cued recall test over that in the other two tests, in both experiments. Statistical evaluation of the data was accomplished by means of *t* tests

[3] I am grateful to Perry Gluckman for suggesting this analysis.

TABLE 2

MEAN PERCENTAGES AND STANDARD DEVIATIONS OF TARGET WORDS RECALLED AND RECOGNIZED IN THREE TESTS AS A FUNCTION OF ENCODING CONTEXT

Experiment and encoding context	Test: Cued recall, extralist cues		Subject-generated recognition		Cued recall, list cues	
	M	*SD*	*M*	*SD*	*M*	*SD*
Experiment I ($N = 50$)						
Incongruous	51.5	34.0	26.3[a]	31.5	60.5	21.6
Congruous	52.0	27.1	36.5[a]	32.3	49.8	22.4
Identical	39.0	30.0	24.6[a]	31.1	46.5	26.1
M	47.5	23.4	28.6[a]	22.9	52.2	16.9

[a] $N = 45$.
[b] $N = 32$.

after the data in various tests were normalized in order to equate the three tests for maximum scores possible. The resultant t test was highly significant when the performance in the third test was compared with the performance in the second test in each of the two experiments, t (49) = 6.75 in Experiment I, and t (35) = 5.28 in Experiment II, both ps < .01. The t values were not significant when recall with input cues was compared with probability of retrieval in the first test in each of two experiments, t (49) = 1.74 in Experiment I, and t (35) = 1.88 in Experiment II, in both cases $.05 < p < .10$.

The data of primary interest concern differences in retrieval of target words that had been presented in different input contexts in the study list. The differences between encoding conditions were evaluated by means of t tests for related measures, separately for each of the three tests in both experiments. The results of these tests are tabulated in Table 3.

Although there was a slight numerical superiority in extralist cued recall and subject-generated recognition scores in the congruous input cue conditions over those in the incongruous input cue conditions, statistical analyses of the data, summarized in Table 3, showed that these differences did not reach acceptable degrees of reliability. The largest difference between the incongruous and congruous encoding conditions was observed in the subject-generated recognition test in Experiment I (26.3% vs. 36.5%), yielding a t (44) = 1.47, $.05 < p < .10$. In Experiment I, recall in response to list cues of target words that had appeared in the context of incongruous input cues was higher (60.5%) than recall of target words that had appeared in the context of congruous encoding cues (49.8%), t (49) = 2.80, $p < .01$, and this difference might be regarded as tempering the conclusion about lack of evidence for the effect of encoding conditions on retrievability of target words by extralist cues or their copies, but since Experiment II did not replicate this finding, its implications cannot be taken too seriously.

Since each to-be-remembered list word served as a target word in two successive tests, it was possible to examine recall or nonrecall of individual words in one test in relation to their recall or nonrecall in the other test. Indeed, the phenomenon of recognition failure of recallable words that provided the starting point for the present experiments can be most directly defined by demonstrating that subjects cannot

TABLE 3

SUMMARY OF t STATISTICS FROM TESTS COMPARING RECALL AND RECOGNITION SCORES BETWEEN PAIRS OF ENCODING CONDITIONS

Comparison	Cued recall, extralist cues		Subject-generated recognition		Cued recall, input cues	
	Experiment I	Experiment II	Experiment I	Experiment II	Experiment I	Experiment II

** $p < .01$.

identify copies of target words as "old" but can produce these *same* words in presence of list cues. In the analysis of the "fate" of individual words that follows, retrieval of target words in extralist cue tests is compared with their retrieval in the final list-cue test.

Frequencies of words that are recalled in *both* the extralist cue test and the final list-cue test, as well as words that are recalled in *neither* of these two tests, are of little immediate interest. These data may reflect general "ease" or "difficulty" of words, breadth of encoding or failure of storage, effects of recoding or strengthening of traces in the first test, and other similar factors. Words that were retrieved only in the extralist cue test or only in the list-cue test provide more interesting data from the point of view of encoding specificity. These data are tabulated in Table 4.

Table 4 lists total frequencies of target words that were recalled or recognized in the extralist cue test but not recalled in the final list-cue test, and frequencies of target words not recalled or recognized in the extralist cue test but recalled in the final test. These two categories of words will be referred to as RN words and NR words, respectively, indicating the words' recall (R) or nonrecall (N) in the first (extralist cue) and the second (list cue) test. The left-hand panel of Table 4 presents data for target words initially tested in the extralist cued recall test, and the right-hand panel contains data for target words tested in the subject-generated recognition test.

Each entry in Table 4 consists of two figures. The first gives the total frequency (with the data pooled over all 50 *S*s in Experiment I and 36 *S*s in Experiment II) of RN words, while the second represents the total frequency of NR words. Each entry thus can be thought of as a ratio of two quantities, the number of RN words to the number of NR words, and the numerical value of this ratio, or some transformation of it, could be used as a rough index of the magnitude of the recognition failure of recallable words or the magnitude

TABLE 4

TOTAL FREQUENCIES OF TARGET WORDS RECALLED ONLY IN TEST WITH EXTRALIST CUES, IN RELATION TO FREQUENCIES OF WORDS RECALLED ONLY IN TEST WITH LIST CUES

Encoding condition	Recall with extralist cues			Subject-generated recognition test		
	Experiment I	Experiment II	Total	Experiment I	Experiment II	Total
Incongruous	17/45	15/54	32/99	10/47	17/26	27/73
Congruous	27/33	9/32	36/65	15/29	16/28	31/57
Identical	15/40	8/33	23/73	8/30	11/20	19/50
Total	59/118	32/119	91/237	33/106	44/74	77/180

of the failure of extralist cues in retrieval of words known to be represented in the episodic memory store.

Three features of the data in Table 4 should be mentioned. First, the data, pooled over both experiments, are rather similar in the two panels of Table 4, suggesting that underlying retrieval processes are probably not entirely dissimilar in extralist cued recall test and the subject-generated recognition test. Second, in all three encoding conditions, in both experiments and in both tests, the number of target words accessible only through list cues (NR words) was higher than that of words accessible only through extralist cues (RN words). Third, extralist cues were somewhat more effective for target words encoded in the congruous input condition than for those encoded under the other two conditions, as judged by the ratio of RN words to NR words, although the relatively small number of observations on which these data are based renders the differences statistically unreliable.

Discussion

The primary purpose of the experiments was to evaluate the hypothesis that specificity of encoding manifested in the phenomenon of recognition failure of recallable words (Tulving & Thomson, 1973) is a matter of specificity of semantic meaning of the to-be-remembered words and retrieval cues. Since in earlier experiments the target words were encoded in relation to list cues possessing little semantic similarity to target words and extralist cues, it seemed reasonable to argue that considerable semantic discrepancy existed between the target word as stored in that particular context and the literal copy of the target word presented as retrieval cue in the subject-generated recognition test. The graphemic units might have been the same in both cases, but they represented different bundles of semantic information.

The results of the present experiments do not provide much support for this semantic interpretation of encoding specificity. Some facilitation of retrieval of target words by extralist cues was observed under conditions where target words had been encoded in relation to cue words semantically much more compatible with both target words and extralist cues, in comparison with retrieval of target words encoded in relation to less congruous cues, but this facilitation was rather small and statistically not reliable. Furthermore, a considerable number of target words encoded in presence of congruous input cues were still not recognized in the subject-generated recognition test and could not be recalled to strongly associated extralist cues, even though they were recalled subsequently in presence of list cues, indicating that relevant information was available in the store. Finally, extralist cues were least effective, both in the recall and the subject-generated recognition tests, when target words were presented under the identical encoding condition where the input cue was nominally most compatible with the target word.

It is entirely possible that the hypothesis of semantic determination of encoding specificity fared so poorly in these experiments simply because the congruous encoding conditions were not congruous enough and the identical encoding conditions did not produce semantic encoding. If greater care were taken to ensure a high degree of semantic overlap between list cues and extralist cues the hypothesis might give a better account of itself. Nevertheless, the fact that it is not easy to eliminate the encoding specificity effect by manipulating the relation between input cues and extralist cues suggests that encoding of a familiar word in certain episodic memory tasks (Tulving, 1972) may entail degrees of specificity that cannot be achieved by changing semantic context of words. It may be more appropriate, therefore, to think about properties of memory traces of particular events and episodes as going beyond the properties of words as communicative units of language. It is [illegible] clear what these nonsemantic properties are.

The low level of recall and recognition of target words that had been presented in the input list under identical encoding conditions was quite unexpected. Several previous experiments, cited in the introduction, have shown that associated extralist retrieval cues are quite effective in facilitating recall of target words when these words occur in the study list without any manipulated context, and when the subjects are left free to encode them any way they want. There was no particular reason to expect, before doing the experiments described here, that the presentation of two identical copies of a word, one as "cue" and the other one as "target," would make any

substantial difference in the encoding of these list words. Yet the data were quite clear in showing that the Identical encoding condition was associated with lowest levels of recall and recognition, both in extralist cue tests and the final input cue test. It is this finding that appears to be most difficult to reconcile with the "semantic" interpretation of encoding specificity, suggesting that other or at least additional factors are involved.

The data from the practice list, in which immediate recall of target words was just about the same under identical encoding and incongruous encoding conditions, suggest that it was not the initial level of storage of "identically" encoded words that was impaired but rather that the low level of subsequent recall was some consequence of events that took place after the study of the list. It is difficult to say anything definite about this impairment on the basis of existing data. It may be that subjects encoded target words under identical conditions primarily in terms of their phonetic properties, in terms of a clang association between the cue and the target word, and that this information was lost more rapidly than the specific "semantic" information, or that the subsequently presented retrieval cues were somewhat less appropriate for providing access to this kind of information. It is also conceivable that the low level of retrieval of target words under identical conditions was a consequence of a high degree of similarity of encoding operations performed on these target words during the presentation of the list. If part of the information stored in the memory trace of an event represents the encoding operation performed on the input (Tulving & Thomson, 1973), then a high degree of similarity of encoding operations performed on a number of list items could render the resulting traces less unique and hence somehow less readily retrievable (Lesgold & Goldman, 1973; von Restorff, 1933). Be it as it may, the present data rather clearly suggest that the identity relation between two items, one designated as cue and the other as target, does not represent the extreme position on the dimension of associative or semantic relatedness.

Finally, in relation to earlier experiments (Tulving & Thomson, 1973) the present data showed rather a high degree of effectiveness of extralist retrieval cues, despite the fact that the materials for the present experiment were specially selected from among those used in earlier studies to yield a minimal level of retrieval in presence of extralist cues. It was hoped that such minimal levels of retrieval would have made it easier to demonstrate the effect of a congruous semantic input context. It may be that the use of a study list containing different sorts of cue–target relations was responsible for the discrepancy between the present and earlier experiments with respect to effectiveness of extralist cues, although for the time being this must remain pure speculation.

BODY TEMPERATURE AND TEMPORAL ACUITY [1]

JAMES F. O'HANLON,[2] JAMES J. McGRATH,[3] AND MICHAEL E. McCAULEY

Human Factors Research, Inc., Goleta, California

Two experiments were conducted to determine the relationship between temporal acuity and body core temperature; a third experiment served as a control. In Experiment I, thresholds for the perception of the succession of dichoptic light flashes were tested when body core temperature was normal and after it was increased to 38.3°C. by diathermy. In Experiment II, critical flicker frequency (CFF) thresholds and an electroencephalogram (EEG) were measured during euthermic, hyperthermic (39.0°C.), and recovery conditions. Results of both experiments indicated that temporal acuity increased with hyperthermia. Perception of succession and CFF were both facilitated by increasing body core temperature. The EEG alpha frequency also varied directly with body temperature, but was not significantly correlated with CFF. In Experiment III, no change in pupil diameter was found during hyperthermia, eliminating an interpretation of the results of Experiments I and II based on the Ferry-Porter law. These results were interpreted as supporting "psychological moment" theory.

A common premise shared by many theorists (Craik, 1948; Kristofferson, 1967; McReynolds, 1953; Shallice, 1964; Stroud, 1955; Walter, 1950; White, 1963; Wiener, 1948) is that the nervous system does not process all sensory inputs continuously, but briefly samples each input and routes selected inputs serially into the perceptual process. The time required to complete one sampling cycle has become known as the "psychological moment." According to Harter (1967), an assumption frequently made by the "moment" theorists is that the nervous system codes all sensory information in terms of sequential order of occurrence. All information arriving in the nervous system within one moment is encoded similarly and perceived as instantaneous and simultaneous; information arriving over the course of more than one moment is perceived as having duration. Discrete stimuli which are perceived in different moments are perceived as differing in time of occurrence.

According to Stroud (1955, p. 181), identical visual events that differ in time of occurrence are psychologically differentiated at a maximum rate of one per moment. By his reasoning, temporal acuity (the ability to discriminate between the occurrence of events in time) would be proportional to the moment frequency.

Still other theorists have used the moment concept to explain the perception of time passing (Treisman, 1963; White, 1963). Their premise has been that somehow the nervous system registers the accumulation of moments between events in time in a manner permitting the perception of the relative durations between those events. To those authors, the mechanism responsible for the moment also functions as a neural pacemaker which governs the perceived rate of time passing. That assumption implies that a factor which influences the neural pacemaker would affect both temporal acuity and the perception of time passing. Whether hyperthermia is such a factor is the question addressed in the present research.

Induced hyperthermia has been found to increase the perceived rate of time passing; i.e., subjective estimates of a unit of time are systematically shortened as body temperature increases (Hoagland, 1933; Kleber, Lhamon, & Goldstone, 1963; O'Hanlon, Danish, & McGrath, 1968). Hoagland attributed this result to the physiochemical effect of temperature on a hypothetical

pacemaker located in the central nervous system. However, some investigators (Bell, 1965; Bell & Provins, 1963) have failed to find any significant relationship between hyperthermia and performance in time-keeping tasks. But those negative results have been attributed to possible confounding effects of interpolated tasks and the relatively small induced changes in body temperature (Fox, Bradbury, Hampton, & Legg, 1967).

Various investigators have sought to determine whether induced hypothermia, as well as hyperthermia, affects time perception in the manner predicted by Hoagland's pacemaker model. In two studies (Fox et al., 1967; Lockhart, 1971), an increase in the perceived rate of time passing was found in both hyperthermic and hypothermic conditions. However, Baddeley (1966) found a significant decrease in the perceived rate of time passing in scuba divers exposed to cold water as predicted by the model. Further support was provided by O'Hanlon et al., who found that the perceived rate of time passing decreased with hypothermia and increased with hyperthermia in the same *S*s. Therefore, while the evidence is by no means unanimous, there appears to be a substantial degree of support for the existence of a temperature-dependent neural pacemaker.

If the neural pacemaker and the psychological moment are related, as suggested by White (1963), then hyperthermia would be expected to increase temporal acuity. Thus, the major purpose of the experiments described here was to determine if temporal acuity, like the perception of time passing, varies with hyperthermia. A secondary purpose of this research was to ascertain whether a change in the brain's dominant alpha rhythm parallels any hyperthermia-induced change in temporal acuity. Several authors have suggested a relationship between alpha frequency and temporal acuity (Harter, 1967; Kristofferson, 1966, 1967), but no conclusive evidence has been offered (Legg, 1968).

Two separate experiments were performed to determine the relationship between temporal acuity and hyperthermia. In the first, temporal acuity was determined from a test of the perception of succession (Type 2 test, Fraisse, 1963); in the second, it was determined using a version of the test for critical flicker frequency (CFF). Electroencephalogram (EEG) recordings were taken during the second experiment. A third experiment was conducted to ascertain whether hyperthermia changes pupillary diameter in any way which might affect interpretation of the results from the former experiments.

Experiment I

Method

Subjects. The *S*s were 11 male 21–28-yr.-old college students, who were paid for their participation. All had experienced induced hyperthermia in a previous experiment.

Experimental setting. The laboratory consisted of two adjacent rooms. The *S*'s room contained a standard hospital bed, a shortwave diathermy machine (Liebel-Flarsheim, No. SW-660), and a visual display. The *E*'s room contained apparatus for controlling the display and recording *S*s' temperature and responses.

Apparatus. The visual display was a standard Lafayette binocular viewing chamber (No. 1202C). The display contained two Sylvania glow-modulator lamps (No. R1166), each of which illuminated a circular diffusion screen with a diameter of 1.3 cm. The two diffusion screens were 7.0 cm. apart and were viewed from a distance of 38 cm. through an eyepiece. An opaque septum within the chamber permitted dichoptic stimulus presentation. Each lamp provided a flash luminance of about 41.56 cd/m² against a background of less than 16 cd/m² at the eyepiece. The display control was a modified Lafayette flicker-fusion unit (No. 1202A). The modification permitted the administration of two flashes, 10 msec. in duration, one to each eye. Two Hunter timers controlled the duration of the interval between flashes of the two lights. Tympanic temperature, which approximates brain temperature (Benzinger & Taylor, 1963) was recorded by a Digitec digital thermometer (No. 500) connected by cable to a thermistor fixed in *S*'s external auditory meatus, against the tympanic membrane.

Task. Two pairs of light flashes were presented in the visual display; one pair was simultaneous, the other was successive. The onsets of successive flashes were separated by 10-, 20-, 30-, or 40-msec. intervals, and all flashes were of 10-msec. duration. Upon observing both pairs of flashes, *S* was required to state which pair consisted of successive flashes. If he was unsure, both pairs were presented again. The task conformed to the psychophysical method of constant stimuli with a forced-choice response.

Procedure. Each *S* was scheduled for a sequence of three sessions with 1 wk. between sessions.

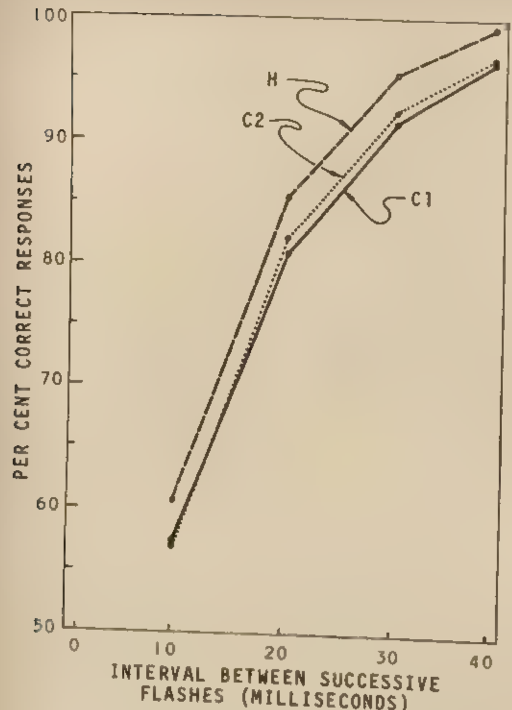

FIGURE 1. The percentage of correct responses by 11 *S*s as a function of the duration between successive flashes in the first control condition (C_1), hyperthermia condition (H), and the second control condition (C_2).

The first session was a training condition. The second session was comprised of a control condition (C_1) followed by the hyperthermia condition (H). The second control condition (C_2) was administered during the third session. In each session *S* wore a sweat suit and reclined on the bed under blankets. Upon request, he was given cold water from a thermos, which was replenished whenever necessary. His tympanic temperature was recorded continuously.

In the training condition, *S* performed the task in 40 trials with knowledge of results after each trial, and then in four blocks of 40 trials without knowledge of results. In C_1, *S* performed the task

TABLE 1

SUMMARY OF A NEWMAN–KEULS TEST OF DIFFERENCE IN TOTAL NUMBER OF CORRECT RESPONSES BY 11 *S*, COMPARING ALL POSSIBLE PAIRS OF CONDITIONS

Comparison	Total difference	*q*	*df*	*p*
H–C_1	63	6.80	3, 20	<.01
H–C_2	55	5.94	2, 20	<.01
C_1–C_2	8	.86	2, 20	*ns*

Note. Abbreviations: H = hyperthermia, C_1 = first control condition, and C_2 = second control condition.

in four blocks of 40 trials. Between [illegible] he rested for 5 min. At the end of C_1, *S* reste[illegible]r 15 min., and then began H. In H, diathermy [illegible] applied to the thorax, abdomen, and thighs, [illegible]hat *S*'s tympanic temperature was raised from [illegible]erage euthermic level of 37.0°C. to 38.3°C. [illegible]om 60–90 min. of diathermy were required to [illegible]omplish this change in body temperature. [illegible] the criterion temperature, diathermy was discont[illegible]ed, and *S* performed the task in four blocks of 40 [illegible]als each. Tympanic temperature was maintaine[illegible] between 38.25°C. and 38.35°C. by applying diath[illegible]y whenever necessary during the 5-min. rest per[illegible]ds between blocks of trials. In C_2 the procedure [illegible] the same as in Condition C_1.

In all conditions, each block of 40 trials had [illegible] following characteristics: (*a*) In 20 trials, the pa[illegible] of flashes were simultaneous–successive, and in [illegible] trials they were successive–simultaneous. (*b*) Th[illegible] sequence of flashes in the successive pair was left–right in 20 trials, and right–left in 20 trials. (*c*) Each interflash interval (10, 20, 30, or 40 msec.) occurred 10 times in the 40 successive pairs. Each interflash interval was used an equal number of times with each order of pairs and each sequence of flashes. The order of pair presentations and the order of interflash intervals were randomized independently within each block of trials.

Results

Training session data from each *S* were inspected to ensure that he had arrived at a stable level of performance. These data were not analyzed further.

The percentage of correct responses was tabulated for each interflash interval in Conditions C_1, H, and C_2. These percentages are shown in Figure 1 as functions of the duration of the interflash interval. The percentage of correct responses was greater in H than in either of the control conditions for all values of interflash intervals. The differences among performances in the C_1, H, and C_2 conditions were tested for statistical significance using a two-way mixed-design analysis of variance of the total number of correct responses. That analysis revealed that the differences among total correct responses in the three conditions were significant, F (2, 20) = 3.74, $p < .05$. A Newman–Keuls test was applied to determine the significance of the differences between all possible pairs of conditions. The results are summarized in Table 1.

The difference in the total number of correct responses between the H session

and each control condition was significant beyond $p < .01$. There was no significant difference between the control conditions.

Experiment II

Method

Subjects. The same 11 men who had served as *Ss* in the first experiment served in the second.

Apparatus. The display control apparatus was modified for estimating *Ss'* CFF, according to the version of the psychophysical method of limits developed by von Békésy (1947). Briefly, the lamps were made to flash in unison with a 50/50 light to dark ratio, and the flash frequency was made to vary continuously at a rate of .5 Hz/sec. This was done with a reversible servomotor which drove the oscillator that controlled the flicker rate, as well as a potentiometer which yielded a voltage analog of flicker frequency to drive a pen in a strip-chart recorder. After initial adjustment, *S* determined the duration of frequency change by depressing a handheld switch which caused the servomotor to reverse direction after an 8–10-sec. delay. These responses were recorded by a brief pen deflection on the chart recording.

Two channels of a Gilson polygraph (M8PM) recorded EEG from Grass silver subdermal electrodes placed over *S*'s right and left occipital cortices. The active recording electrodes were referenced to linked, clip-type, silver electrodes attached to both earlobes.

Task. The task consisted of pressing the response switch whenever the lamp's brightness appeared constant after it had been flickering, or whenever the brightness seemed to flicker after it had been constant. The former response marked *S*'s fusion threshold, the latter response marked his flicker threshold. The midpoint of a line between fusion and flicker thresholds on the chart recording was the measurement of CFF.

Procedure. Each *S* participated in three sessions scheduled 1 wk. apart. Conditions C_1, H, and C_2 were administered in successive sessions.

In C_1 and C_2 the task was administered in four 10-min. tests, interspaced with 5-min. rests. Recordings of EEG were made during 5-min. periods before the first test and after the final test. During all EEG recordings, *S* reclined quietly with his eyes closed.

In H, *S* rested as before for 5 min. while his EEG was recorded. Next, he undertook a 10-min. version of the CFF test. Diathermy was then administered to *S* for 30 min., and his CFF was tested as before. The sequence of heating and testing was repeated until *S*'s tympanic temperature had risen by 2.0°C. This took 90–120 min. to complete. After reaching the criterion temperature, *S* was allowed to recover to his normal temperature. During recovery, *S*'s CFF and EEG were measured in alternate 10- and 5-min. periods. Recovery lasted 55–75 min.

Eight separate CFF determinations were made in each 10-min. test. These were averaged to provide a single CFF measurement for each *S* in each test.

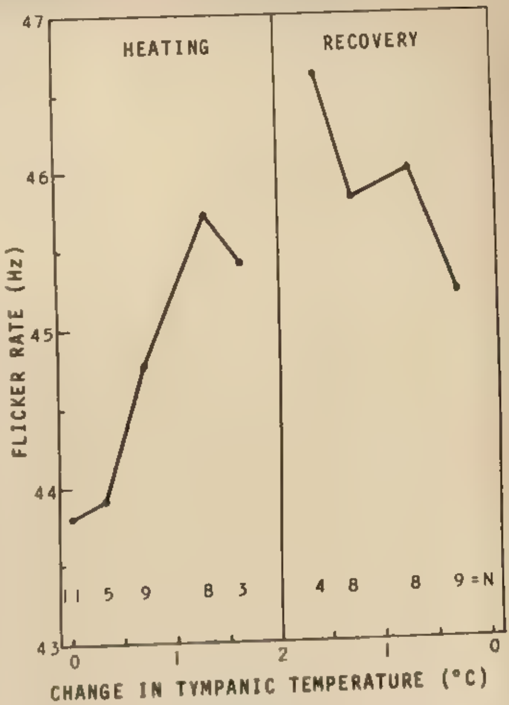

Figure 2. Mean critical flicker frequency as a function of the change in tympanic temperature during the hyperthermia condition.

Results

In both control conditions, C_1 and C_2, *Ss'* mean CFF varied in a nonsignificant manner between about 43.5 Hz. and 44.3 Hz. In H, mean CFF varied as a function of tympanic temperature as shown in Figure 2.

The data in Figure 2 were obtained by computing the mean CFF for each .5°-C. interval of changing tympanic temperature. However, all *Ss* were not tested within the same .5°-C. intervals due to differential body heating rates, so the mean values shown in Figure 2 were necessarily based upon a different number of observations. The *N* for each mean is included in Figure 2 below the respective data point. The product-moment correlation coefficient between mean CFF and mean tympanic temperature was $r = .78$, $p < .05$.

The EEG recordings from one *S* were practically devoid of alpha activity. These data were not used. The mean ($\pm SE$) alpha frequency for the remaining 10 *Ss* was 10.7 Hz. ($\pm .25$) in both C_1 and C_2.

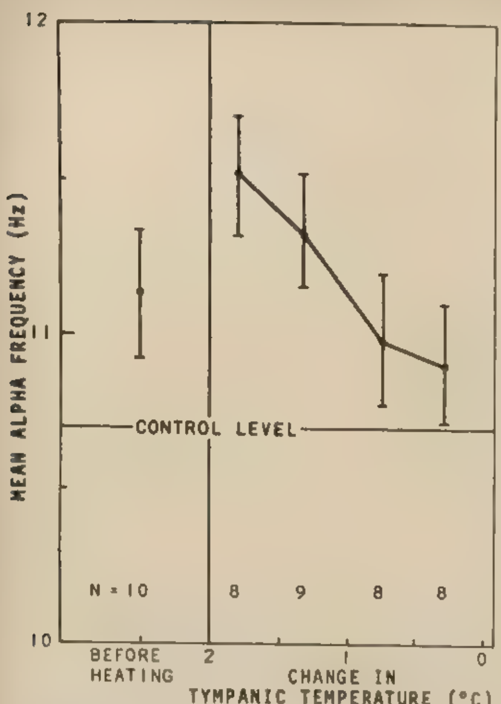

FIGURE 3. Mean alpha frequency ($\pm SE$) before hyperthermia and as a function of the change in tympanic temperature during recovery from hyperthermia.

During H, mean ($\pm SE$) alpha frequency varied with tympanic temperature as shown in Figure 3.

Even before heating, the mean alpha frequency was higher in H than the 10.7 Hz. of C_1 and C_2. There was a further increase upon heating the *Ss*, up to a maximum mean of 11.5 Hz., followed by a decline as their temperatures returned to normal. The difference between the mean alpha frequency in C_1 and the first measurement (preheating) in H approached significance, t (9) = 2.19, $p < .10$. The difference between mean alpha frequency in C_1 and the second measurement in H (i.e., during maximum hyperthermia) was significant, t (7) = 4.05, $p < .01$. However, the difference between the first and second measurement in H was not significant, t (7) = 1.27.

In spite of the increase in mean alpha frequency during heating, no significant correlation was found between alpha frequency and CFF in either C_1 or H. The correlation between the changes in CFF and in alpha frequency that occurred with changing tympanic temperature was similarly nonsignificant.

EXPERI[illegible]

Interpretation of th[illegible] from Experiment II was made di[illegible] the failure to control or measure [illegible]pillary diameters while their core tem[illegible]es changed. A systematic increase in [illegible] diameter with temperature *might* have [illegible]used the observed change in CFF [illegible] to the Ferry–Porter law (Brown, [illegible]). The relationship between core temperature and pupillary diameter was not revealed by an extensive review of the literature. Therefore Experiment III [illegible] supply the data requi[illegible]g whether any such rel[illegible]

Method

Subjects. The *Ss* were three 27–34-yr.-old healthy males.

Apparatus. The diather[illegible] used to induce hypertherm[illegible] complished with a Nikon F[illegible] Nikkor 55 mm. F3.5 len[illegible] was measured from photographic enlargements with dial calipers (Mitutoyo, No. 505-626). Rectal temperature was measured, using the Digitec thermometer.

Procedure. The *Ss* were heated to a temperature of 39.0°C. Heating was accomplished in 37–81 min., depending on the *S*. At 15-min. intervals during heating, a series of three photographs of *S*'s left eye were taken within a 30-sec. period. After reaching criterion temperature, *Ss* were allowed to recover, and a similar series of photographs was taken at approximately 15-min. intervals, until a drop of 1.0°C. during recovery. This degree of recovery was obtained in 16–40 min., depending on the *S*. During photography, *Ss* looked at a fixation point on a blank field at a distance of 38 cm. Luminance at *S*'s eye was a constant 164 cd/m². A circular paper spot of known diameter was attached to *S*'s lower eyelid as a calibration for pupil measurement from photographic enlargements.

Results and Discussion

Pupil diameter during heating and recovery is shown in Figure 4, where each data point represents the mean pupil diameter of the series of three photographs.

According to Hakerem (1967), spontaneous changes in pupillary diameter under dim illumination are of the order of 1–1.5 mm., and typically greater fluctuation oc-

curs with normal light conditions. It is apparent from Figure 4 that there were only the normal spontaneous fluctuations, but no systematic change in pupil diameter with hyperthermia.

According to the Ferry–Porter law, with constant luminance, an increase in pupillary diameter of approximately 58%, more than doubling the retinal illuminance, would be required in order to increase CFF to the degree recorded in Experiment II, i.e., 4 Hz. Because no such change in pupillary diameter was observed as a consequence of hyperthermia in Experiment III, it may be concluded that the increase in CFF was attributable to factors other than a change in pupillary diameter.

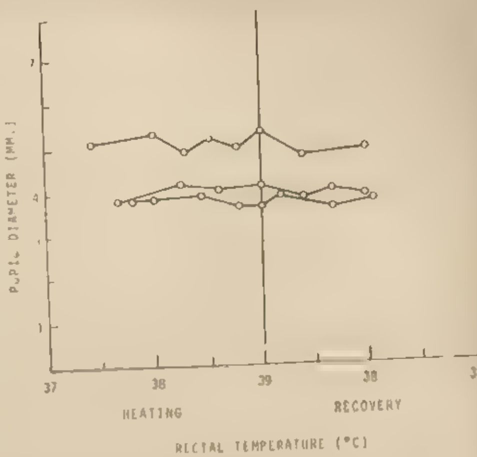

FIGURE 4. Pupil diameter during hyperthermia and recovery for three *Ss*.

General Discussion

The results from both Experiments I and II indicate that temporal acuity increased during hyperthermia. Perception of succession and CFF were both facilitated by increasing body temperature.

In Experiment I, under control conditions, *Ss*' 75% correct response level corresponded to an interflash interval of about 17.3 msec. This value will therefore be considered the average threshold of succession in the present study.

The average threshold of succession may be used to estimate the duration of the psychological moment. An interval separating events by half of the duration of the moment should lead to a rate of correct responding that is 50% greater than the rate expected by chance alone. If the first and second events fell within different halves of the same moment, they would be perceived as successive. Since the first event has an equal likelihood of falling any time within the moment, that particular pair of events would be perceived as simultaneous half of the time and as successive half of the time.

If *S* responds at the 75% correct level on a forced-choice basis, his threshold of succession is actually producing correct responses at a rate of 50% greater than the rate (50%) expected by chance alone. From this, it might be reasoned that the threshold of succession is half the duration of the moment. However, this reasoning ignores the fact that the flashes used to demark the interflash interval had themselves a finite duration—10 msec. in this experiment. Neurophysiological evidence indicates that elements in the retina and cortex respond vigorously to both the onset and offset of a light stimulus (see the review by Grossman, 1967, pp. 213–260). Presumably, the first neural events would arise from the onset of the first flash; the final neural events follow the offset of the second flash. Thus, the duration of the second flash, 10 msec., should be added to the threshold of succession, 17.3 msec., as an estimate of half of the duration of the moment. This results in a value of 54.6 msec. as our best estimate of the *S*'s average normal duration of the psychological moment in this experiment.

Our estimate of the psychological moment is in remarkable correspondence with Kristofferson's (1966, p. 7) average estimate of 54.3 msec. The correspondence is even more surprising in that Kristofferson's test of the perception of succession employed long-lasting (2 sec.) and mixed sensory (auditory and visual) pairs of test stimuli.

During hyperthermia, *Ss*' threshold of succession dropped to an average of 15.7 msec., a reduction of 1.6 msec. from control conditions. It was estimated, in the manner described above, that their average moment was shortened to 51.4 msec., a reduction of about 6% from control conditions.

In Experiment II, the CFF was shown to increase as a function of increasing body temperature. Lockhart (1971) reported similar changes in *Ss*' CFFs as they were tested in a hot (49.2° C.) environment, which raised their mean body temperature by .6°C. The failure to demonstrate any systematic effect of hyperthermia on pupillary diameter in Experiment III leads us to interpret these findings as further evidence that temporal acuity varies as a function of body temperature.

The EEG alpha frequency also increased with body temperature in Experiment II, which supports the findings of Hoagland (1936). The relative changes in alpha frequency and CFF may be similar enough (a maximum 7% increase in alpha; a corresponding 6% increase in CFF) to warrant further consideration of a relationship between these variables. However, neither we nor Lockhart (1971) found any significant relationship between changes in alpha frequency and CFF.

It is of interest to note that the mean alpha frequency recorded prior to heating in Condition H was greater than the control values. Though this result was only marginally significant ($p < .10$), it may indicate that anticipation of heating accelerated *S*s' alpha frequency.

In the present experiments, temporal acuity, as judged from tests of the perception of succession and CFF, increased with core temperature. Previous studies, cited above, have shown that temperature exerts a similar influence upon the perception of time passing. Both phenomena may be explained as resulting from a shortening of the psychological moment; and both may reflect the direct action of temperature on a neural pacemaker.

JUDGMENT OF RECENCY FOR PICTURES AND WORDS[1]

GARY L. LASSEN, TERRY C. DANIEL, AND NEIL R. BARTLETT[2]

University of Arizona

An experiment was conducted comparing judgment of recency (JOR) for line drawings and printed words representing common objects. In a mixed design, groups of 15 *Ss* were tested using either pictures or words at either of two presentation rates. Upon an item's second occurrence, which was marked to be easily distinguished as a test, *Ss* were required to make a judgment of recency, their best estimate of the actual lag for that item. It was found that as lag length increased, accuracy of recency judgment declined. More importantly, an interaction was found between stimulus type and rate of presentation. Words were found to be superior to pictures at a rate of 2-sec. exposure per stimulus, while this pattern was reversed at the 4-sec. exposure rate. The results are discussed in reference to a memory-strength interpretation of JOR and the dual-coding theory of Paivio.

How is the judged recency of a remembered event determined? Recent accounts have related judged recency of an event to the memory strength for that event. Memory strength is usually assumed to be maximal at the time of occurrence of the event and then to decline over time. The stronger the memory trace for an event, the more recently it will be judged to have occurred. The most explicit memory-strength interpretation was presented by Hinrichs (1970; Hinrichs & Buschke, 1968), who extended the basic strength and decision processes proposed in models of event memory to the judgment of recency (JOR). He proposed a two-process memory-strength theory of JOR that described the data for recency judgments of letters reasonably well.

A characteristic finding in both recall and recognition memory paradigms is that information presented pictorially is less susceptible to forgetting than is information presented verbally (Paivio, 1971; Shepard, 1967). This has been interpreted as indicating slower decline (decay) of memory strength for pictorial information than verbal information. Pictorial and verbal materials are known to produce different effects in a variety of other paradigms as well.

The dual-coding theory of Paivio (1971) distinguishes between sequential and parallel accessing of information in memory; the hypothetical verbal system being suited to sequential processing, while the image system is a parallel processing system that organizes input spatially. The theory generally predicts superiority of words to pictures in serial tasks, but negligible differences between pictures and words are expected if the pictures could have been easily labeled.

Pictures have been found to be superior to words in serial tasks using recency paradigms. Yntema and Trask (1963), for example, found discrimination of relative recency (DR) of two unrelated stimuli to be less accurate when the items were nouns than when they were pictures. Using the same paradigm, Fozard (1970) presented pictures and words in the same sequence at a rate of 1.5 sec. per item. He found the best recency discrimination when both items compared were pictures. Further, Fozard and Weinert (1972) found superior JOR performance for pictures when a self-paced procedure was used. Even though *Ss* may have had time to verbally code the picture stimuli in these experiments, the superiority of pictures to words in these tasks presents some difficulty for Paivio's (1971) conceptualizations.

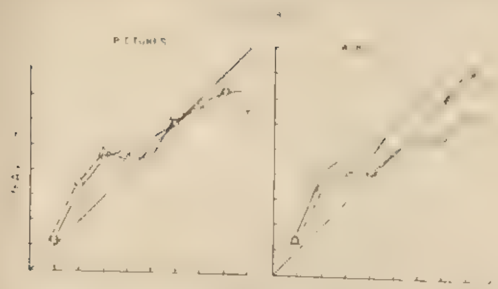

FIGURE 1. Mean judgment of recency (JOR) as a function of Rate of Presentation × Lag Length treatment combination for pictures and words separately.

The present experiment investigated judgment of recency for pictures and words. Picture or word stimuli were presented serially at either a fast (2.0 sec. per stimulus exposure) or a slow rate (4.0 sec. per stimulus exposure). On signaled test trials *Ss* judged the recency of occurrence of the indicated item. The rate factor is relevant to memory-strength interpretations of JOR (e.g., Hinrichs, 1970). The slower rate of presentation results in longer intervals between items and should result in generally longer judgments of recency than the faster rate of presentation. Further, if memory strength for pictorially presented items decays less rapidly over time than does memory for verbal items, the slower rate of presentation should have less effect on JOR for picture items than for words. Also, at either rate of presentation, picture stimuli may be judged to have occurred more recently than word stimuli at the same lag. With regard to Paivio's (1971) hypothesis, rate of presentation would not be expected to produce marked effects as the fastest, 2.0-sec. exposure, rate is sufficiently slow that all *Ss* should be able to code verbally the picture stimuli.

METHOD

Design and subjects. Two between-*Ss* variables, type of stimulus (picture or word) and stimulus exposure time (2 sec. or 4 sec.) were combined with two within-*Ss* variables, trials and lag length (number of items plus one intervening between two occurrences of the same stimulus) into a 2 × 2 × (5 × 9) factorial design. The sixty *Ss* (30 males and 30 females) were volunteers from introduct[illegible] psychology courses at the University of [illegible]zona. Groups of *Ss* were randomly assigned to [illegible]her a "picture" or a "word" stimulus conditio[illegible] [illegible]d to either a 2-sec. or 4-sec. stimulus exposure c[illegible]tion.

Stimuli. Line drawings of familiar objec[illegible] [illegible]sted for prompt common naming, and their corr[illegible]nding word names were photographed and mo[illegible] [illegible] on 35-mm. slides. Stimuli were projected onto [illegible] [illegible]ar-projection screen by a modified Kodak [illegible] [illegible]usel (Model 801) slide projector. Random lists [illegible] [illegible]ach class of stimuli were formed with the restricti[illegible] [illegible]hat no item was reused until at least 10 differen[illegible] [illegible]ms intervened (see Hinrichs, 1970). Five subli[illegible] [illegible]ere formed according to the stimulus ordering te[illegible] [illegible] of Nickerson and Brown (1963). This or[illegible] [illegible]ng technique insured exactly one test at each of [illegible]gs 1 through 9 within each sublist. These sublists [illegible]ere presented to *S* one after another, without pau[illegible] as one continuous list.

Procedure. Each *S* was instructed to mak[illegible] [illegible]n estimate of the lag between two occurrences of [illegible] same stimulus item at the time of its second o[illegible] rence. An item's second occurrence was cle[illegible] designated as a test. The correct recency judgm[illegible] they were instructed, consisted of the numbe[illegible] intervening items since the most recent non[illegible] presentation of that item including itself, or t[illegible] number of intervening items plus one. The *S*s [illegible] sponded verbally, giving "judgments of recency" upon each occurrence of a test. A short practi[illegible] session using similar stimuli was always given [illegible] make sure *S* understood the requirements of th[illegible] task.

RESULTS

Mean JORs at each lag are presented in Figure 1 for all four experimental conditions. In spite of the apparent lack of rate of presentation effect for picture stimuli, there was a general tendency for *Ss* to underestimate the true lag at the 2.0-sec. rate and to overestimate the lag at the 4.0-sec. rate. The main effect of rate was statistically reliable, $F(1, 56) = 4.97$, $p < .05$. Inspection of Figure 1 strongly suggests that rate of presentation had different effects for pictures and words, but the Rate × Stimulus Type interaction was only marginal, just failing to reach the .05 level of significance. Apparently the lack of rate differences for either pictures or words at the short lags (one to four) prevented the rather dramatic differences at the longer lags from emerging in the analysis of variance. This interpretation gains support from the significant Rate × Lag Length interaction, $F(8, 448) = 2.19$, $p < .05$,

indicating that the principal locus of rate effects was at the longer lags.

There was a small but consistent tendency for judgments to become larger as a function of trials (experience), F (4, 224) $= 6.27, p < .01$. Judgments became larger on later trials, but the differences involved were small and followed no significant trend. A significant Trials × Lag Length effect was found, F (32, 1972) $= 3.12, p < .01$. Again, no consistent trend was apparent in the data.

Accuracy of JORs was assessed in terms of absolute deviation of JOR from actual lag. These data can be seen in Figure 1 by comparing mean JOR with true lag indicated by the solid line diagonal. Mean absolute deviations for picture and word stimuli at each presentation rate are also presented in Table 1.

Analysis of variance revealed a significant Stimulus Type × Rate of Presentation effect for mean absolute deviations from actual lag, F (1, 56) $= 5.22, p < .05$. The most notable difference was between words at the slow and fast rates. Pictures differed considerably less as a function of rate. Subsequent post hoc testing (Tukey HSD—Kirk, 1968) disclosed that the fast-word condition was significantly more accurate than the fast-picture condition. The slow-picture condition was significantly more accurate than the slow-word condition. The fast-word and the slow-picture conditions were not significantly different.

TABLE 1

MEANS (AND STANDARD DEVIATIONS) OF ABSOLUTE DEVIATIONS FROM ACTUAL LAG

Stimulus type	Rate of presentation	
	2 sec.	4 sec.
Pictures	1.812 (1.349)	1.479 (1.555)
Words	1.516 (1.316)	1.976 (1.748)

DISCUSSION

The observed superiority of words over pictures in accuracy of JOR at the faster rate of presentation appears to be consistent with Paivio's dual-coding theory. Words arouse the verbal code that is crucial to performance on sequential tasks more readily than do pictures. This difference is usually restricted to cases where the rate of presentation is quite fast, reducing the possibility that pictures would be verbally coded. Contrary to this analysis, pictures were found to be superior to words in JOR accuracy at the slow rate of presentation. This finding is difficult to explain if verbal coding is assumed to mediate performance on sequential memory tasks. While the slow rate of presentation surely provided ample time for *S*s to verbally label the pictures, it seems unlikely that the verbal code for the pictures was more effective in the JOR task than the verbal code for the words themselves. The availability of a verbal code does not appear sufficient to explain all of the observed differences in JOR accuracy for pictures and words. Perhaps the verbal coding system is preferred when rate demands are high, but "imaginal" coding is more effective at slower rates of presentation in spite of the large serial processing component of the JOR task.

The picture–word differences also present difficulty for Hinrichs' (1970) memory-strength interpretation of JOR. The slower presentation rate did not lead to longer JORs for pictures as was predicted by the memory-strength interpretation. The slower rate actually led to more accurate JORs than the faster rate. It may be that contrary to Hinrichs' memory-strength hypothesis, high memory strength for an event need not produce a judgment that the event occurred recently. Instead, high memory strength may produce a more accurate judgment of when the item occurred. The *S*s presented with pictures in the JOR task apparently made beneficial use of the extra 2-sec. stimulus exposure provided by the slow rate of presentation to overcome the effects of longer delays. The *S*s presented with words apparently did not benefit sufficiently from the extra processing time to overcome the detrimental effects of longer delays.

An extension of Morton's (1969) "logogen" model of memory offered by Seymour (1973) may prove useful in explaining picture–word differences as a function of rate. The model proposes that visual inputs for words and pictures are distinguished early in processing and undergo different coding processes. If the ultimate response is vocal, the route for

words is more direct than that for pictures Word input, after having been graphically analyzed, proceeds directly to an exit node where it is available for vocal output. To reach this same node, picture input must first be pictorially analyzed, proceed to a pictorial exit node, and then be interpreted in semantic memory before reaching the vocal exit node. Because there are additional stages in the encoding of pictures, words would have an advantage over pictures in vocalization tasks particularly when fast rates are demanded. These same additional stages may contribute to superior performance with pictures in other memory tasks.

PROACTIVE INTERFERENCE AND DIRECTED FORGETTING IN SHORT-TERM MOTOR MEMORY[1]

LESLIE BURWITZ[2]

Department of Physical Education and Recreation, Acadia University, Wolfville, Nova Scotia, Canada

Motor proactive interference (PI), produced by requiring *S*s to recall five linear lever displacements in reverse order after a 90-sec. retention interval, was completely eliminated by an instruction to forget the first four positions given prior to the presentation of the criterion (fifth) response and significantly reduced by a similar instruction given immediately before recall. The ability of *S*s to intentionally forget prior motor responses was assumed to explain the inconsistent findings of short-term motor memory research, although it appeared that to-be-forgotten prior items were not completely "discarded," since they were recalled equally as well as to-be-remembered prior items. The discussion centered on the cognitive control of motor behavior and, in particular, on the mechanisms of set differentiation, selective rehearsal, and selective search.

The importance of eliminating irrelevant information was known to the ancients (Cicero, 1959, p. 427). More recently Bjork (1972, p. 218) has suggested that intentional forgetting is fundamental to the efficient functioning of man, since without it he would "degenerate to a proactive-interference-induced state of total confusion." Intentional or directed forgetting has received considerable experimental attention recently in the area of verbal short-term memory (for reviews see Bjork, 1972; Epstein, 1972) but it has not been considered within the realm of motor behavior. This experimentation has led to an increased understanding of verbal memory and one might expect that motor memory research would also benefit from a systematic study of the effect of instructions to forget. The present study was the first such investigation and, since it was specifically designed to test the effect of instructions to forget prior motor learning, the results were relevant to the understanding of short-term motor memory (STMM) proactive interference (PI).

The initial research concerned with the effect of prior motor learning on the retention of a motor response was conducted by Adams and Dijkstra (1966). A Peterson–Perterson (Peterson & Peterson, 1959) paradigm was employed whereby *S* was required to learn and recall seven different linear displacements in turn and, in contrast to the results of verbal short-term memory (STM) research (Keppel & Underwood, 1962) there was no evidence of PI over trials. The null PI finding stimulated further research and, although Montague and Hillix (1968) and Schmidt and Ascoli (1970) reached essentially the same conclusion, Ascoli and Schmidt (1969), Stelmach (1969), and Williams (1971) reported conflicting evidence, in that criterion (final) response recall was indirectly related to the number of prior motor learning movements. The initial motivation for the present research was a desire to resolve this inconsistency, which appeared to be a function of procedural differences. That is, the studies that found no evidence of PI used a Peterson–Peterson learn–recall paradigm (single-trial design), whereas those that were successful in their efforts to produce PI required *S* to learn and

[1] This paper was submitted as a PhD dissertation to the Physical Education Department at the University of Illinois. recall in reverse order a number of different movements within one trial.

The reverse order or multiple-trial design was introduced by Ascoli and Schmidt (1969) to permit the inclusion of a number of motor items into STM very rapidly. Ascoli and Schmidt reasoned, on the basis of a verbal STM study conducted by Bjork, LaBerge, and Legrand (1968), that, because verbal PI is reduced by an instruction to forget previous items, prior motor learning may not interfere with a criterion response if *S* is allowed to "discard" previous traces from STM. They suggested that motor PI is not produced in a single-trial design because *S* is allowed to intentionally forget prior motor learning. To some, this argument may seem irrational. After all, there is ample evidence that directed forgetting affects verbal learning and yet PI is produced in single-trial design experiments in verbal learning (Keppel & Underwood, 1962). The difference between the findings of motor and verbal single-trial design experiments indicates, however, that there is an inherent danger in considering that one set of principles governs behavior in both domains. The single-trial verbal STM studies generally test the retention of trigrams (three items) on a dichotomous (right or wrong) scale, while the single-trial motor STM experiments use only single items and measure retention on a continuous (graded in millimeters or $\frac{1}{8}$-in. units) scale. Thus, the verbal and motor single-trial experiments are not identical and an explanation that does not account for the data in one domain may very possibly explain behavior in the other area.

The ability of *S* to intentionally forget prior motor learning is unknown but, if it is possible, one would appear to be justified in concluding that the inconsistent STMM PI findings are a function of procedural differences which permit or restrict intentional forgetting of prior learning. That is, if *S* can make use of a forget instruction to eliminate motor PI, one would not expect to find PI in a single-trial design, where *S* is allowed to learn, recall, and completely forget each response prior to the pres ta- tion of the next distance, whereas one w ld expect to find PI in a multiple-trial de n, because *S* is required to remember all is- placements in reverse order and is give no opportunity to forget prior learning.

The underlying assumption of the pre nt research was that motor PI, which oc rs in a multiple-trial design, is a manif a- tion of cognitive processes, which o ur consequent with or subsequent to encod . To test this hypothesis the mechanis s, which have been proposed to expl in directed forgetting in verbal STM, w considered to determine which, if any, w relevant to the study of motor mem The six mechanisms, which were subje to analysis, have been referred to erasure, set differentiation, selective hearsal (Bjork et al., 1968), recall lo d (Reed, 1970) or anticipatory recycli g (Epstein, 1969), initial registration (Ree , 1970), and selective search (Epstein, 197 Support for any of the hypotheses w assumed to lend credence to the view th motor behavior is controlled by cogniti processes.

Method

Experimental Design

Thirty *S*s were randomly assigned to each of th 10 independent treatments of a 2 × 5 factorial de sign. The two levels of the first factor involved retention intervals of 5 and 90 sec. The five levels of the second factor were referred to as PI, forget late (FL), forget early (FE_1 and FE_5), and control (CO). The PI treatment involved four prior learning (PL) responses, a criterion response, and an instruction to remember all five responses in reverse order at recall. The FL group received four PL, a criterion response, and an instruction to forget the first four responses presented immediately prior to recall. The two FE treatment groups were given four PL, a criterion response, and an instruction to forget the first four responses given prior to the presentation of the criterion. The FE_1 treatment group was reminded immediately prior to recall to reproduce only the criterion response, whereas in the FE_5 condition *S*s were instructed to recall all five responses in reverse order at that time. Learning and subsequent recall of only one response acted as CO. Absolute and algebraic error scores were computed for the criterion response and for the prior learning (first four) responses recalled in the PI and FE_5 conditions.

Apparatus

The task employed involved linear lever-positioning. The *Ss* were able to hear movements of the almost frictionless lever but they were restricted from viewing the apparatus by means of opaque goggles. The apparatus consisted of two 72-cm. long Thomson case-hardened steel rods, which were mounted at their ends into aluminum blocks so that the rods were horizontal, parallel, and 5-cm. apart. The aluminum blocks were secured onto a 78 × 22 × 1 cm. aluminum base plate, which was in turn screwed to a wooden table of normal height. A slide consisting of four Thomson ball-bushing sleeves (each 3-cm long), an aluminum plate, and a steel handle (8-cm. high) moved freely along the trackway with a range of 0-47 cm. Eight holes, located in the baseboard, accepted a steel pin, which effectively arrested carriage movements at 5, 10, 15, 20, 25, 30, 35, and 40 cm. The criterion distance was 20 cm. and a scale marked in millimeters was used by *E* to measure error indicated by a fine pointer.

Experimental Procedure

On entering the experimental room, *S* was seated in front of the apparatus so that his right shoulder was opposite and a full arm's length from the right-hand edge of the carriage. A demonstration (47 cm.) and a standard set of instructions were given. The instructions informed *S* that he would either have to make one or five movements down to a stop and then, after a rest, he would have to reproduce some or all of the movements without the assistance of the stop. The *Ss* were told that they would not be given instructions as to which movements they would have to remember until later in the experiment and they were informed that the best procedure was to try to remember every position until they heard otherwise.

On the command "grasp" *S* took hold of the handle and waited for the instruction "move." On this signal *S* moved the handle at a moderate, deliberate pace from right to left until he hit the stop. He maintained his grasp on the handle for a period of 3 sec. at which time he was instructed to "relax," which meant he was to place his hand on a pad located on the table in front of him. The sequence of events described above defined a learning trial and for *Ss* in the CO treatment the retention interval followed. After the retention interval *S* was given recall instructions. The commands "regrasp" and "estimate" acted as signals for *S* to move the lever to where he thought it had been during learning.

If *S* received PI, he made four movements before the sequence described above. The prior positions were 5 or 10 cm. longer or shorter than the criterion distance of 20 cm. The number of possible permutations of previous positions was 24. The order of previous positions was randomized but each of the 24 permutations occurred approximately as often. The intertrial interval was 10 sec. The stop, defining the distance of each movement, was positioned by *E*, and he was also responsible for all return movements of the handle to the start position.

The forget instruction, given in the FE_1, FE_5, and FL treatments, informed *S* that he was to completely erase the first four responses and concentrate only on the last (criterion) response. The FL instruction was given in a 5-sec. period immediately prior to recall, and FE instructions were presented in the last 5 sec. of the 10-sec. intertrial interval between the fourth and the criterion response. The recall instructions were presented in a 5-sec. period immediately prior to recall. The PI and FE_5 *Ss* were told to recall all five responses in reverse order (10-sec. intertrial interval), FL and FE_1 *Ss* were instructed to recall only the criterion response, and CO *Ss*, to reproduce their one position. Following the final recall trial, a postexperimental interview was conducted to determine what strategy *S* used, what he thought he did with recall and forget items, and what effect the forget instruction had had.

Subjects

The *Ss* were 300 (153 male, 147 female) right-handed volunteers (average age, 19 yr., 9 mo.) from the general student body at Acadia University, Nova Scotia. There were approximately an equal number of males and females in each treatment, the largest discrepancy being an overload of 16 to 14 in either direction.

RESULTS

Absolute Error

Criterion response. The analysis of absolute error indicated that *Ss* were on average 2.93 cm. off target. There was no difference between the performance of males (3.00) and females (2.88). The Retention Interval × Treatments (2 × 5) analysis revealed that the retention interval and treatment main effects were significant, $F(1, 290) = 37.05$, $p < .001$, and $F(4, 290) = 8.97$, $p < .001$, respectively. The *Ss* recalled more accurately at 5 sec. (2.21) than after a 90-sec. retention interval (3.57), and a Newman Keuls test indicated that both the FL (3.32) and PI (3.99) treatments recalled significantly (FL at .05 level; PI at .01 level) less than CO (2.23), FE_1 (2.37), and FE_5 (2.55) conditions. None of the other differences was significant.

The Retention Interval × Treatment interaction was also significant, $F(4, 290) = 3.34$, $p = .01$. Figure 1 graphically illus-

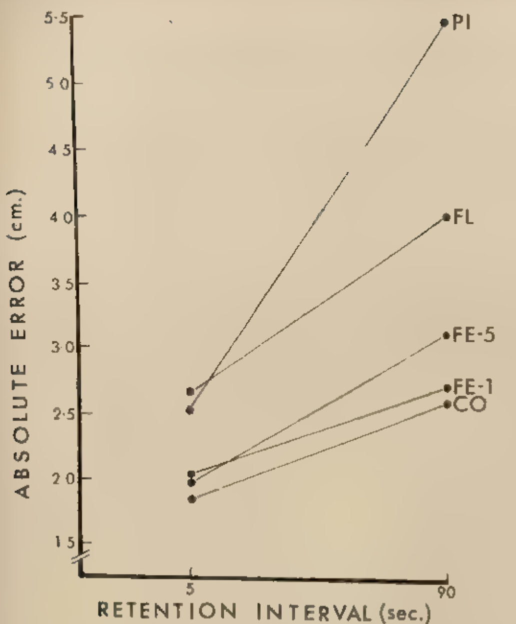

FIGURE 1. Criterion response: Retention Interval × Treatment interaction. (Abbreviations: PI = proactive interference, FL = forget late, FE_1 = forget early, remember one, FE_5 = forget early, remember five, and CO = control.)

trates the interaction and a post hoc Newman–Keuls test indicated that significant recall decrements occurred 5–90 sec. under PI ($p < .01$) and FL ($p < .05$) but not under FE_5, FE_1, and CO. There were no differences between the five treatments at 5 sec., but at 90 sec. PI recall (5.44) was significantly ($p < .01$) worse than FL (4.00), FE_5 (3.12), FE_1 (2.69), and CO (2.60) recall. In addition, FL recall was significantly ($p < .05$) worse than that of the FE_1 and CO treatments.

Prior learning responses. Four treatments (PI at 5 and 90 sec. and FE_5 at 5 and 90 sec.) contributed data to the Treatment × Retention Interval × Trials (PI, FE_5 × 5, 90 sec. × 1–4) repeated measures analysis. The treatment and retention interval main effects were not significant, F (1, 116) = 2.79, $p > .05$, and F (1, 116) <1, respectively. There was no difference between PL recall of *Ss* who were trying to remember the first four responses (PI = 5.10) and those who had been instructed to forget prior positions (FE_5 = 6.28).

The main effect for trials was significant, conservative F[3] (1, 116) = 4.76, p .05. A post hoc Newman–Keuls test indicated that Trial 1 (4.34) was significantly different from Trial 2 (5.80, .05 level), Trial 3 (6.48, .01 level), and Trial 4 (6.1[illegible] .05 level).

The Treatment × Retention Interval × Trials analysis indicated that none of the interactions was important, with the exception of Retention Interval × Trials, which was marginally significant, conservative F (1, 116) = 3.02, $p < .10$. A post hoc Newman–Keuls test revealed that none of the eight cells differed significantly from each other (all ps > .05).

Algebraic Error

Criterion response. The analysis of algebraic error data indicated that *Ss* tended to undershoot the criterion very slightly (−.11 cm.). There was no difference between the performance of males (.03) and females (−.25). The Retention Interval × Treatment (2 × 5) analysis revealed no significant effects (all Fs < 1).

Prior learning responses. The Treatment × Retention Interval × Trials (2 × 2 × 4) repeated measures analysis revealed a slight tendency to overshoot (1.9 cm.) on Trials 1–4. The treatment, retention interval, and trials main effects were not significant, F (1, 116) < 1, F (1, 116) = 1.62, $p > .10$, and conservative F (1, 116) = 1.57, $p > .10$, respectively, and neither were any of the interactions.

Discussion

The directed forgetting paradigm employed in the present study contributed in a general and positive way to the understanding of motor memory. The results support the hypothesis that the inconsistency in STMM PI research is a function of procedural differences, which either permit or restrict intentional forgetting of prior learning. Proactive interference was produced by using a multiple-trial design, where *S* was not allowed to forget the first four responses since he was required to

[3] The conservative F test was used for within-*Ss* data to guard against probable positive bias of standard F ratios.

reproduce them after the criterion response at recall. The effect of PL was completely eliminated by an early instruction to forget the first four positions (FE) as well as being substantially reduced by a similar instruction not presented until immediately prior to recall (FL). Thus, Ascoli and Schmidt (1969), Stelmach (1969), and Williams (1971) were able to produce PI by adopting a multiple-trial design, which restricts intentional forgetting of prior learning, while Adams and Dijkstra (1966), Montague and Hillix (1968), and Schmidt and Ascoli (1970) found no evidence of PI because they used a single-trial design that contained an implicit cue to forget previous learning prior to the presentation of each criterion response.

The PI reduction following forget instructions indicates that motor PI is not a consequence of prior motor activity per se. Motor PI was not affected by the mere act of responding to or encoding prior movements but by operations, which can be assumed to be cognitively based, since they occurred contiguous with and/or subsequent to encoding. Verbal researchers have referred to these operations as erasure, set differentiation, selective rehearsal (Bjork et al., 1968), recall load (Reed, 1970) or anticipatory recycling (Epstein, 1969), initial registration (Reed, 1970), and selective search (Epstein, 1972). The present study was designed to determine which, if any, of the above mechanisms was relevant to the study of motor behavior and, although further research is necessary to substantiate the findings, the interaction data indicated that the mechanisms of selective rehearsal, set differentiation, and selective search were the most influential.

Analysis of the interaction revealed that the FE_1, FE_5, and FL treatments reduced PI, that there were no differences between any of the five treatments at 5 sec., and that there was a significant difference between FE_1 and FL conditions. The largest reduction in PI occurred under FE_1. Each of the various hypotheses is able to account for the reduction. The forget early cue may have allowed *S* to (*a*) completely "discard" prior learning (erasure), (*b*) tag or organize recall items in such a way as to separate them from forget items (set differentiation), (*c*) concentrate rehearsal time on the criterion response (selective rehearsal), (*d*) recall the criterion without having to recycle prior learning for subsequent recall (anticipatory recycling), (*e*) properly encode the criterion at the time of its presentation (initial registration), and/or (*f*) reduce the size of the search set from which the criterion was to be recalled (selective search).

The second largest reduction in PI occurred under FE_5. The finding discriminates between the six hypotheses offered to explain directed forgetting. The erasure, set differentiation, selective rehearsal, and initial registration notions are able to account for the difference but the result contradicts the predictions of the anticipatory recycling and selective search hypotheses. The anticipatory recycling hypothesis postulates that having to recycle other material for subsequent recall is detrimental to criterion response recall. Thus, it predicts no difference between FE_5 and PI, because both conditions required *S* to recycle four prior learning responses during criterion response recall. One might argue that the first four responses were stronger under PI because FE_5 *Ss* were instructed to forget prior learning and, although this argument seems plausible, it is undermined by the fact that the first four positions were recalled with equal facility under the two conditions. Apparently, the to-be-forgotten items did not interfere at recall in the manner outlined by the anticipatory recycling hypothesis despite being strong enough to do so. Additional evidence against the recycling notion was provided by the nonsignificant difference between FE_1 and FE_5. Evidently the size of the recall load did not affect directed forgetting.

The nonsignificant difference between the first four responses under FE_5 and PI provides strong evidence against the erasure hypothesis and support for the set differentiation and selective search notions. The to-be-forgotten positions were not completely "discarded" but rather they appeared to be stored separately (set differentiation) and recalled equally as well as the to-be-remembered items, when *S* was aware within which set to search (selective search).

The set differentiation and selective search mechanisms are considered by Epstein (1972) as necessary conditions for directed forgetting in verbal learning. The present data indicate that there is no reason to doubt that partitioning the input is fundamental to directed forgetting in motor learning but the selective search mechanism does not appear to be as vital within the realm of motor behavior. In verbal learning, Epstein, Massaro, and Wilder (1972) and Shebiske and Epstein (1972) report that forget instructions are only effective when there is a difference in search-set

size. In the present study, search-set size was equated using a procedure much the same as that employed by Shebilske and Epstein, and the difference between the FE_5 and PI treatments indicates that forget instructions reduce motor PI in the absence of search-set differences. The finding contradicts the search-set hypothesis and suggests that the selective search mechanism may be a necessary condition for directed forgetting in verbal learning but not motor learning.

Of the four hypotheses capable of explaining the reduction of PI under FE_5, the erasure notion appears to be the weakest, since forget items were not completely "discarded." The initial registration, selective rehearsal, and set differentiation explanations are considered below. The initial registration hypothesis postulates that prior motor learning impairs criterion response acquisition and that this, rather than interference, causes the PI effect. The hypothesis is able to account for the reduction of PI under the two forget early conditions but it cannot explain the fact that none of the treatments differed significantly from each other at 5-sec. recall. If one assumes that immediate recall (5-sec.) reflects original learning, the equality of the conditions at this point in time indicates that prior learning does not influence criterion response acquisition. In addition, the enhanced encoding position is unable to explain the reduction of PI following the FL cue. The difference between PI and FL treatments contradicts the idea that PI reduction is a consequence of an event that precedes the presentation of the criterion response.

The difference between the PI and FL treatments also proves to be difficult for the selective rehearsal notion to explain. The hypothesis postulates that PI is a consequence of divided rehearsal time. Having to share rehearsal attention over the retention interval is assumed to reduce the probability of the correct response being accurately reproduced. The FL and PI treatments had essentially the same rehearsal opportunities and consequently one would expect there to be no difference between them. A proponent of the rehearsal position might argue that the difference between PI and FL treatments could be attributed to the extra few seconds of rehearsal time FL *S*s had between the FL cue and recall. This possibility, although it cannot be dismissed, seems unlikely as a few seconds would hardly appear to be long enough to produce such a difference.

The significant reduction of PI under FL can be explained by the erasure, anticipatory recycling, selective search, and set differentiation hypotheses. The first three explanations have been discussed above and weaknesses have been pointed out in each. The set differentiation hypothesis is also unable to explain all the data. The significant difference between FE_1 and FL conditions contradicts Bjork's (1970) suggestion that the ability to tag or organize recall and forget items is unaffected by the placement of the forget cue. The finding does not necessarily contradict the idea that partitioning of the input must be assumed in any account of directed forgetting (Epstein, 1972), but it does indicate that FE_1 *S*s either originally learn the criterion response better than FL *S*s (initial registration) or that they are better able to retain the criterion response because they are allowed to concentrate their rehearsal time on that response rather than having to divide it between five different positions (selective rehearsal). The difference in initial registration was not apparent at 5 sec. and, although any difference in original learning may interact with the length of the retention interval, it would appear that the selective rehearsal hypothesis is better able to explain the difference between FE_1 and FL. Further research is obviously necessary to substantiate this point.

It is clear from the above discussion that, when *S* is instructed to forget a number of prior motor responses, he responds by invoking more than one of the mechanisms described above. The set differentiation, selective search and selective rehearsal operations were considered the most important, as, in combination, they were able to explain all of the data without the assistance of the erasure, anticipatory recycling, and initial registration hypotheses. In addition, the latter three hypotheses received no direct support as forget items were not completely forgotten, an increased recall load did not prove to be detrimental to recall, and there were no differences between the five treatments at 5 sec.

In conclusion, the present study indicates that the inconsistent findings in STMM PI research are a function of procedural differences which either permit or restrict intentional forgetting of prior learning. That is, motor PI is produced not merely by the occurrence of prior learning but by requiring *S* to remember five movements and reproduce them all in reverse order after a 90-sec. retention

nterval. It appears that, when S is able to orget prior learning, he voluntarily sets aside prior, potentially interfering responses, selectively rehearses the criterion response, and finally, selectively searches either the recall or forget set to find the appropriate response, which is subsequently accurately reproduced regardless of which store it is located in. Thus, the mechanisms that operate in motor memory are assumed to be cognitively oriented and, although this may seem dubious to those who view the mental and motor domains as completely separate, there are others (Adams, 1971) who appreciate that higher order processes are involved in even the simplest motor behaviors.

REGRESSION EFFECT AND INDIVIDUAL POWER FUNCTIONS OVER SESSIONS[1]

ROBERT G. WANSCHURA AND WILLIAM E. DAWSON[2]

University of Notre Dame

Stevens attributed individual differences in power function exponents mainly to differences in "the regression effect" and suggested that balancing for regression may largely do away with individual differences. Cross-modality matches of loudness to apparent time duration, and vice versa, were repeated over six sessions for each of 20 *S*s with 24 hr. between sessions. Individual differences, indicated by analysis of variance, Kendall's *W*, and significant positive correlations across sessions, occurred before and after regression balances. Group exponents for duration matches increased over sessions, but those for loudness matches and those obtained by regression balance did not change significantly.

The development of direct scaling techniques, e.g., magnitude estimation and cross-modality matching, has shown that sensory magnitude grows as a power function of stimulus intensity when data are averaged for a group of *S*s (Stevens, 1961, 1971). In addition, there is evidence that the power law may provide an adequate description of the data of individual *S*s (Marks & Stevens, 1966; Stevens & Guirao, 1964), although some investigators (Luce & Mo, 1965; Pradhan & Hoffman, 1963) find the description a poor one. Even when individual data yield power functions, exponents vary widely across *S*s. These individual differences appear to be reliable effects, since when a group of *S*s repeats a task like magnitude estimation, *S*s' later exponents are correlated with their earlier ones (Rule, 1966).

Luce (1972), noting the wide variation in exponents, has doubted the possibility of finding invariant relations among measures in psychophysics as well as the development of a "coherent system of units as has been done in physics [p. 100]." He concludes that individual differences do not allow the specification of a unit of sensory magnitude apart from the individual.

Various explanations for idiosyncratic exponents have been offered. Rule (1966) and Rule and Markley (1971) interpreted them as reflecting consistent individual response strategies. They feel, as do others (Jones & Marcus, 1961), that *S*s tend to use a characteristic range of the variable under their control with some *S*s using a narrow range and others more extended ones. Ekman, Hosman, Lindman, Ljungberg, and Akesson (1968) pointed to differences in perceptual sensitivity as well as to response biases when not all of their variance due to *S*s was accounted for by the latter.

Teghtsoonian and Teghtsoonian (1971) have suggested that session-to-session correlations are transitory and are mainly due "to chance factors when the constraints introduced by repeated judging are minimized [p. 149]." They find that such correlations are not significant for intersession intervals greater than 24 hr. and argue that a sensory or judgmental trait of individual *S*s would not disappear in this manner.

Stevens (1971) suggested that individual differences are due largely to the regression effect (Stevens & Greenbaum, 1966). This effect is a tendency for the person to use a shortened range of the variable under his control, whether it be the number continuum as in magnitude estimation, or a physical continuum as in cross-modality matching. The shortening takes place about the average value of the variable

---

[1] Based on a master's thesis completed by the first author at the University of Notre Dame. Also, presented as a paper at the meeting of the Midwestern Psychological Association, Chicago, May 1973.

under control. Such a tendency to "regress" toward the mean value of a series of controlled stimuli was first noted by Hollingworth (1910).

Because of this effect, when one continuum is matched to another, two different power functions are obtained depending on which is the adjusted variable. Each of these functions is a straight line in a log–log plot but one has a steeper slope than the other. To present both functions on the same plot, the ordinate and the abscissa are interchanged for that curve obtained by adjusting the variable represented on the abscissa. This necessitates drawing a line with a slope equal to the reciprocal of the exponent of the regularly fitted power function. Indow and Stevens (1966) have argued that the most representative function that describes the relation between the two continua is a power function with an exponent that is the geometric mean of the exponents for the two power functions in such a plot. Such an exponent is considered balanced for the regression effect and is obtained directly as the geometric mean of the exponent for the ordinate continuum and the reciprocal of the exponent for the abscissa continuum.

No one to date has thoroughly investigated whether balancing for regression will do away with reliable differences in exponents. The present research attempts to answer this question, and furthermore it examines whether or not these effects are stable with repetition of the scaling task over several sessions. Stevens (1971) reported that on some occasions exponents may change with repetition. Teghtsoonian and Teghtsoonian (1971) found that exponents for apparent length and apparent area were steady over five sessions and Mitchell and Gregson (1971) reported individual differences in olfactory exponents that were stable over four sessions. Otherwise, not much has been reported about repetition effects for more than two sessions.

Two questions were of primary focus: (*a*) Do consistent individual differences occur across sessions? If so, do these differences disappear when the exponents are balanced for regression in judgments? (*b*) Are group exponents stable over repeated sessions or do they change with repetition? If they change, is this change symmetrical for both tasks, i.e., does it disappear when the regression effect is balanced out using the geometric mean?

Apparent time duration and loudness were chosen as modalities primarily for the reproducible regression effects that have been obtained with them previously. Cross-modality matches were undertaken in which loudness was adjusted to match given time intervals and, in turn, apparent time duration was adjusted to match given levels of loudness.

Method

Subjects. The *S*s were 20 naive volunteers, 16 of whom were undergraduate or graduate students attending summer school at the University of Notre Dame. Three *S*s were wives of graduate students and 1 was an undergraduate not attending summer school. Ten men and 10 women participated.

Apparatus. For matches of loudness to given time intervals, an audio oscillator produced a 1,000-Hz. tone whose output level was controlled by a variable attenuator and a sone potentiometer (Poulton & Stevens, 1955) in series with a pair of earphones. Each *S* listened to the tone while adjusting the potentiometer for the appropriate loudness. The phones were calibrated so that the voltage measured across them could be converted to sound pressure readings in dynes/cm². Eleven intervals were used: .30, .42, .60, .84, 1.20, 1.70, 2.40, 3.40, 4.80, 6.80, and 9.60 sec. Time durations were controlled by a Hunter timer, which lighted a small white lamp for the appropriate interval.

When apparent duration was the adjusted variable, *S* turned on the lamp for the desired duration by pressing a key, and the duration was recorded by a Standard timer. The levels of loudness matched were produced by 11 discrete sound pressure levels (re .0002 dynes/cm²), which varied 40–90 db. in 5-db. steps.

Procedure. Each *S* participated in six sessions scheduled at the same time each day over 6 consecutive days. In a session, *S* matched both duration to loudness and loudness to duration with half of the *S*s first making all the time matches and then all of the loudness ones. The remaining half began by adjusting loudness and then continued with duration. The order in which each modality served as the matched variable was randomly assigned to both *S*s and sessions under the constraints that, for any *S*, half of the sessions began with duration and, for any session, half of the *S*s began with duration. Within any session, the stimuli were presented in random order with *S* making only one match to each

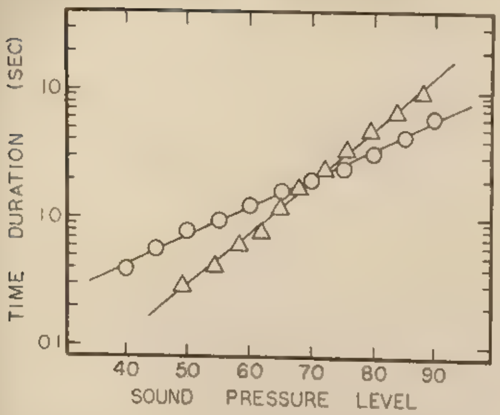

FIGURE 1. Cross-modality matches of apparent duration to loudness (circles), and vice versa (triangles), for the data pooled over sessions and *S*s.

stimulus level. For each part of each session an appropriate set of instructions was read by *S* before he began.

RESULTS

Geometric means of the matches made to each stimulus were computed for the data pooled over (*a*) *S*s and sessions, (*b*) *S*s for each session, and (*c*) sessions for each *S*. Power functions were then fitted to each of these sets of geometric means for both duration and loudness adjustments. Time and sound pressure, respectively, were the independent variables in the equations fitted. In addition, power functions were fitted to each *S*'s matches for each session.

Group data. Figure 1 shows that the group data combined over sessions is described well by power functions for both cross-modality matches. The duration exponent (DE), for the matches where time was adjusted, is indicated by a slope of .45. The loudness exponent (LE) was 1.24, and hence the figure gives t e reciprocal of this value, .81, for the slo where loudness is the adjusted variable. sence of a regression effect is indicate v the difference in slope for the two tches. The regression angle (RA) between e two fitted lines amounts to .259 radian Taking the geometric mean of .45 and . gives .60 as the balanced exponent (BE

Previous studies place the expo t for apparent duration at 1.10 (Stevens 1961) or, more recently, at 1.03 (Stevens & reenbaum, 1966). For loudness, exp ients from .60 (Stevens, 1961) to .68 (St vens, 1969) have been reported. Thus, th predicted slope of the equisensation fu tion lies in the interval from .60/1.10, or . 5, to .68/1.03, or .66. If values of .64 for oudness and 1.03 for duration are taken the predicted slope for the cross-mo lity match is .62, a value only slightly l rger than the .60 obtained as the BE.

Analyses of the data for each session are summarized in Table 1. The DEs show an orderly increase over sessions, but the LEs are more stable. Again, most of the BEs lie in the interval .55–.66. Figure 2 gives plots of the geometric means of the matches for each session, and these results are well described by power functions as indicated by the straight lines fitted to the datum points.

Individual data. Random samples of the results of individual *S*s are plotted in Figures 3 and 4. The results, combined over sessions, for six *S*s chosen at random are given in Figure 3; those for six *S*s in single sessions are given in Figure 4. The individuals vary considerably in their manner of responding in the cross-modality matches. Data combined over sessions

TABLE 1

SESSION MEANS FOR THE FOUR MEASURES

Measure	Session						
	1	2	3	4	5	6	*M*
Duration exponents	.38	.44	.43	.45	.49	.51	.45
Loudness exponents	1.21	1.33	1.20	1.22	1.24	1.22	1.24
Balanced exponents	.59	.60	.61	.62	.66	.67	.62
Regression angles (in radians)	.36	.27	.32	.28	.26	.25	.29

tend to approximate a power function better than data for one session.

Balanced exponents for each *S* in each session were obtained by taking the geometric mean of the appropriate duration and inverse loudness exponents (ILEs). In addition, for the same 120 combinations of session and *S*, RAs were computed.

Changes over sessions. To assess the stability of the various measures, a Treatments × *Ss* analysis of variance was applied to each matrix of 120 measures. Thus, four analyses in all were conducted, one each for DEs, LEs, BEs, and RAs. The sessions effect was significant when duration was adjusted, F (5, 95) = 5.56, $p <$

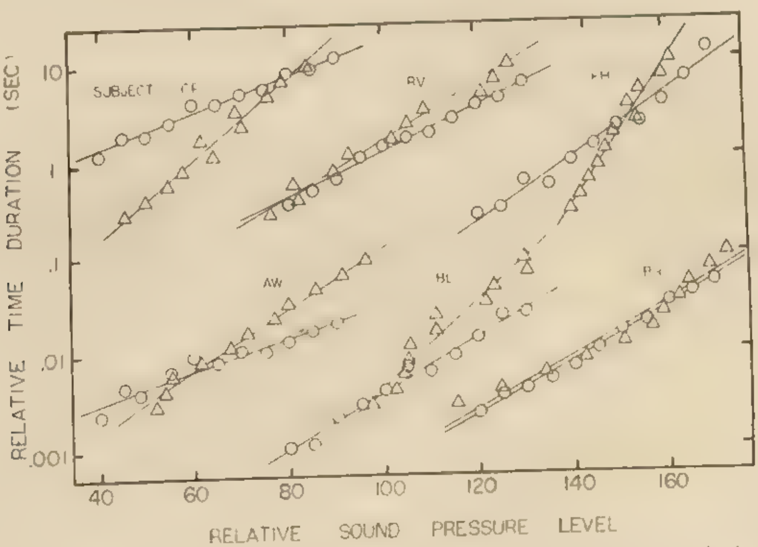

FIGURE 3. Matches of apparent duration to loudness (circles), and vice versa (triangles), for each of six randomly selected *Ss* with their data pooled over sessions. (All pairs of curves, except the upper left, have been shifted to the right or downward for presentation.)

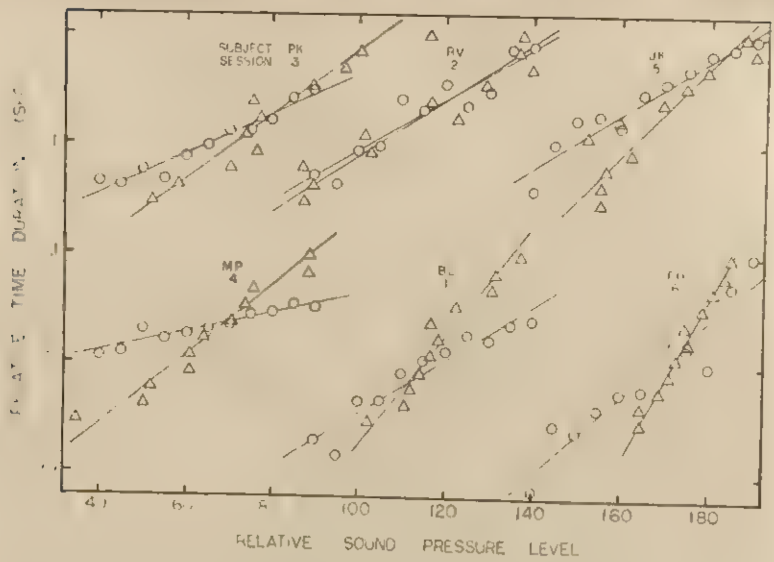

FIGURE 4. Single session matches of apparent duration to loudness (circles), and vice versa (triangles), for each of six randomly selected *Ss*. (All pairs of curves, except the upper left, have been shifted to the right or downward for presentation.)

.001, but not when loudness was, F (5, 95) = .862, $p > .05$. The BEs for the group data tended to increase over sessions but not significantly, F (5, 95) = 2.14, $.05 < p < .1$. On the other hand, RAs changed reliably, F (5, 95) = 3.62, $p < .01$.

Additional comparisons were undertaken for those measures where a sessions effect occurred. Duncan's new multiple range test indicated that the DE for Session 1 was significantly less than those for Sessions 5 and 6, but other comparisons of session means yielded no difference. With RA means, Session 1 was greater than Session 6, but other comparisons were not significantly different.

Individual differences. Tukey's test for nonadditivity (see Myers, 1972) was carried out for each of the four measures. Nonadditivity effects were not significant with F (1, 94) = 2.98, 1.54, 2.47, and <1 for DEs, LEs, BEs, and RAs, respectively. Thus, it was permissible to test the *Ss* effect for each of the measures. In all cases this effect was significant at the .001 level: DEs, F (19, 95) = 9.73; LEs, F (19, 95) = 13.18; BEs, F (19, 95) = 12.87; and RAs, F (19, 95) = 10.29.

The fact that the Tukey tests found the additive model to be appropriate implies that *Ss* were not differentially affected by sessions. In order to examine the consistency of *S* differences over sessions, Kendall's coefficient of concordance was calculated for each of the four measures. All were significant at the .001 level with W (19) = .64, .74, .72, and .67 for DEs, LEs, BEs, and RAs, respectively. Similar evidence for persisting individual differences was given by intersession product-moment correlations (df = 18), all of which were positive. For DEs, all 15 possible rs were significant at the .05 level using a one-tailed test and all but 2 were so at the .025 level. With LEs, all rs were significant at the .01 level, while for BEs, all were reliable at the .05 level with all but 2 being at the .005 level. The rs for RA were all significant at the .05 level, and all but 2 were at the .025 level. Table 2 presents the intersession correlations for successive pairs of sessions. The Session 1 vs. Session 2 values tend to be lower than succeeding correlations.

Correlational analysis was also used to examine further Stevens's contention that

individual exponents may be mainly due to regression. Under Stevens's hypothesis, a negative correlation is expected between individual duration exponents and their corresponding inverse loudness exponents. That is, if regression balances for all individuals are to lead to the same exponent, then an *S* with a low DE must have a compensatingly high ILE and vice versa. Cross-modal Pearson *r*s were calculated between these individual exponents both for each session and using individual exponents based on all sessions. The correlations between modalities at each session were all positive, with only Session 2 significant, r (18) = .51, $p < .05$. The correlation based on combined sessions was not significant, r (18) = .30, $p > .1$.

Discussion

In general, results provide additional support for the use of direct scaling methods and the assertion of the power law for both the data of groups and individual *Ss*. The presence of regression in judgments was apparent, and balances for this effect yielded several interesting results.

Stability of the measures. A change in exponents with repetition occurred for apparent duration but not for loudness. The DE change was in the direction of decreased regression over sessions, and it occurred gradually. Since the balanced exponents are based on the DEs and LEs, it is not surprising that they tend to increase over sessions even if not significantly so. Although the BEs are, in effect, stable, the RAs indicate that regression decreases significantly over sessions. Stevens and Greenbaum (1966) suggested that regression balances may not be perfectly stable when they stated that

> the distorting constraints that affect one variable, say, magnitude estimation, may be different from the constraints that affect the other variable, which may involve, for example, the turning of a knob that has peculiar characteristics of its own. It seems unlikely that the errors in two such different tasks as magnitude estimation and magnitude production would inevitably cancel exactly and completely [p. 446].

A possible reason for the difference between the sessions effects for DEs and LEs lies in the manner in which the two continua were adjusted. Loudness adjustment was continuously variable in both directions of intensity, but duration adjustment was only possible in an increasing direction. Loudness matches did not require return to a "zero" intensity before increasing or decreasing the intensity. With duration, *Ss* had to start over in order to produce a longer or shorter interval. There are two ways in which such adjustment differences could be avoided. First, *Ss* could be required to make loudness matches in a manner analogous to duration ones, that is, by increasing monotonically from zero loudness for all settings. Another approach would be to use continua which are usually adjusted in a similar fashion, e.g., time duration and force of handgrip or loudness and brightness. Whether some types of adjustment lead to stable exponents, while others do not, deserves to be investigated.

TABLE 2

Intersession Correlations for Successive Pairs of Sessions

Measure	Adjacent sessions				
	1–2	2–3	3–4	4–5	5–6
Duration exponents	.45	.56	.66	.77	.68
Loudness exponents	.65	.84	.72	.78	.86
Balanced exponents	.71	.78	.74	.67	.85
Regression angles	.39	.69	.54	.66	.69

Individual differences. The results, in agreement with earlier research, demonstrate that consistent individual differences persist over sessions. Since only one match per stimulus for each continuum was made per session and since there were approximately 24 hr. between sessions, it was expected that the intersession correlations, especially for Session 1 vs. Session 2, would be low and possibly nonsignificant. Teghtsoonian and Teghtsoonian (1971) found nonsignificant correlations in such a situation for magnitude estimation data. The present results, however, were obtained with cross-modality matching which conceivably could make for the difference. For both continua, all entries in the correlation matrices and the *Ss* effects of their analyses of variance were significant, indicating that there is a consistency in responding even with a 24-hr. intersession interval. The highly significant Kendall's *W*'s indicated reliability of individual differences over repetitions.

The attempt to remove individual differences by balancing for regression was not successful. They were still present with BEs as indicated by the analysis of variance, the *W*,

and the intersession correlations. Other sources of idiosyncratic exponents must still exist—perhaps several causes will be found responsible. The fact that the average intersession correlation for BEs was about the same as those for the DEs and LEs suggests that the proportion of variance attributable to individuals is similar in all three cases.

The positive cross-modal correlations between DEs and ILEs argue against Stevens's expectation that individual differences will largely vanish after a regression balance. As mentioned earlier, in order for all individual BEs to converge on the same value, a DE that is relatively low must be accompanied by a relatively high ILE, and so forth. Thus, negative correlations would be expected. Incidentally, they would also be expected by a "general range hypothesis." According to such a hypothesis, idiosyncratic exponents would be due to consistent use by individuals of a relatively constant proportion (large or small) of the range of any adjusted variable as they go from continuum to continuum. Some investigators (Rule, 1966; Rule & Markley, 1971) have suggested that the individual differences arise from the idiosyncratic use of the dependent variable—a sort of response style. According to a general range hypothesis, such response styles would be expected to transfer across continua.

What other possible sources of *S* differences might there be? Stevens (1961) earlier suggested three components of variability: *S*'s modulus, *S*'s conception of a subjective ratio, and the operating characteristic of *S*'s sense organ. Stevens (1971) rules out the latter because normal sense organs do not vary as widely as individual exponents. Differences in the modulus can be ruled out since they presumably affect the multiplicative constant but not the exponent of a power function. Differences in subjective ratios clearly would affect the exponent and it is known that they occur. Svenson and Akesson (1966), for example, find such differences but they also show that *S*s differ in other ways as well. Accounting for individual variability will probably entail discovering at least several factors and assessing how they operate in combination as Stevens (1971) has suggested.

PRESENTATION RATE AND INTRALIST REPETITION EFFECTS IN IMMEDIATE PROBE RECALL[1]

V. DAVID BURNS[2]

University of Maryland

Recall in an immediate memory study was tested by a missing-item probe for two levels of presentation rate (1 and 4 items per second) and four intralist repetition conditions. The presentation rate results contradicted the single-process forgetting hypotheses that were considered, including constant or variable time decay and interference-only. Repetition effects supported a multistore or multiprocess hypothesis. The divergent performance patterns exhibited by groups of Ss who were exposed to different presentation rate orders emphasize the importance of separating strategy from memory effects.

Two important issues which have been investigated in the study of short-term memory are sources of forgetting (time decay versus interference) and intralist repetition effects. These issues have ordinarily been examined in isolation from each other and hence it is reasonable to investigate their interaction; however, both are related to the more general problem of whether multiple memory systems (e.g., Atkinson & Shiffrin, 1968) or multiple encoding or retrieval processes (e.g., Craik & Lockhart, 1972; Murdock, 1972) are necessary to describe human performance in the immediate memory paradigm. This latter question was examined in the present study by testing the predictions of a number of "single process" models either for presentation rate or intralist repetition effects.

With respect to the presentation rate variable, model predictions are based on the following assumptions: (*a*) that forgetting rates as a function of intervening items are most appropriately measured by sensitivity estimates as prescribed by signal detection theory (see Banks, 1970), (*b*) that *S*s adhere to nonrehearsal instructions when given, and (*c*) that only a single response is required per trial, as in Waugh and Norman's (1965) probe procedure. If it is hypothesized that the only cause of forgetting is interference from subsequently presented items within a list (Norman, 1966), forgetting rates should not differ across presentation rates. Support for this hypothesis has been found by Norman (1966) and has been replicated (Anderson & Burns, 1973) using a missing-item probe with visual presentation (four digits per exposure), required voicing of individual items, and nonrehearsal instructions.

Alternatively, rate of forgetting is predicted to be greatest at the slowest presentation rate according to any of the following hypotheses: pure time decay, a combination of interference and time decay (Wickelgren, 1970), or differential degrees of processing across presentation rates (Massaro, 1970). Wickelgren (1970) has reported an experiment in which this prediction was supported for a recognition task. One purpose of the present study was to replicate Anderson and Burns (1973) with visual presentation of individual list items. Estimates of sensitivity and reaction time for individual *S*s were obtained in order to allow a test of the forgetting rate hypotheses.

The second variable examined in the present study was the frequency and spacing of intralist repetitions. For all three

[1] This research is based on a master's thesis submitted to the Graduate School of the University of Maryland and was completed while the author held a Maryland Fellowship. Support was furnished by the Biomedical Sciences Support Center of the University of Maryland to the Center for Language and Cognition, and computer time was provided in full by the Computer Science Center. The author wishes to thank Nancy Anderson for advice and assistance throughout all stages of the project and John Holmgren and David Horton for critical readings of the manuscript.

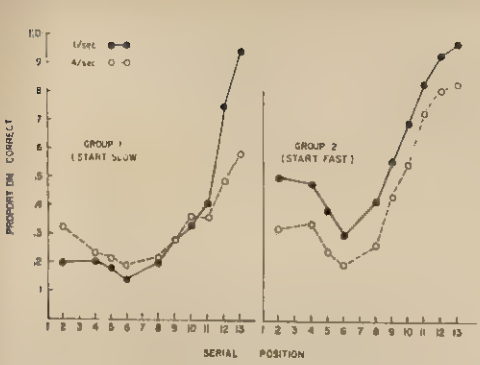

FIGURE 1. Proportion correct as a function of serial position for each rate and group.

previous studies in which no evidence indicating time decay was obtained (Anderson & Burns, 1973; Norman, 1966; Waugh & Norman, 1965), stimulus sequences were used in which the repetition of critical (tested) items was not investigated. It is possible that the failure to find evidence for time decay can be partially attributed to the absence of a control for repetition of critical items. However, repetition effects are important in themselves, since at least three different outcomes are predicted depending on the theoretical model chosen. First, if recall in the immediate memory paradigm reflects the contribution of two distinct memory systems (i.e., recently presented items tend to be recalled from a short-term store whereas earlier items are retrieved from a long-term store), one would expect repetitions to affect performance differentially across serial position. This hypothesis is suggested by the facilitative effect of repetitions found in "long-term" memory studies (e.g., Waugh, 1970) but the absence of any facilitation when a single item is repeated in the "probe memory-span" task (Jahnke, 1969). Second, repetitions may facilitate performance across all serial positions (Bernbach, 1969). Third, repetitions may degrade performance if item-to-item associations mediate recall (e.g., Wickelgren, 1966). According to the associative hypothesis the repetition of an item in a sequence should decrease the probability of recall of the items immediately following the repeated item (if different) because of competing A–B, A–C associations. These three hypotheses were tested by varying the repetition ructure of the stimulus lists.

METHOD

Lists of fifteen digits were composed ·ing all 10 digits (0 to 9) with the restriction t' no item occur more than twice per list. Each l was constructed according to one of the fol ng constraints, which define the four repetitio ditions: (*a*) The critical item was repeated at , of one intervening item (i.e., . . . iji . . . wh i is the critical item and j is any other digit w' is not repeated)—condition CR-1. (*b*) The cr l item was repeated at a lag of six intervenin items—condition CR-6. (*c*) The item in the ser osition preceding the critical item was repeated lag of six intervening items, and the critical ite as not repeated—condition PR. (*d*) Neither t ritical item nor the preceding item was repeat in the list (although other items did repeat)— dition NR. When an item was purposely repeat it was always repeated on only one side of th ritical position. Hence, if j $\geq$ 8 was the critical serial position, the repetition was always placed before the critical item, and conversely for j $<$ 8.

Presentation rates of one and four digits per second (with item "on-times" of approximately 1 and .27 sec., respectively) were chosen to replicate previous studies. On any single trial only one digit was probed and the critical item occurred only in serial positions 2, 4, 5, 6, 8, 9, 10, 11, 12, or 13. Each *S* was exposed to all (80) levels of the three main variables of Presentation rate × Repetition × Serial position. The two levels of presentation rate were varied across sessions, but the 40 possible Repetition × Serial position conditions occurred equally often in a random order within each session. Six University of Maryland undergraduates were recruited as *S*s and paid $2 per hour plus a bonus based on proportion correct. Each *S* participated in nine sessions (120 lists per 50-min. session) at the slow rate and three (320 lists in 75 min.) at the fast presentation rate. As a control for order effects one group of three *S*s (Group 1) was exposed to the slow presentation rate initially, and another group of three *S*s (Group 2) was exposed to the fast presentation rate initially. Because of scheduling conflicts, the only constraint imposed was that Group 1 (start slow) *S*s be exposed predominately to the slow presentation initially, and that Group 2 (start fast) *S*s be exposed predominately to the fast presentation initially. The consequence of this arrangement was that *S*s were exposed to the following sequence of sessions:

Group 1:	Group 2:
SSSSSSSFFSSF (2 *S*s)	FSSFFSSSSSS
SSSSSSSFFSFS (1 *S*)	FSFSFSSSSSSS (1 *S* each)
	FSFFSSSSSSSS.

Stimuli were displayed and responses recorded by means of a CRT terminal connected to the time

sharing computer system at the University of Maryland. After a ready signal on the CRT, *S* initiated the stimulus presentation. Each digit was displayed individually to the right of the preceding digit such that no two items were ever visible simultaneously. Each digit was read aloud as it appeared on the screen, and *Ss* were instructed not to rehearse previous items. The instructions were repeated on numerous occasions throughout the experiment.

Following presentation of the 15 digits, the missing-item probe, consisting of the stimulus list which just occurred except for a single missing digit, was displayed and two hyphens were printed at the position of the item which was to be recalled. One of the 10 digits and a confidence judgment were entered while the probe remained visible, then the screen was cleared and another ready signal given. Two rest intervals lasting a minimum of 1 min. were provided at equal intervals during the session.

Results

Performance as measured by proportion correct is summarized for each presentation rate in Figure 1. An analysis of variance of the arcsin transform of proportion correct indicated that performance at the slow presentation rate was superior, F (1, 4) = 15.8, $p < .05$ (mean difference = .087). Presentation rate interacted with serial position only for Group 1 (start slow), F (9, 18) = 11.5, $p < .001$, which accounts for the significant Groups × Rate × Serial position interaction, F (9, 36) = 3.56, $p < .005$.

Since the forgetting rate predictions for all models are specified in terms of sensitivity estimates, Memory Operating Characteristic (MOC) curves were generated and A_g, a nonparametric estimate of sensitivity representing the area under the MOC, was calculated for each *S* and condition. The sensitivity estimates are plotted in Figure 2 for each group and presentation rate. Performance as estimated by A_g is superior at the slow presentation rate for both groups. (The sharply reduced A_g in serial positions 12 and 13 for Group 2 reflects the inadequacy of this measure when performance is almost perfect.)

The slopes of the linear least-squares fits to log A_g as a function of number of intervening items (the reverse of serial position) were employed as estimates of forgetting rates, as specified by the models

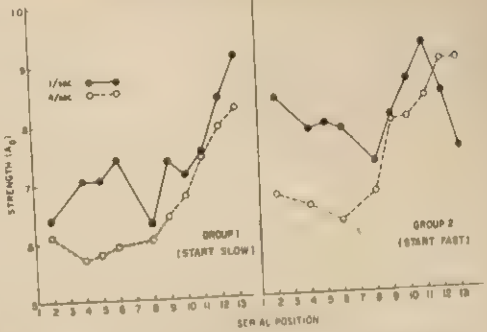

FIGURE 2. Strength (A_g) as a function of serial position for each rate and group.

considered above. (If A_g for serial positions 2 or 4 exceeded the minimum A_g for a given *S* and rate by .1, or if the difference in A_g for positions 12 or 13 and the maximum A_g exceeded .1, those positions were not included in the slope estimate.) The forgetting rates obtained by this procedure were greater at the fast presentation rate for all *Ss*, and the slope differences were significant for four of six *Ss* (two-tailed confidence interval, $p < .05$). The zero-intercepts estimated by least-squares were greater at the fast presentation rate for four of six *Ss*.

Mean reaction times were significantly longer at the slow presentation rate, F (1, 4) = 85.33, $p < .005$, (mean difference = 5.3 sec.). This result has also been obtained by Norman (1966) and Murray (1968).

The overall differences among repetition conditions were not significant but a significant interaction of repetitions with presentation rate and serial position was observed for Group 1, F (27, 54) = 2.83, $p < .001$. Separate analyses performed on the first and last five positions indicated that this interaction was significant only for the first five positions tested, F (9, 19) = 3.52, $p < .025$. Performance was generally superior for condition CR-6 but the differences among conditions varied across presentation rate and position.

For Group 2 (start fast) repetitions interacted with serial position, F (27, 54) = 2.98, $p < .001$, and the differences among repetition conditions were significant only

for the first five positions tested, $F(3, 6) = 6.9$, $p < .025$. For these positions (2, 4, 5, 6, and 8) the critical item was recalled with highest probability when repeated, regardless of lag (conditions CR-1 and CR-6). Recall was poorest for condition NR in which neither the preceding nor the critical item was repeated, and performance was intermediate for lists in which the item preceding the critical item was repeated (condition PR).

Group 2 (start fast) *S*s performed significantly better than Group 1 (start slow) *S*s, $F(1, 4) = 26.86$, $p < .01$ (overall difference in proportion correct = .20), and a similar pattern of group differences was apparent for the A_g measure. The performance superiority exhibited by Group 2 *S*s was restricted primarily to early positions at the slow rate and later positions at the fast rate. Aaronsson (1967) has reported a similar result.

Discussion

The forgetting rate differences obtained in the present study contradict all "single process" models considered, namely, models in which it is assumed that encoding across serial position is constant (for a given presentation rate and nonrehearsal instructions), and that forgetting results either from interference, time decay, or some combination. The forgetting rate differences obtained are consistent with a number of multiprocess models (e.g., Atkinson & Shiffrin, 1968), since performance for recently presented items (later serial positions) is predicted to be independent of presentation rate but recall of items in early positions is assumed to be an increasing function of study time. In addition, the multiprocess model can more easily account for the pronounced primacy effect apparent in Figures 1 and 2 without resorting to post hoc explanations.

Additional evidence that the memory process used by *S*s in this task is not unitary was indicated by the significant effects of repetitions for early but not later serial positions. Although repetitions interacted in a complex manner with presentation rate and serial position for one group, recall was generally facilitated by item recurrence for early but not later serial positions. This supports the hypothesis that the processes of encoding and/or retrieval for early items are analogous to those involved in "long-term" recall studies, whereas retention of later items more closely corresponds to the mnemonic processing which takes place in the memory span task. Neither of the other two hypotheses considered regarding repetition effects were supported.

The pattern of group differences supports the hypothesis suggested by Aaronsson (1967), that *S*s trained at a slow presentation rate tend to adopt an "immediate" perceptual strategy at both presentation rates, whereas *S*s trained at a fast rate tend to adopt a "delayed" identification strategy. However, in the present study it may be more appropriate to hypothesize that the group differences result from a differential delay in "deeper-level" or "long-term memory" processing. Group 1 *S*s (exposed to the slow rate initially) may have attempted to maximize the "depth" of processing of individual items at both presentation rates. However, Group 2 *S*s, trained initially at the fast rate, may have delayed "deeper-level" processing at both presentation rates, since any processing of individual items was impossible at first. The result of utilizing a delayed strategy would be to acquire greater information about the relationship among items, hence Group 2 *S*s would be expected to show superior performance particularly for early serial positions at the slow presentation rate. The "immediate" strategy has the additional disadvantage of requiring more processing time per item, resulting in a greater probability that the encoding of later items at the fast presentation rate is disrupted.

The results of varying both presentation rate and intralist repetition provide further evidence for the necessity of postulating more than a single memory process or dimension to describe retention in the immediate probe recall paradigm. The differences between groups can be accounted for in terms of strategy differences which are compatible with the multiprocess model. The two memory processes hypothesized may be more clearly differentiated by varying the degree of redundancy over more intricately patterned stimulus sequences.

EFFECTS OF POSITIVE AND NEGATIVE FORCE-CONTINGENT REINFORCEMENT ON THE FRUSTRATION EFFECT IN HUMANS[1]

GAIL DITKOFF[2] AND RONALD LEY

State University of New York at Albany

Ninety college undergraduates learned a force-discrimination lever-press response under conditions of positive or negative reinforcement. The magnitude of the reinforcement *S*s received for correct training-trial responses was varied. Following training, *S*s received five extinction trials. Consistent with a generalized-drive interpretation of the frustration effect (FE), during early extinction mean response force on a nonreinforced lever (L_2) increased for both the positive-reinforcement and the negative-reinforcement groups. An unexpected finding was a decrease in mean response force on the force-contingent reinforcement level (L_1) from late training trials to early extinction trials by the negative-reinforcement groups. The L_1 and the L_2 data suggested a trend in which the magnitude of the FE increased as the magnitude of reinforcement on training trials increased.

Amsel's (1958) frustration–drive hypothesis states that nonreinforcement following the development of an anticipation of reinforcement results in the aversive motivational state of frustration. According to frustration–drive theorists, frustration acts as a source of drive (D), which results in an increase in the vigor of behavior that immediately follows frustration (the frustration effect—FE). Empirical support for the notion that nonreinforcement following a history of *positive* reinforcement is motivating has been obtained with infrahuman *S*s, using double-runway, hurdle-jump, and operant lever-press apparatuses (Amsel & Rousel, 1952; Daly, 1971; Marzocco, 1951), and with humans, using force, movement speeds, and latency of lever-press responses as dependent variables (Blixt & Ley, 1969; Ryan & Watson, 1968). With respect to *negative* reinforcement, a comparatively small amount of research has been reported. Although Lambert and Hammond (1970) were unable to obtain an FE in rats using escape from shock as a negative reinforcer in a double runway, Graham and Longstreth (1970) did obtain FEs in rats in a double-runway study in which shock escape served as the negative reinforcer. The primary purpose of the present study was to extend the investigation of the effects of termination of negative reinforcement (avoidance of monetary loss) on the FE to the realm of human behavior. In the context of this study, the termination of negative reinforcement during extinction trials consisted of punishment, i.e., monetary loss following responses which had previously been negatively reinforced. On the basis of current theories of the FE, it was hypothesized that the termination of reinforcement following both positively and negatively reinforced training would result in the FE in humans.

The secondary purpose of the present study was to investigate the effect of different magnitudes of both positive and negative reinforcement on the FE. According to both Amsel (1958) and Spence (1960), the magnitude of the FE is related to the strength of *S*'s anticipation of reinforcement (r_G). As the strength of r_G increases, nonreinforcement should produce greater amounts of frustration. Researchers have found that the magnitude of the FE increased (*a*) when the similarity between a runway and its goal box was increased (Amsel & Hancock, 1957), (*b*) when *S*'s nearness to task completion when he was thwarted was increased (Hanner & Brown,

[1] This research was supported in part by a State University of New York Research Foundation Grant in Aid to the second author.

[2] Requests for reprints should be sent to Gail Ditkoff, who is now at the University of Pittsburgh, Johnstown, Pennsylvania 15904.

1955), and (*c*) when the number of reinforced acquisition trials given prior to nonreinforcement was increased (Penny, 1960). According to Spence (1960), another way in which the strength of r_G may be varied is by varying the magnitude of the reinforcement that *S*s receive during training; i.e., *S*s which receive larger reinforcements during training should develop stronger r_G, and hence show greater FEs, than *S*s which receive smaller reinforcements during training. On the basis of this theoretical position, the second hypothesis of the present study was that the magnitude of the FE would be a function of the magnitude of reinforcement (both positive and negative) received during training, i.e., as the amount of reinforcement received for each correct training-trial response increased, the magnitude of the FE would increase.

In the double-runway studies (e.g., Amsel & Rousel, 1952) the use of the same reward (i.e., food) in the goal boxes of both the first runway (R_1) and the second runway (R_2) has led to the question of whether an increase in R_2 response vigor reflects an increase in general drive level or an increase in food-related motivation. Levine and Loesch's (1967) finding that the vigor of a continuously reinforced instrumental response (food-reinforced lever presses) increased during periods when a dissimilar instrumental response (water-reinforced chain pulls) was being extinguished was interpreted as evidence for the hypothesis that nonreinforcement, following continuous reinforcement, leads to increases in D. The tertiary purpose of the present study was to test further the hypothesis that the FE reflects an increase in D, which will be evidenced in an increase in the force of a second response (a response unrelated to the reinforcement contingency of the frustrated response).

By means of a double-lever force-contingent reinforcement apparatus, *S*s successively pressed each of two levers (L_1 and L_2) on each experimental trial. Correct L_1 responses were either positively or negatively reinforced during training trials and were not reinforced during extinction trials. Lever 2 responses were never reinforced. Therefore, a significant L_2 frustration effect (i.e., an increase in the force of L_2 responses following L_1 nonreinforcement) could not be interpreted as the result of the termination of L_2 reinforcement and would support an explanation in terms of the FE reflecting increases in D.

Method

Subjects. The *S*s were 90 undergraduate students enrolled at the State University of New York at Albany.

Apparatus. A modification of the force-contingent reinforcement apparatus designed by Blixt and Ley (1969) was used to measure changes in the force of responses on a force-contingent reinforcement lever (L_1) and a nonreinforced lever (L_2) when a series of continuously reinforced responses was followed by nonreinforcement. These two vertical 48.26-cm.-high steel levers were mounted side-by-side (30.5 cm. apart). There was no discernable movement of the levers when force was applied. The left-hand lever was painted red and the right-hand lever green. Two signal lights (one red and one green) were directly behind and approximately 5 cm. above their correspondingly colored levers. Between the two signal lights, at approximately eye level, was a digit counter (Lafayette Model 57-7-B). At the middle of each lever (front and rear) were two bonded strain gauges (SR-4 Type FA-50-35, 350 ohm resistance, manufactured by Baldwin-Lima-Hamilton) which measured the amount of force applied to the levers. Pressure on the levers resulted in the development of a small signal voltage which was routed through a Carrier amplifier to a Brush eight-channel pen recorder (Model RD-1682-30) and caused a pen deflection on a moving (1 mm/sec) graphical tape. The graphical tape was preexperimentally scaled, and since each lever was connected to a separate pen, a direct reading in grams of force on each lever was possible.

A test control box was manually set at a constant 5-sec. intertrial interval. Beginning with the red light, each of the two signal lights was successively activated for 5-sec. durations. The red-light circuit activated and reset one of two force-band discriminators that monitored voltage output from the strain gauges. Located on Force Band Discriminator 2 was a control switch that enabled *E* to program the L_1 response force-counter activation contingency; i.e., *E* controlled the amount of force that would activate the counter.

Procedure. From the total sample of 90 *S*s, an equal number of *S*s ($n = 15$) was randomly assigned to each of six reinforcement-type (positive reinforcement—PR—or negative reinforcement—NR) by magnitude-of-reinforcement (0¢, 5¢, or 10¢) groups, i.e., PR-0¢, PR-5¢, PR-10¢, NR-0¢, NR-5¢, and NR-10¢. The *S*s were instructed to press L_1 after

the onset of the L_1 signal light and to press L_2 after each L_1 press, but not until the onset of the L_2 signal light. The *Ss* were further instructed that the function of L_2 was to reset the recording mechanism in L_1.

The PR *Ss* were instructed that following each correct L_1 press (3–5 kg.) a point would accumulate on the counter, while NR *Ss* were instructed that following each incorrect L_1 press (a press less than 3 kg. or greater than 5 kg.) a point would accumulate on the counter. The PR *Ss* were further instructed that each counter point represented 5¢ (Group PR-5¢) or 10¢ (Group PR-10¢) that they had earned, while NR *Ss* were told that they initially had $4.00 to work with and that each counter point represented 5¢ (Group NR-5¢) or 10¢ (Group NR-10¢) which would be deducted from their $4.00. The PR control *Ss* (Group PR-0¢) were told that regardless of their performance they would be paid $1.50 for participating in the study, but that they should try to accumulate points, while NR control *Ss* (Group NR-0¢) were told that they should try not to accumulate points.

Following a practice period, which was designed to familiarize *Ss* with the experimental apparatus and with the proprioceptive feedback associated with a correct L_1 response, training trials were administered until a criterion of five consecutive correct L_1 responses following the tenth training trial was reached. Following training trials five extinction trials were given during which, regardless of the correctness of L_1 responses, no points (additional money) accumulated for the PR groups, whereas one point (a loss of money—punishment) accumulated for the NR groups.

The magnitude of the FE was assessed by comparing the response force of the first L_2 response that followed planned L_1 nonreinforcement (i.e., L_2 force on extinction trial 1—L_2 postfrustration trials) with the mean L_2 response force on the last five training trials (L_2 prefrustration trials), and by comparing the response force of the first L_1 response which followed planned L_1 nonreinforcement (i.e., the L_1 force on Extinction Trial 2—L_1 postfrustration trials), with the mean L_1 force on the last four training trials plus the first extinction trial (L_1 prefrustration trials).

RESULTS

The performance data in terms of mean force of response for each of the six experimental groups (positive or negative reinforcement by 0¢, 5¢, or 10¢ magnitude of reinforcement) on pre- and postfrustration trials for Levers 1 and 2 are given in Table 1. These data were analyzed by means of a four-variable mixed factorial design in which the between-*Ss* variables were reinforcement magnitude (0¢, 5¢, or 10¢) and reinforcement type (positive or negative reinforcement), and the within-*Ss* variables were trials (pre- and postfrustration trials) and levers (L_1—the force-contingent reinforcement lever—and L_2—the reset lever).

With respect to the primary hypothesis, the Reinforcement Type × Trials × Levers interaction was significant, F (1, 84) = 8.70, $p < .005$, thus indicating that the Reinforcement Type × Trials interaction was different from L_1 to L_2. Separate analyses of this interaction revealed that on L_2 the Reinforcement Type × Trials interaction was not significant, F (1, 81) = .14, $p > .05$, whereas on L_1 the Reinforcement Type × Trials interaction was, F (1, 84) = 8.28, $p < .005$. The means of the PR and NR groups on the pre- and postfrustration trials on L_2, which are plotted in Figure 1, clearly indicate an

increase in force of response from pre- to postfrustration trials for both the PR and NR groups, F (1, 84) = 4.11, $p < .05$. That is, with respect to L_2, the FE was obtained under negative as well as positive reinforcement, results consistent with the primary hypothesis. The observed difference between the PR and the NR groups was not significant, F (1, 84) = .10, $p > .05$.

The means of the PR and NR groups on the pre- and postfrustration trials on L_1, which are plotted in Figure 2, indicate an observed increase in force of response from pre- to postfrustration trials for the PR group, findings consistent with the data based on L_2 and with the primary hypothesis, but a decrease in force for the NR group, F (1, 84) = 5.25, $p < .05$, findings opposite to those based on PR on L_1 and opposite to those based on both PR and NR on L_2.

Contrary to the second hypothesis, reinforcement magnitude was not significant, F (2, 84) = 1.19, $p > .05$. Furthermore, neither the four-factor interaction nor any of the two-factor or three-factor interactions including the reinforcement magnitude variable were significant.

Consistent with the third hypothesis, response force on L_2 (a response unrelated to the reinforcement contingency of the frustrated response) showed a significant increase from pre- to postfrustration trials. This effect is illustrated in Figure 1 and was presented in the context of the results with respect to the first hypothesis. It should be noted, however, that the mean force of response on L_2 (M = 4.76) was significantly greater than the mean force of response on L_1 (M = 3.68), F (1, 84) = 42.26, $p < .001$—results that might be expected since reinforcement was contingent on *S*s' restricting their force of response on L_1 within a relatively light force band, whereas reinforcement never followed L_2 responses, regardless of the force *S*s exerted.

Consistent with expectations based upon previous research (Otis, 1973), the FE was found to dissipate rapidly over time. Analyses of changes in response force from prefrustration trials to delayed postfrustration trials (Extinction Trials 3–5 on L_1 and Extinction Trials 2–4 on L_2) showed the relevant main effects and interactions to be nonsignificant.

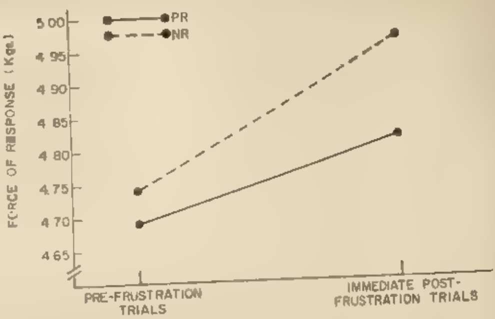

FIGURE 1. The mean Lever 2 response force as a function of trials and reinforcement type (PR = positive reinforcement, NR = negative reinforcement).

Table 2 presents the mean number of incorrect L_1 responses as a function of trial blocks for each reinforcement-type group. A Trial Blocks × Reinforcement Type analysis of variance was computed and indicated no difference between reinforcement type groups, F (1, 88) = .12, $p > .05$; a significant trial blocks factor, F (6, 528) = 22.13, $p < .001$; and a nonsignificant interaction, F (6, 528) = 1.54, $p > .05$. The significant trial blocks factor reflects the complete elimination of incorrect L_1 responses in Trial Block 7, consistent with the fact that training trials were terminated when *S*s reached a criterion of five consecutive correct L_1 responses.

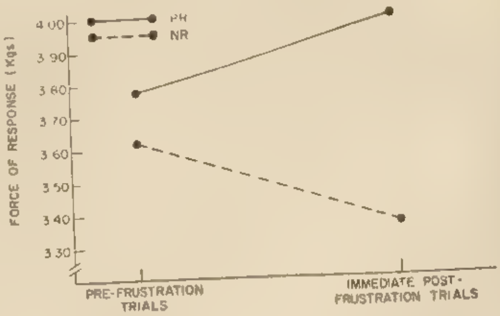

FIGURE 2. The mean Lever 1 response force as a function of trials and reinforcement type (PR = positive reinforcement, NR = negative reinforcement).

Note. Abbreviations: PR = positive reinforcement, NR = negative reinforcement.

Discussion

With respect to the primary purpose of the present study, the data indicate that the termination of negative reinforcement, as well as positive reinforcement, results in the FE in human *Ss*. The evidence that indicates an increase in force of response following the termination of positive reinforcement supports Amsel's (1958) frustration–drive hypothesis and is consistent with the findings of Blixt and Ley (1969). The demonstration of the FE in terms of an increase in force of response following the termination of negative reinforcement is unique with respect to both human and animal studies. With respect to other measures of the FE (e.g., start speeds from the first goal box of the double runway), the results are consistent with those of Graham and Longstreth (1970), who obtained the FE in rats using escape from shock as the negative reinforcer. It is important to note, however, that under conditions of negative reinforcement, the FE (an increase in force of response) was limited to L_2, the lever which was not instrumental in obtaining reinforcement during any phase of the experiment. With respect to L_1, the results were directly opposite of those expected, i.e., under conditions of negative reinforcement, force of L_1 responses decreased from prefrustration to postfrustration trials. This decrease may have been the result of greater aversiveness of nonreinforcement following negative reinforcement than nonreinforcement following positive reinforcement. In the present study, nonreinforcement for the negative-reinforcement groups consisted of punishment (i.e., the presentation of an aversive stimulus following the correct response); whereas nonreinforcement for the positive-reinforcement groups did not consist of punishment. If punishment leads to a depression in performance, perhaps the greater aversiveness of nonreinforcement under the NR condition resulted in a depression of response force which overrode the energizing effects of frustration. This explanation does not contradict those data that demonstrate the FE for both positive and negative reinforcement on L_2, since reinforcement and subsequent extinction contingencies were limited to L_1 responses (L_2 responses were never reinforced). This explanation proposes that under NR conditions there may be two processes which influence changes in L_1 response force following nonreinforcement: (*a*) the effects of frustration, which energize performance, thus resulting in an increase in L_1 response force, and (*b*) the effects of the aversiveness of punishment, which depress performance, thus resulting in a decrease in L_1 response force. Consistent with this explanation, the data of Table 1 show that the changes in L_1 response force from prefrustration trials to postfrustration trials were (*a*) a sharp decrease in force by Group NR-0¢, the group for which the effects of frustration would be expected to be weakest, (*b*) a slight decrease in force by Group NR-5¢, and (*c*) a slight increase in force by Group NR-10¢, the group for which the effects of frustration would be expected to be strongest.

With respect to the second purpose of the present study, both the L_1 data and the L_2 data showed a trend in the direction of a positive relationship between increases in force of response, following reinforcement termination, and magnitude of reinforcement. A perusal of the L_2 data of Table 1 indicates that the 10¢ groups showed an increase in mean response force from prefrustration trials to postfrustration trials of .18 kg., while both the 5¢ and the 0¢ groups showed increases of .15 kg. With respect to the L_1 data, the 10¢ groups showed an increase in mean response force from prefrustration trials to postfrustration trials of .14 kg., the 5¢ groups showed an increase of .04 kg., and the 0¢ groups showed a decrease of .36 kg. This trend suggests that greater manipulations of reinforcement magnitude may produce results consistent with those predicted from Spence's (1960) theory.

With respect to the tertiary purpose, the results of the present study support a generalized-drive explanation of the FE. The FE

was clearly evidenced on L_2 (the nonreinforced lever) under conditions of both positive and negative reinforcement. In addition, . . results are consistent with those of ...ne and Loesch (1967), who demonstrated ...he generalization of the FE following termination of positive reinforcement. Furthermore, the results of the present study extend the findings of Levine and Loesch to human behavior and to situations involving negative reinforcement.

THE MODALITY EFFECT: IS PRECATEGORICAL ACOUSTIC STORAGE RESPONSIBLE? [1]

RANDALL W. ENGLE [2]

King College, Bristol, Tennessee

Auditory presentation typically gives better performance than visual presentation in short-term memory experiments. This modality effect is theorized to be due to a precategorical acoustic store (PAS). Two experiments were conducted using the suffix procedure with free or serial recall of words. The findings did not support the PAS interpretation of modality effects as it now stands. That is, the suffix did not eliminate the modality effect which it should have according to the PAS interpretation.

The question is a very old one. Does auditory presentation of materials to be learned or remembered result in better learning or memory than those materials presented visually, or vice versa? A corresponding question that has attracted considerable interest is whether some people have primarily auditory memories while others favor the visual modality. This paper is concerned primarily with the initial question. If uncertainty is aroused by the second question then the reader is referred to Jensen (1971) for a partial answer.

A great deal of evidence has been compiled recently that modality of presentation is a potent variable in short-term memory experiments. The usual finding is that retention in immediate memory is much better for auditorily presented materials than for those presented visually. There is also evidence that visual presentation with concomitant vocalization of the material leads to better performance than just visual presentation (Murray, 1966). The supremacy of auditory presentation, known as the modality effect, has been observed using paired-associates (Murdock, 1966) and free recall (Craik, 1969) as well as paradigms involving order information (Murdock, 1967). The modality effect is typically obtained with both recall and recognition type retention tests.

In single-trial free recall situations the auditory superiority is most prominent over the last four or five serial input positions, in other words, the recency items. The earlier list items seem to be affected very little by modality manipulations except that occasionally a slight facilitation is found for the visual group on the primacy items (Craik, 1969; Murdock, 1966).

Craik (1969) and Murdock and Walker (1969) have attempted to delineate the theoretical implications for modality effects in short-term memory. One explanation for the results is that the short-term store is primarily auditory or acoustic in nature and auditorily presented materials enter the STS directly but visually presented materials must be translated into the acoustic code. This notion would predict auditory supremacy for all serial input positions and not, as is typically found, just those at the terminal end of the input list. Therefore, this idea seems to be somewhat discounted.

Another explanation makes use of preperceptual or prelinguistic stores. This explanation takes two forms. Crowder and Morton (1969) and Crowder (1970) have proposed that there is a precategorical acoustic store (PAS) similar in nature to the visual icon (Neisser, 1967) except of a longer duration. They argue that PAS is capable of holding information sufficiently long to affect the immediate memory task (on the order of 2 sec.). Information is supposedly lost from PAS due to displacement by subsequent acoustic events and/or decay with the passage of time. Crowder

[1] The experiments were conducted as part of a senior seminar by Glen Camenish, Luke Houchins, Kathy Lane, Terri Macray, Will Kniseley, John Saavedra and Sandy Sharp.

[2] Requests for reprints should be sent to Randall Engle, Department of Psychology, King College, Bristol, Tennessee 37620.

posits that presence of this prelinguistic information for auditory presentation is responsible for the modality effect. Crowder and Morton see no need for separate long-term and short-term memory stores. They feel that the concept of a PAS coupled with some form of articulatory coding makes the notion of a short-term store counterproductive.

The other attempt to explain the modality effect also relies on the notion of a PAS. Craik (1969) argues that the superiority of auditory presentation over the recency portion of serial position retention curves reflects the output from a postlinguistic or postcategorical short-term store which is itself indifferent with respect to input mode but which can, in some instances, be augmented by relatively unprocessed information still present in the visual and acoustic stores (icon and PAS). The modality effect is viewed as resulting from output from the short-term store being supplemented by the information in PAS for auditory presentation. Since the icon decays too quickly to be of benefit for visually presented items, the recency effect in single-trial immediate free recall is considered to be pure output from the short-term store.

As a phenomenon, the PAS has been studied almost exclusively by something called the suffix technique. The usual procedure, perfected by Crowder and his colleagues, is to present a sequence of items (typically digits) auditorily with a redundant nonrecalled suffix following the last item. This suffix is usually something like the word "zero" spoken at the end of each list. The serial recall data typically take the form of an increase in errors over the terminal (two–three) items in the suffix group as compared to a nonsuffix control group. Theoretically, the acoustic representation of the last few items in the list is still in the PAS at the time the suffix is presented and when the suffix enters the store it overwrites or interferes with the acoustic representation already there.

Since both major theoretic notions regarding modality effects rely on the PAS concept it seemed that the suffix procedure might be a useful converging operation to tease out those factors involved in the interpretation of the modality phenomenon. The first experiment was set up to be a simple demonstration that the suffix procedure would eliminate the superiority of auditory presentation over the terminal items in single-trial immediate free recall. This did not prove to be the case and thus led to the second experiment.

Experiment I

In terms of the PAS explanation, a redundant nonrecalled word at the end of auditorily and visually presented lists should have differential effects. If the suffix eliminates the ancillary information usually available in PAS for auditory presentation then the auditory suffix group should become exactly like the visual suffix and nonsuffix groups over the terminal or recency items. In other words, the prediction of Craik (1969) and Crowder (1970) should be that the suffix would affect the visual groups little, if at all. The auditory nonsuffix group should exhibit the typical supremacy over the visual groups for the terminal items, while the auditory suffix group, as a consequence of having the extra PAS information removed, should be no different than the visual groups. This should yield a Modality × Suffix and a Modality × Suffix × Serial Position interaction effect.

Method

Materials. Twenty-four lists of 12 items each were composed from the Kucera and Francis (1967) norms. The lists were recorded for auditory presentation at a 1-sec. rate and typed on paper for visual presentation by memory drum (also at a 1-sec. rate). Each list was used in both suffix and nonsuffix conditions but never with the same *S*.

Design. Half of the *S*s received the lists via auditory presentation and half by the visual mode: The visual and auditory groups were further subdivided into within-subjects suffix and nonsuffix conditions. In the suffix condition the lists ended with the word "zero." The "zero" was not to be recalled and *S* was told to either use it as a cue to recall or ignore it altogether if he so desired. The nonsuffix lists, of course, consisted of just the 12 words without the suffix. The *S*s served in the suffix and nonsuffix conditions in separate half-hour

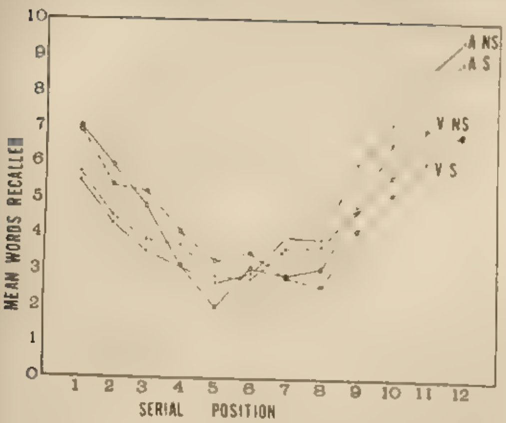

FIGURE 1. Mean free recall as a function of serial position, modality (auditory—A, or visual—V) and presence (S) or absence (NS) of a suffix.

sessions (12 lists per session) separated by 24 hr. The order of the suffix and nonsuffix sessions and set of lists in the two sessions were counterbalanced across subjects.

Subjects. The design above resulted in eight different conditions and since each of the four experimenters ran 1 *S* in each condition, 32 *Ss* were needed. The *Ss* were college sophomores at King College and served as part of a course requirement.

Procedure. The *S* was seated at a table facing either a Lafayette memory drum or Sony tape recorder depending on the appropriate condition. The *S* was instructed to recall the words in any order he deemed desirable with 60 sec. allowed for him to write his recall in a prepared booklet.

Results

The data from the first two lists in each session were discarded as practice lists. The recall data for each serial input position were combined across the remaining 10 lists for each of the four major conditions and these are depicted in Figure 1. Analysis of variance on the two modalities, two suffix conditions, and 12 serial positions showed that only the main effect of serial position and the Modality × Serial Position interaction were significant. The main effect of Serial Position resulted in F (11, 330) = 56.06, $p < .001$, and the Modality × Serial Position interaction resulted in F (11, 330) = 7.10, $p < .001$. Neither the Modality × Suffix nor Modality × Position × Suffix interactions were significant, contrary to the predictions of the PAS interpretation of the modality effect. Both interactions resulted in $F < 1$.

The absence of a Modality main effect, F (1, 30) = 1.36, $p > .10$, seemed to be due to the nearly perfect crossover of the auditory and visual groups, as is clearly shown in Figure 1. Therefore separate analyses were carried out for Positions 1–4 and 9–12. The analysis on the primacy items (1–4) resulted in significant Position, F (3, 90) = 32.38, $p < .001$, and Modality, F (1, 30) = 5.06, $p < .01$, main effects. This indicates that, for the four primacy positions, the visual presentation was, in fact, superior to the auditory presentation.

Of more importance to the present study was the analysis of the terminal positions (9–12). Auditory presentation was superior to visual presentation, F (1, 30) = 8.58, $p < .001$, showing the usual modality effect for the recency items. The Suffix and Serial Position main effects were also significant, with F (1, 30) = 5.05, $p < .01$, and F (3, 90) = 54.49, $p < .001$, respectively. None of the interactions were significant including the predicted Modality × Suffix interaction which resulted, again, in $F < 1$. This means that auditory presentation was superior to visual presentation for all four terminal positions and that the suffix did hinder recall for these terminal items. But it also means that the suffix was equally effective on these terminal items for both auditory and visual groups.

A further post hoc analysis was conducted in an attempt to ascertain the locus

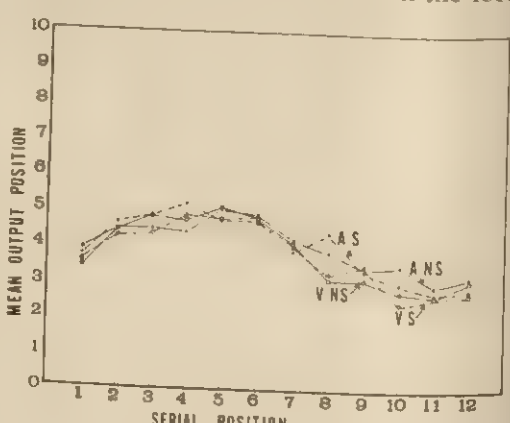

FIGURE 2. Mean output position as a function of serial position, modality (auditory—A, or visual—V) and presence (S) or absence (NS) of a suffix.

the rather surprising experimental re-ts. Following the lead of Murdock and ker (1969) the output order of the re-d items was analyzed. Figure 2 shows mean output position as a function of he recalled items input position. As can e seen from this Figure there are no major between-groups differences.

Discussion

Let us first dispense with the superiority of the visual groups to the auditory groups for the primacy items. As was mentioned in the introduction to this paper, this is an occasional result of modality experiments. Murdock (1966) used four or six paired-associates with e of the pairs being tested for retention. For his six item lists he found superiority for the visual presentation on the primacy items. Craik (1969), among others, has obtained this result with free recall, i.e., better performance on positions 1–3 for visual presentation than auditory presentation. Jensen (1971) has also reported data in which visual presentation is superior to auditory presentation. He used the memory span procedure and presented digits either visually or auditorily. The *Ss* recalled either immediately after presentation or after a delay of 10 sec. filled with a rehearsal preventative task. Jensen found that, with immediate recall, auditory presentation was slightly superior to visual presentation. However, the delayed recall results exhibited much better performance for the visual group than for the auditory group.

A probable explanation is that visual superiority in these situations is due to differential cumulative rehearsal strategies. Waugh (1960) has suggested that digit series are rehearsed cumulatively and Rundis and Atkinson (1970) have demonstrated that *Ss* in a free recall task do rehearse in a cumulative manner. Corballis (1966) found that with digit strings presented visually *Ss* did cumulatively rehearse but with auditorily presented strings there was very little cumulative rehearsal. Many subjects report a kind of "echo box" phenomenon with auditory presentation which would fit the PAS model. This quite likely leads the *S* in auditory groups to rehearse less or at least differently than the *S* in a visual group. The auditory *S* would be a great deal more passive and rely on the "echo box" while the visual *S* would need to rehearse in some manner. This would explain the differences for the primacy positions. This would also explain Jensen's (1971) findings since the PAS ("echo box") would decay leaving the auditory *S* with very little remaining information. The visual *S*, on the other hand, would be better off on delayed recall since he rehearsed the items. Other possible support for the rehearsal differences notion come from the fact that in free recall situations, facilitated primacy for visual items is usually observed when the subject serves in only the visual group or only the auditory group, i.e., between-*Ss* designs, and is not observed in within-*Ss* designs. See Craik's (1969) two experiments as evidence for this informal observation.

With respect to the analysis of the terminal positions, the prediction of the PAS explanation of modality effects seemed to be that the suffix should have eliminated any superiority for the auditory group over the visual group. The suffix did hinder recall but it did so for both the auditory and visual groups. And the suffix did not bring the auditory group down to the level of the visual nonsuffix group. This clearly does not support the PAS interpretation. One possibility for the contradiction between present findings and prior suffix procedure results might be that prior experiments using the suffix have typically used serial recall whereas the present experiment made use of free recall.

Experiment II

Since most previous experiments using the suffix procedure to study PAS have used serial recall, a second experiment was conducted to test the possibility that type of retention test contributed to the failure to support the PAS interpretation of modality effects.

Method

The same materials and design were used as in Experiment I with the exception that *Ss* were instructed to recall the items in the order they were presented. The *Ss* were 32 introductory psychology students who served as part of a course requirement.

Results

Again, the first two lists in each session were discarded as practice lists. The serial position curves are shown in Figure 3. The overall analysis of variance resulted in significant effects of Serial Position, F (11, 330) = 18.28, $p < .01$, Modality × Suffix, F (1, 30) = 12.76, $p < .01$, and Mo-

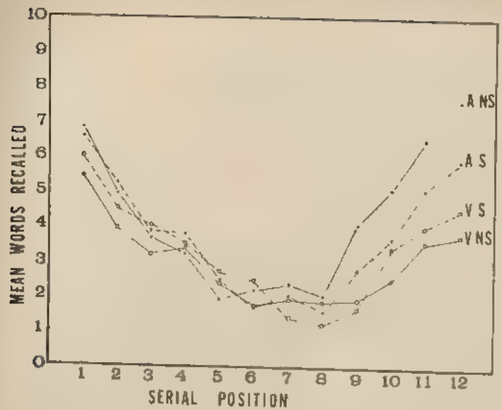

FIGURE 3. Mean serial recall as a function of serial position, modality (auditory—A, or visual —V) and presence (S) or absence (NS) of a suffix.

dality × Serial Position, F (11, 330) = 1.78, $p < .05$. Since the thrust of the study was aimed at the terminal positions, a further analysis was performed on Positions 9–12. This analysis resulted in a significant effect of Modality, F (1, 30) = 5.36, $p < .05$, showing that, for the terminal positions, auditory presentation was superior to visual presentation. The main effect of Suffix was not significant, F (1, 30) = 3.84, $p > .05$, but the Modality × Suffix interaction was significant, F (1, 30) = 13.77, $p < .01$. Paired comparisons showed the auditory suffix group to be lower than the auditory nonsuffix group, t (30) = 2.40, $p < .05$, but still significantly higher than the visual nonsuffix group, t (30) = 2.29, $p < .05$. So the suffix was effective, as the PAS interpretation predicts, in decreasing recall for auditorily presented terminal items. However, it still was not so effective as to make the auditory group identical to the visual group.

Another point of interest is that inspection of Figure 3 shows the visual superiority for primacy items found in Experiment I, to be absent in the present experiment. This supports the observation that the visual supremacy over the primacy positions is usually obtained with free recall.

Discussion

The PAS interpretation of modality effects seemed to predict that the addition of a redundant nonrecalled suffix to an auditorily presented list would result in recall curves very much like those of a visually presented list. While the suffix did have derogatory effects in both Experiment I and Experiment II it did not eliminate the superiority of auditory presentation over the recency positions.

There are several problems inherent in using the present data to argue about the contribution of PAS to the modality effects. As previously mentioned nearly all previous research on the PAS has made use of serial recall of short lists of digits. The current experiments used lists of words which were 3 4 items longer than the typical s[illegible] procedure list. Even though the second ex[illegible]ent used serial recall, there is a great diffe[illegible] between serial recall of an 8 or 9-item list [illegible]dily available digits and that of a 12-ite[illegible]t of words of considerably less availabili[illegible]nd more semantic content than the 10 d[illegible]

Nevertheless, the preca[illegible]rical acoustic store, as proposed by Crowder and Morton (1969), should not be affected by the availability of the items stored therein or their semantic content. Also, the modality effect is certainly found in nonordered recall tasks. Therefore, these tasks should be amenable to study.

One alternative might be to say that the suffix is not completely effective in eliminating the trace of those items in PAS or that the PAS is of longer duration than is typically suggested. Data pertinent to this point were reported by Murdock and Walker (1969). They randomly switched from auditory to visual within a single list and observed auditory superiority over a full 10-item list. This represented five full seconds and if PAS is responsible for their findings it must be of, at least, 5-sec. duration.

The Murdock and Walker (1969) study used words and free recall, as did the present research. This raises the completely speculative possibility that PAS is physical in nature but its duration and capacity may depend on the type of material presented, i.e., phonemes, digits, words, etc., and the type of task being used. This, of course, suggests some strategic control over the PAS.

One last word of caution should be mentioned with regard to the decrease in performance for the visual suffix group on terminal items. There is no obvious reason why this could have happened and Crowder and Morton (1969) found no such effect of suffix on recall

[a] visually presented string of digits. It may, [th]erefore, be a spurious result.

RECOGNITION TIME FOR WORDS IN SHORT-TERM, LONG-TERM, OR BOTH MEMORY STORES[1]

RICHARD C. MOHS AND RICHARD C. ATKINSON[2]

Stanford University

The *S*s memorized a long-term set (LT-set) of 24 words before the start of a recognition memory test. On each trial a new short-term set (ST-set) of two or four words was given; on some trials either half or all of the ST-set words were also members of the LT-set. The *S*s gave a positive response to test words that were: (*a*) only in the ST-set (new ST-set words), (*b*) only in the LT-set (LT-set words), or (*c*) in both sets (old ST-set words). Negative responses were given to words not in either set (distractors). Reaction time (RT) to both old and new ST-set words was a function of ST-set size; the RT functions for these two conditions had equal slopes but the function for old ST-set words had a smaller intercept. The ST-set size had no effect on RT to LT-set words or to distractors. In contrast to the results usually obtained using this paradigm, RT to distractors was less than RT to LT-set words. The results are interpreted in terms of a model which assumes that *S*s assess the "familiarity" of a test word before searching the memory sets.

A paradigm developed by Sternberg (1967, 1969) has been used extensively in recent years to investigate search processes in short-term memory (STM). In this paradigm *S*s are given a series of trials; on each trial *S*'s task is to decide as quickly as possible whether or not a test stimulus (probe) is a member of a previously memorized set of items (the positive set). In studies using small positive sets (six items or less) Sternberg typically finds that reaction time (RT) is a linear increasing function of the size of the positive set and that the slopes for positive and negative response functions are nearly equal. To account for these results Sternberg has proposed a theory of high speed scanning in memory. According to this theory the time between stimulus presentation and response execution is occupied by a series of stages including a stimulus encoding stage, an exhaustive serial comparison process, and a response selection stage. Because the comparison process is assumed to be serial and exhaustive, this model predicts a linear increase in RT with the size of the positive set and equal slopes for positive and negative response functions.

Although the serial–exhaustive scanning model has been supported by a number of short-term recognition experiments, data inconsistent with the predictions of the model have been reported by several investigators (see Nickerson, 1972). In an attempt to account for some of these inconsistencies Atkinson and Juola (1973, 1974) have proposed that *S*s may, in some cases, be able to execute fast responses based on a test item's "familiarity" without scanning the positive set. The familiarity model was originally formulated (Atkinson & Juola, 1973) to account for RT and error data from recognition memory studies using long, well-memorized lists of items stored in long-term memory (LTM); it has subsequently been applied both to short-term recognition studies and to studies involving searches of both STM and LTM (Atkinson, Herrmann, & Wescourt, 1974; Atkinson & Juola, 1974). The model assumes that test items (e.g., digits, words) are represented in memory as nodes and that each node, when accessed, can yield an index of that item's familiarity. Familiarity values are assumed to range over a continuum of values with the familiarity of a particular node being a function of the time since that node was last accessed

[1] This research was supported by Grant MH-21747 from the National Institute of Mental Health and Grant NSFGJ-443X3 from the National Science Foundation.

relative to the number of times that node has been accessed in the past. That is, a single presentation of an infrequent item increases that item's familiarity more than does a single presentation of a frequently occurring item. Subsets of the total set of test items are defined in terms of the frequency and recency of presentation of items in that subset; for each subset there is a density function which reflects the probability that a member of that subset will yield a particular familiarity value. It is usually assumed that all familiarity distributions are normal and have a common variance but that the mean of a distribution increases with frequency and recency of presentation.

If the pool of test items used in a recognition memory test is large enough so that stimuli not in the positive set (distractors) are repeated infrequently, the mean familiarity value for items in the positive set (target items) may be considerably higher than the mean familiarity value for distractor items. In such a situation *S*s may adopt a strategy involving a check on each test item's familiarity value before the test item is scanned against the positive set. If the test item's familiarity value falls above an upper criterion or below a lower criterion, *S* executes a positive or a negative response, respectively, without a memory scan. Only if the test item's familiarity value falls between these two criteria does *S* conduct a search of the positive set. The slope and intercept of the RT function, then, are predicted to depend not only on the encoding, comparison, and response processes, but also on the proportion of trials on which *S*s execute fast familiarity responses. This proportion, in turn, depends on the distributions of familiarity values for targets and distractors and the position of the decision criteria relative to these familiarity distributions.

The present experiment was designed to investigate recognition memory processes in a task in which the items to be recognized were stored in LTM, in STM, or in both memory stores. The *S*s were given a long-term memory set (LT-set) of 24 words to be memorized before the start of the recognition test and were given an additional short-term memory set (ST-set) of 2 or 4 words at the start of each test trial. The *S*s' task was to give a positive response to test words from the LT-set or the current ST-set and to give a negative response to test words not in either set. Previous experiments (Mohs, Wescourt, & Atkinson, 1973; Wescourt & Atkinson, 1973) using this paradigm have shown that RT to test items drawn from the ST-set is a function of ST-set size, but that RT to items drawn from the LT-set and to distractor test stimuli does not depend on ST-set size. The present experiment differed from these previous experiments in that some of the words used in the ST-sets appeared on more than one trial and in more than one memory set; on some trials in the present experiment either all or half of the ST-set words were also members of the LT-set. Thus, there were three types of target words in this experiment: (*a*) words in the LT-set but not in the current ST-set, (*b*) words in the current ST-set but not in the LT-set (new ST-set words), and (*c*) words in both memory sets (old ST-set words).

Of primary concern in the present experiment was the relationship between the RT functions for positive responses to new and old ST-set words. For a given set of decision criteria the familiarity model predicts that the proportion of correct fast familiarity responses for a subset of items from the positive set varies directly with the mean familiarity value of that subset. If words in both STM and LTM at the time of test have a higher mean familiarity than do words in STM alone, the model predicts both a smaller intercept and a smaller slope for old ST-set words than for new ST-set words; that is, the model predicts that *S*s would conduct memory scans on fewer of the trials with old ST-set probes than on trials with new ST-set probes.

Method

Subjects. Eight female students at Stanford University served as *S*s. Each *S* was paid $5 for participating in two test sessions.

Stimuli. Words for the LT-set, new ST-set words, and words used as distractor test stimuli were taken from the Thorndike–Lorge (1944) word list. All words were four to eight letters in length, had two syllables, and had frequency counts of more than 20 per million. New ST-set words and distractor words were each used on only one trial in the entire experiment; that is, they were presented only once to each *S*. A single list of 24 words was used as the LT-set for all *S*s. The first 2 and the last 2 words on the list were the same for all *S*s and were tested only on warm-up trials. The middle 20 words on the list were given in a different random order to each *S*.

Ten blocks of 28 trials each were constructed. Two of the blocks served as practice blocks and were given at the beginning of the first test session; these two blocks were constructed in the same manner as were the eight experimental blocks. Within each block, ST-sets of two and four words appeared equally often. For each of the two ST-set sizes each block contained 4 trials on which the test word was a member of the ST-set: 1 trial on which the probe was a new ST-set word drawn from a pure ST-set (i.e., an ST-set containing only new words), 1 trial on which the probe was an old ST-set word drawn from a pure ST-set (i.e., an ST-set containing only old words), 1 trial on which the probe was a new ST-set word drawn from a mixed ST-set (i.e., an ST-set containing half new and half old words), and 1 trial on which the probe was an old ST-set word drawn from a mixed ST-set. For each ST-set size each block contained 3 trials on which the probe was a member of the LT-set but not a member of the ST-set: 1 trial on which the ST-set contained all new words, 1 trial on which the ST-set contained all old words, and 1 trial on which the ST-set was mixed. Negative test trials were constructed so that negative and positive responses were required equally often for each ST-set size and type (pure or mixed). Within each block the test trials were presented in a different random order.

Within each block each of the middle 20 LT-set words appeared either in an ST-set or as a test probe at least twice and not more than three times. Over all 10 blocks of trials each of the middle 20 LT-set words was tested twice as an old ST-set word and three times as a long-term memory item (i.e., on a trial when it was not a member of the ST-set). No LT-set word was tested more than once in a single block. For mixed ST-sets the position of the old words was balanced so that they appeared equally often in each position for each trial type. Also, the serial position of test words drawn from ST-sets was counterbalanced across blocks for each trial type.

Two additional blocks of six trials each were constructed for use as warm-up trials. One block was given at the start of each session. These trials were similar to those used in the regular test blocks except that one of the first two and one of the last two LT-set words were tested in each warm-up block.

Apparatus. The ST-sets for each tri[illegible]ere presented through the speaker system of a ta[illegible]ecorder.

Each test stimulus was typed in ca[illegible]l letters on a white 6 × 9 in. index card wit[illegible]n IBM Executive Registry typewriter. The s[illegible]uli were presented in an Iconix tachistoscope[illegible]ey appeared at the center of the visual fi[illegible]d subtended a visual angle of about 2 degree[illegible]fixation target of four dots in the shape of a r[illegible]gle was displayed at the center of the field fo[illegible]c. prior to the onset of the test stimulus. Th[illegible]ay was dark between trials.

On a table to the right of *S* three [illegible]buttons were arranged along an arc. The *S* co[illegible]est her forefinger on the center button between[illegible]ls and make short movements to the left or ri[illegible] strike one of the two response buttons. Hal[illegible]the *S*s were assigned the right button as the p[illegible]tive response and the left button as the negative [illegible]sponse; the assignment was reversed for the othe[illegible]. The *S* held in her left hand a button used [illegible]nitiate display of the test stimulus on each trial

Procedure. Each *S* was contacted by[illegible]one at least 18 hr. prior to the first test sessio[illegible]The *S* was given the LT-set and was told to mem[illegible]ze the list so that it could be recalled in correct s[illegible] order at the first test session. Test sessions w[illegible]cheduled for two successive days.

All *S*s satisfied a learning criterion for th[illegible]T-set by giving both written and oral recalls of th[illegible]T-set in correct serial order at the start of the f[illegible]t test session. After completing both recalls correctly *S* was seated at the tachistoscope and given instructions about the task. The *E* explained that the experiment involved a series of test trials and that the following sequence would be followed on each trial: (*a*) the *E* would start each trial by saying "ready"; (*b*) the *E* would turn on the tape recorder and *S* would hear an ST-set of either two or four words; (*c*) the *S* would then repeat the ST-set aloud; (*d*) when *S* was ready she was to push the start button in her left hand; (*e*) this would cause a fixation box to appear in the tachistoscope for .5 sec., and then a test word would appear; (*f*) the test word would remain visible until *S* made a positive or a negative response by pressing the appropriate button; (*g*) the *S* would then repeat the ST-set aloud once more (this was done to ensure that old ST-set words were maintained in STM as well as LTM during the recognition test); and (*h*) the *E* would record the RT and a new trial would begin. The *E* then explained fully the nature of the ST-sets; the *S* was told that some of the ST-sets would be all new words, that some would contain only words already in the LT-set, and that some would contain half new and half old words. The *S* was not told that only the middle 20 words of the LT-set would be tested during regular test blocks. The *S* was told that the positive set on each trial consisted of the words in the LT-set, words presented from the tape recorder on that trial, and words in both the ST-set and the LT-set. It was explained that new ST-set words and distractor words would

...ed on only one trial in the entire experiment. ...nstructions emphasized that S was to respond ...dly as possible while trying to avoid errors. ...E was sure that S understood the instructions, ...first warm-up block was given. After the ...rm-up block S was asked if she had any questions. When S's questions, if any, were answered, the two practice blocks and three test blocks were given. During testing Ss were informed whenever they had made an error. The time between trials was about 10 sec.

At the start of the second day's session S was again required to give both a written and an oral recall of the LT-set. The instructions were then reviewed and S was given another warm-up block and five regular test blocks. Each session lasted about 1 hr.

Results and Discussion

The RT data from eight test blocks, the last three given in the first session and the five given in the second session, were included in the analysis. Data from trials on which an incorrect response was made were excluded from the analysis.

A preliminary analysis of the RT data for positive responses to words in the ST-set suggested that ST-set type (pure vs. mixed) had no effect on RT. This variable was included in the experiment in order to determine whether the familiarity value of a test word from the ST-set was affected by the familiarity of other ST-set words. An analysis of variance using S means as scores was performed with ST-set type, ST-set size (two or four words), and probe type (new or old) as factors. The analysis showed that the main effect of ST-set type and all interactions involving ST-set type were not significant, F (1, 7) < 1 in all cases.

Since ST-set type clearly had no effect on RT, the data for pure and mixed ST-sets were pooled. Table 1 presents a summary of the pooled data. Trials on which Ss gave a positive response to a new ST-set word are labeled Y(ST-new); trials on which Ss gave a positive response to an old ST-set word are labeled Y(ST-old); trials on which Ss gave a positive response to an LT-set word not in the ST-set are labeled Y(LT); and trials on which Ss gave a negative response to a distractor word are labeled N(D). In the second column of Table 1 are the two ST-set sizes for each condition, and in the third column is the total number of observations made for all Ss over eight test blocks. Using the raw data collapsed over ST-set types, the mean RT for each of the eight trial types was computed for each S. Outlying scores for each S were eliminated from computations by the following method: (*a*) for each trial type, the mean was calculated, (*b*) each score that was more than 1.5 times the mean was deleted, and (*c*) the mean was recalculated from the remaining scores. This procedure eliminated about 2.5% of the scores. The mean and standard deviation of S means for each of the trial types are presented in the fourth and fifth columns of Table 1. The last column presents the error rate for each trial type.

TABLE 1

Number of Observations, Reaction Time Means, Standard Deviations, and Error Rates for All Trial Types

Condition	ST-set size	No. of observations	*M* (msec.)	*SD* (msec.)	Percent errors
Y(ST-new)	2	128	626	133	1.6
	4	128	663	122	.8
Y(ST-old)	2	128	604	111	.0
	4	128	636	108	.0
Y(LT)	2	192	766	139	3.7
	4	192	771	108	8.6
N(D)	2	448	752	158	.9
	4	448	762	184	.2

A graph of the means from Table 1 is presented in Figure 1. Lines for the Y(LT) and N(D) conditions were drawn at the mean RT for the two ST-set sizes while the lines for the Y(ST-new) and Y(ST-old) conditions connect the two points for each condition. An equation for each line is given in the figure.

A comparison of the RT functions for the Y(ST-old) and Y(ST-new) conditions presented in Figure 1 indicates that the intercept for the Y(ST-old) condition is slightly smaller than the intercept for the Y(ST-new) condition but that the slopes for the two conditions are nearly identical. A two-factor analysis of variance using individual S means for these two condi-

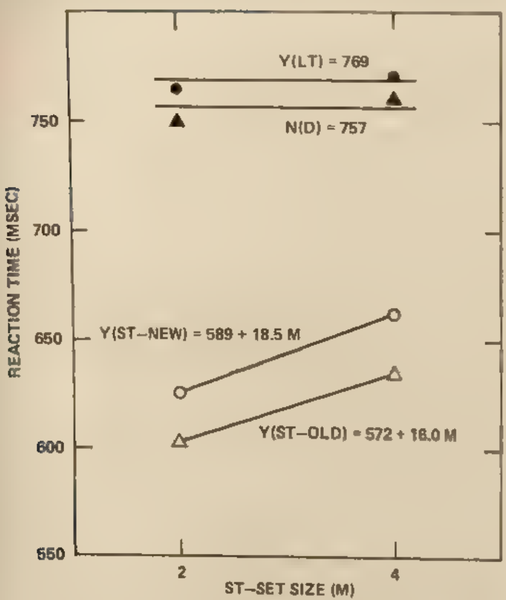

FIGURE 1. Mean reaction time vs. short-term (ST) set size for all conditions. (See text for explanation of conditions.)

tions as scores showed that the effect of ST-set size on RT was significant, F (1, 7) = 10.7, $p < .025$, that the effect of probe type was marginally significant, F (1, 7) = 4.1, $.05 < p < .10$, and that the interaction between these two variables was not significant, F (1, 7) < 1. The lack of a significant interaction between set size and probe type suggests that the difference in RT between new and old ST-set words was not due to a difference in familiarity; a greater mean familiarity for old ST-set words would have produced both a smaller slope and a smaller intercept for the Y(ST-old) function. It is possible, however, that the intercept difference shown in Figure 1 reflects the fact that old ST-set words were encoded more quickly than were new ST-set words. That recognition involves a stimulus encoding process which is separate from the comparison process has been demonstrated by Sternberg (1967). Furthermore, this interpretation of the intercept difference is consistent with the results of previous experiments in which familiarity could play no role (Kreuger, 1970; LaBerge & Tweedy, 1964), showing that RT decreases for more frequent test stimuli even when response frequency is controlled. An encoding difference could have resulted, then, because old ST-set words were each used as probes on several trials while new ST-set words were each presented only once in the entire experiment.

The fact that no evidence was found indicating a greater mean familiarity for old ST-set words than for new ST-set words suggests that a limit on the range of mean familiarity values must be included in the familiarity model. That is, the distribution of familiarity values for items currently being maintained in STM has a mean that is as great, or nearly as great, as the mean familiarity value for any set of items in LTM, STM, or both stores.

Paired t tests using individual S means as scores indicated that ST-set size had no effect on RT for either the Y(LT) condition, t (7) < 1, or the N(D) condition, t (7) < 1. Previous experiments using a similar paradigm (Mohs et al., 1973; Wescourt & Atkinson, 1973) have also found that ST-set size had an effect on RT to probes from the ST-set but had no effect on RT to probes from the LT-set or to distractor test stimuli. A model that accounts for this basic result by assuming that Ss search STM and LTM in parallel rather than sequentially is presented in both of the cited papers.

The present results are unique, however, in that the N(D) condition had a smaller RT than did the Y(LT) condition. In both of the previous studies of this type (Mohs et al., 1973; Wescourt & Atkinson, 1973) RT to distractor words was over 40 msec. greater than RT to LT-set words. The familiarity model can account for this reversal if it is assumed that Ss in the present experiment set upper and lower criteria in such a way that a high proportion of LT-set words had familiarity values between the criteria and so that a high proportion of the distractor words had familiarity values below the lower criterion. The reason for Ss' positioning the decision criteria in such a manner in the present experiment may be the following: Some Ss reported that they often decided whether a test word was a member of the ST-set,

LT-set, or both memory sets before ...g a positive response. By positioning ...e decision criteria in the manner de...ed above, *S*s could ensure that memory ...rches would be conducted on a high ...roportion of the positive trials and that high proportion of the distractor words ...ould be correctly rejected on the basis of ...amiliarity.

The error data shown in Table 1 provide ...rther support for this explanation of the ...eversal. The familiarity model predicts ...hat errors occur when the familiarity value for a member of the positive set falls below the lower criterion or when the familiarity value for a distractor falls above the upper criterion. We are assuming here three ...verlapping distributions of familiarity values, each normal and with common variance; we assume that the distribution for distractors had a low mean, that the distribution for ST-set words had a high mean, and that the mean for LT-set words was intermediate. If most of the familiarity values for LT-set words were between the criteria, few distractors would have familiarity values above the upper criterion and few ST-set words would have familiarity values below the lower criterion. Given these criteria, then, the model predicts lower error rates for ST-set words and distractors than for LT-set words.

PICTORIAL ELABORATION AND RECALL OF MULTILIST PAIRED ASSOCIATES[1]

EDWARD J. FORBES[2] AND HAYNE W. REESE

West Virginia University

In learning multiple paired-associate lists, all with the same stimuli, *S*s may form a new image for each pair or may progressively elaborate the image for a List 1 pair by incorporating each new response item into the image. In the latter, imagery and response-repetition effects are confounded. Analogues of these imagery types were manipulated by imposed pictorial elaboration in 4 paired-associate lists, with college *S*s. A control for response repetition was included. The elaboration types were found to be equally superior to their controls, for both serial and free recall, and for both immediate and 1-week delayed testing. Thus, elaboration effects are not lost in long-term retention, serial information is not lost in progressive elaboration, and response repetition and elaboration have separable effects.

It is now well established that nonverbal mnemonics, or images, facilitate the learning and short-term retention of a paired-associate list when the images represent interactions between the referents of the stimulus and response items (see review by Paivio, 1971). However, there is contradictory evidence about whether long-term retention is facilitated by these interactive images (e.g., Palermo, 1970).

In multilist paired-associate tasks in which the same stimuli appear with new responses in the different lists, there is some evidence that interactive images facilitate performance, perhaps by reducing associative interference between lists (e.g., Bower & Reitman, 1972; see brief review by Reese, 1972). One mnemonic strategy that *S*s sometimes report (Bugelski, 1968) is to elaborate a progressively more complex image, or "grand imaginal scene" (Bower, 1972), for a given stimulus by incorporating into the original interactive image each new response to be associated with that stimulus in the successive lists. Bower (1970) had suggested that information about serial order might be lost in these built-up images; but Bower and Reitman (1972) obtained contradictory evidence.

Bower and Reitman compared two groups, one given progressive elaboration instructions and the other instructed to form an interactive image for each pair and to replace it with a new image on each new list. Free and serial recall were better in the progressive-elaboration group than in the single-response elaboration group. Furthermore, the effects were obtained in both short-term and long-term (1 wk.) retention.

With progressive elaboration there is repetition of old-list responses in each new-list elaboration of the image. This repetition could be the source of the superiority of progressive elaboration. It would facilitate free recall by increasing the number of learning "trials," and it could facilitate serial recall by giving the response items different "frequencies" in Underwood's (1969) sense, as Reese (1970) suggested. However, if repetition is the source of facilitation, it should be equally effective without the context of imagery. A problem, then, is to determine whether repetition per se is the effective variable in progressive elaboration or whether the interactive imagery involved provides further facilitation. In the Bower and Reitman (1972) study, there were no control conditions in which imagery instructions were omitted, and consequently there was no way to separate the repetition and imagery effects.

To control for effects of repetition, Reese (1972) used imposed pictorial materials generating analogues of the imagery and

[1] A report of the study was given orally at the meeting of the Eastern Psychological Association, Boston, April 1972.

trol conditions. The analogue of giving ery instructions is to show, for each picture of the stimulus and response interacting; the analogue of omitting imagery instructions is to show the mulus and response items side by side d not interacting. In both kinds of con- l condition, S might spontaneously rm interactive images, but the proba- lity of interactive images is assumed to reduced. It was found in a retention st that progressive elaboration was su- erior to single-response elaboration, as in the Bower and Reitman (1972) study; but with response repetition controlled, reten- tion was the same in the two kinds of elaboration condition, and in fact neither was superior to its comparable control con- dition, contrary to the implications of the Bower and Reitman study. However, Reese tested recognition memory instead of recall, and the recognition test was so con- structed that serial retention could not be tested. (In addition, his *Ss* were young children.)

The present study can be considered to be an extension of the Bower and Reitman study, with the response repetition con- trols included (although this study was actually designed and run before the Bower and Reitman study was published). Be- cause of the nature of the control condi- tions, it was decided to use imposed pic- torial materials, as in the Reese (1972) study, but with recall instead of recogni- tion tests. Free and serial recall were tested immediately and again after a one- week delay.

Method

Design. The experimental manipulation involved the presence or absence of imposed pictorial elabora- tion. There were four conditions, each with four lists. (*a*) In a single-response elaboration condition, the stimulus and response items in a given pair in a given list were depicted as interacting in some way (see Reese, 1972, for details). The "scene" was shown only in the list in which it was appropriate. (*b*) In a "standard" control condition, the stimulus and response items in a pair were depicted side by side and not interacting in any way. A given pair was shown only in the list in which it was ap- propriate. This condition is comparable to the single-response elaboration condition, in that both involved presentation of only the currently appro- priate response items in each list. (*c*) In a progres- sive-elaboration condition, each new response item was added to the scene from the preceding list to form a progressively more complex scene that finally incorporated all four of the appropriate response items. The interaction between a response item and the stimulus item was exactly the same as in the single-response elaboration condition. (*d*) In a "row" control condition, the stimulus and response items in a pair in List 1 were presented side by side and not interacting, exactly as in List 1 for the "standard" control condition. In each successive list, however, each new response item was added to the row without deleting the response items already in the row. This condition is comparable to the progressive-elaboration condition, in that both in- volved presentation of the currently appropriate response items in each list together with all previ- ously appropriate response items, thus controlling the amount of sheer repetition of the response items.

The four conditions form a two-by-two factorial matrix with the dimensions: (a) Picture Treatment —imposed vs. no imposed elaboration—and (b) Response Treatment—response items repeated vs. not repeated in subsequent lists. In addition, the design included two other variables of experimental concern, both manipulated within *Ss*: (*c*) Test— free vs. serial recall—and (*d*) List. A fifth variable included in the analyses was (*e*) Order of Tests, re- flecting counterbalancing of the free and serial recall tests. The data from a sixth variable—immediate and delayed testing—were analyzed separately.

Subjects. The *Ss* were 48 students in sections of an introductory psychology course at West Virginia University, who volunteered to serve as *Ss* for extra credit in the course. They were run in groups of 2 to 11 persons. These groups were assigned to con- ditions in such a way that time of testing was varied, the sex distribution was roughly balanced, and inso- far as possible there was rotation through the con- ditions, roughly equating control or experimental conditions in number of *Ss* before repeating the rotation.

Materials. The materials were identical to those used and described by Reese (1972). They were line drawings of animals, used as stimuli, and of common objects, used as responses. They were divided into four five-pair lists, all with the same stimulus items and all with different response items. The pairings were random, except that obviously high associates were not paired. The materials were photographed for slide projection as positives. Projection time was controlled by Hunter decade timers.

Procedure. The *Ss* were run in subgroups, in each of which all *Ss* served in the same condition, but roughly half were given one sequence of the free and serial recall tests and the others were given the reverse sequence.

A study-test procedure was used, in which eight study trials and two test trials were given. Each list was presented twice for study, one pair at a time, before the next list was presented. The order of the pairs was changed in a predetermined, ran-

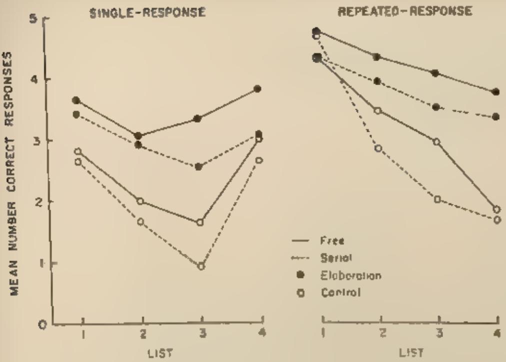

FIGURE 1. Recall in immediate tests.

dom way for each trial, with the restriction that across the eight study trials (two per list, four lists) the mean within-list positions of the stimuli were about the same for all stimuli. The presentation rate was 4 sec. per pair.

The test trials were given immediately after the eighth study trial. Free recall was tested in one of these trials and serial recall in the other. Half of the *S*s had the free-recall test first and the others had the serial-recall test first. The answer sheet for the free-recall test included a list of word labels of the stimulus items in the same predetermined random sequence for all *S*s, and beside each word was a line 5 in. long (12.7 cm). The instructions, printed at the top of the sheet, were to write down the names of the response items in any order. The answer sheet for the serial-recall test included a list of the words, in a different predetermined random sequence from that in the free-recall test to reduce transfer effects, and beside each word were four short lines. The instructions were to write down the names of the response items in the original order of appearance. The duration of each test trial was 3 min. Guessing was explicitly encouraged in the instructions for each test.

Seven days after the initial session, the *S*s were given the two test trials again, in the same sequence as in their initial test and with no further study presentations. The *S*s had not been told that these retests would be given. The *S*s were tested in groups of 15 to 20 in their classroom (these groups included *S*s participating in another study).

Results

Before the detailed findings are presented, it is useful to note that the Bower and Reitman (1972) findings were broadly replicated. In both free and serial recall, tested immediately and after the delay, the progressive-elaboration group was superior to the single-response elaboration group (all ps $< .01$). However, when these groups were compared with their respective control groups, the two types of elaboration were found to be almost exactly equal in overall effectiveness, as detailed below.

Immediate tests. Figure 1 shows the mean numbers of correct responses per list in the elaboration and control groups for free and serial recall. It can be seen, first, that both kinds of elaboration were facilitative, relative to the control conditions. In confirmation, the main effect of picture treatment was significant, F (1, 40) = 15.42, $p < .001$; and although picture treatment interacted significantly with list, F (3, 120) = 3.08, $p < .05$, follow-up t tests indicated that the difference was significant in all lists except the first one (List 1, t = 1.19; all other ts > 3.00, $p < .01$; these ts are Cochran-Cox approximations, with error terms derived from the overall analysis of variance). Second, within each response-treatment condition it can be seen that free recall was better than serial recall, but that the relative effect of elaboration (i.e., the elaboration vs. control difference) was about the same for serial recall as for free recall. In confirmation, picture treatment and test did not interact with each other ($F < 1.00$) nor jointly with any other variable (largest $F = 1.85$, for Picture Treatment × Test × Response Treatment × Order of Tests, df = 1, 40). Finally, it can be seen that the relative effects of elaboration on free and serial recall were about as strong in the repeated-response condition as in the single-response condition. In confirmation, picture treatment, test, and response treatment did not interact (all Fs involving all three variables $<$ 1.00 except that F = 1.85 for the four-way interaction mentioned above). These results show that elaboration facilitated performance, and affected serial and free recall in the same way. Furthermore, single-response elaboration was as facilitative as progressive elaboration when the effect of response repetition was controlled.

The source of facilitation in the elaboration groups seems to have been a reduction in interlist interference. It has already been noted that the elaboration and control groups did not differ significantly in

List 1, and examination of Figure 1 shows that the curves of the elaboration groups were flatter than those of the control groups. The Picture Treatment × List interaction was significant, as already mentioned, and follow-up t tests confirmed the apparent trends. In the combined elaboration groups, List 1 performance was significantly superior to List 3 and 4 performance, and no other differences between lists were significant. Thus, performance dropped after List 1 but immediately leveled off. In the combined control groups, performance was significantly better in List 1 than in all other lists, and significantly better in List 2 than in List 3. Thus, performance dropped continuously through the first three lists before leveling off.

It can also be seen in Figure 1 that typical serial position curves were obtained in the single-response groups and that there was a marked primacy effect and no recency effect in the repeated-response groups. These trends were confirmed by t tests, which were justified by a significant interaction between response treatment and list, F (3, 120) = 10.89, $p < .001$. It is, of course, not difficult to explain the primacy effect in the repeated-response conditions. The effect, which has also been obtained in a recognition test (Reese, 1972), presumably resulted from the extra practice provided when the previously relevant responses were repeated.

The only other significant effects are of no systematic interest: the main effects of response treatment (of no interest because of the interaction with list), test, order of tests, and list; and the interactions of test with order of tests and with list.

Delayed tests. The data from the delayed tests are summarized in Figure 2. (Group means were substituted for the data of one *S* who missed the delayed tests, with appropriate adjustment of *df* in the analyses of variance.) Overall recall was better in the elaboration conditions than in the control conditions, F (1, 39) = 10.98, $p < .005$, but the apparent effect of response treatment was not significant, F (1, 39) = 3.72, $p = .07$.

The only other significant effects were

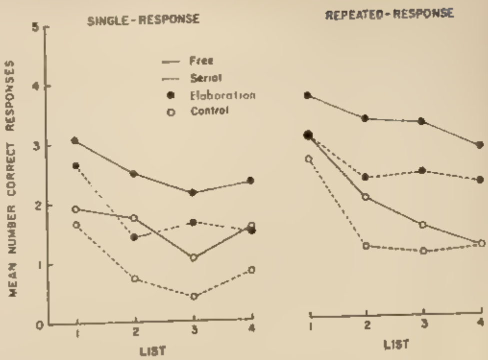

FIGURE 2. Recall in delayed tests.

the main effects of test and list (ps $< .001$) and their interaction, F (3, 117) = 3.71, $p < .025$. Follow-up t tests showed that the recency effect disappeared but the primacy effect remained, and was stronger for free recall than for serial recall. The disappearance of the recency effect wiped out the effect of response treatment on the shape of the retention curves. The effect of elaboration on the shape of the curves did not approach significance (F = 1.12).

The superiority of the elaboration conditions on the delayed tests is ambiguous because of the differences in immediate recall; more was learned, therefore more was retained. To determine whether elaboration affected long-term retention independently of amount learned, the amount of *loss* was analyzed. (The conditional probability of a correct response in a delayed test, given a correct response in the analogous immediate test, could also be used, but because of reminiscence effects it should underestimate retention.)

The only significant effect involving picture treatment was the triple interaction with list and order of tests, F (3, 117) = 3.58, $p < .025$. Of the eight elaboration vs. control differences involved in this interaction, four favored the elaboration group and four the control group, but there was no obvious pattern, overall, and only one difference was significant, favoring the elaboration group in List 1 on the test given second. Thus, in general, loss was not reliably related to picture treatment, indicating that amount lost was generally unrelated to amount originally learned.

The response treatment by list interaction was significant, $F\ (3,\ 117) = 6.95$, $p < .001$. Follow-up t tests showed that in the single-response conditions the most loss was in the recency effect, as theoretical explanations of this effect would predict; and in the repeated-response conditions the most loss was in the primacy effect.

The only other significant effects were order of tests, test, and test by list.

Discussion

Short-term retention. The results show that response repetition facilitates learning of earlier-list responses, presumably because of the extra practice available. Response repetition in the context of elaboration provides more facilitation than response repetition without elaboration, but no more than is provided by single-response elaboration (presumably without response repetition). By analogy, it can be inferred that built-up images facilitate recall partly because of the effect of interactive imagery on retention and partly because of the response-repetition effect on learning. These effects are additive, and equally strong for free and serial recall.

It was expected that free recall would be facilitated more by progressive elaboration than by single-response elaboration. However, they produced equal facilitation, when response repetition was controlled, by equally reducing interlist interference. By analogy, the imagery component of built-up images functions like that of single-response interactive images, and the function is to reduce interference. Thus, interactive imagery per se may produce a basic amount of facilitation, regardless of the complexity of the image (see also Bower, 1972).

An alternative interpretation is possible. Recoding of the stimulus items may have occurred in the single-response elaboration condition (see Keppel & Zavortink, 1969) but not in the progressive-elaboration condition. If so, then the cause of facilitation in the former condition would be reduced stimulus similarity (converting A–B A–C to A–B D–C), and the cause of facilitation in the progressive-elaboration condition might be chunking of the materials (see, e.g., Horowitz, Lampel, & Takanishi, 1969; Taylor, Josberger, & Prentice, 1970). It is possible, in other words, that the finding of equal facilitation for the two kinds of elaboration was fortuitous and does not reflect an underlying single source of facilitation. However, these particular different sources of facilitation do not account for the finding that progressive elaboration and single-response elaboration equally facilitated serial recall as well as free recall. It therefore seems more reasonable to posit a single source of facilitation in the two elaboration conditions, presumably an interactive imagery component. Why it works is not clear, but it appears to function similarly regardless of the complexity of elaboration.

Long-term retention. For long-term retention, neither kind of elaboration provided any *facilitation.* Elaboration effects appeared, but if elaboration had facilitated long-term retention, there would have been less *loss* in the elaboration conditions than in the control conditions. Thus, elaboration did not improve long-term retention; but neither did it interfere.

IMAGERY AND CUED RECALL: CONCRETENESS OR CONTEXT?[1]

RONALD C. PETERSEN[2]

University of Minnesota

Two hypotheses regarding the recall of noun triplets through the use of imagery were investigated in a cued-recall study. An extension of Paivio's conceptual-peg hypothesis for paired-associate learning predicted that the concreteness of the cue word would be the critical factor in determining recall, while a constructive approach to imagery predicted that the retrieval of the context used to construct the image would be the essential element. Sixty-four *S*s formed images for 20 noun triplets with corresponding contexts and were later presented with one member of each triplet and asked to recall the other two members. Results indicated that the elicitation of the context was the single factor determining recall, while concreteness had no consistent effect. Implications of the results for the processes involved in remembering through imaging are discussed.

Imagery has been shown to be an extremely potent variable in many types of learning and memory tasks (see Bower, 1972, and Paivio, 1971, for reviews). While not a greal deal is known about the mechanism by which imagery works, several hypotheses have been offered to explain its effects. For example, to account for the facilitative effect of imagery on paired-associate learning, Paivio (1963, 1965) has offered a conceptual-peg hypothesis. This hypothesis states that when two words are presented together on a study trial, *S* forms a compound image of the referents of these words, such that when one of the words is subsequently presented to *S* on a test trial, it redintegrates the compound image from which the response term is decoded.

From this hypothesis it follows that recall should depend upon the imagery value (*I*) of the members of the pair and, in particular, upon the *I* of the stimlus term. The reasoning for this is that on recall trials, stimulus terms rated high in *I* will be more likely to redintegrate the compound image than those rated low in *I*. A substantial amount of research has been generated by this hypothesis and, almost without exception, has supported the basic position (e.g., Paivio, 1965, 1969, 1971).

Alternatively, if imagery is viewed as a constructive process (Bartlett, 1932; Neisser, 1967), the conceptual-peg hypothesis no longer appears relevant because images are not thought to be "stored" and "retrieved" as such. Instead, an important component of the constructive approach to imagery is the setting or context used to construct the image, and the critical element at the time of recall is the elicitation of this context from which the image can be reconstructed. In other words, a concrete word would be effective as a recall cue only insofar as it elicited the context in which the image was originally constructed. There is nothing inherent in the concreteness itself that makes it particularly effective, and, in fact, an abstract cue word could be more effective than a concrete word as a recall cue if it were more likely to elicit the context.

The present experiment was designed to evaluate these two views of imaging.

[1] This research is based on a PhD dissertation completed at the University of Minnesota. The work was supported in part by grants to the Center for Research in Human Learning at the University of Minnesota from the National Science Foundation (GB-17590), the National Institute of Child Health and Human Development (HD-01136 and HD-00098), and the Graduate School of the University of Minnesota. The author would like to thank his adviser, Paul W. Fox, and the other members of his committee, Raymond O. Collier, Jr., James J. Jenkins, Paul E. Johnson, and David L. Laberge, for their assistance with this research.

TABLE 1

Sample Set of Items as They Appeared to *Ss* in the Associative Rating Task

Cue–context	Responses (high–low)			
Bride–Wedding	4	3	2	1
Glove–Wedding	4	3	2	1
Beauty–Wedding	4	3	2	1
Candle–Wedding	4	3	2	1
Love–Wedding	4	3	2	1
Vows–Wedding	4	3	2	1

Word triplets were used as the materials to be remembered, and each triplet was provided with a context in which the words could be readily imaged. The *Ss*' task was to construct an image for the three words in the setting provided by the context word, such that, when later presented with one of the items in the triplet, they would be able to recall the other two. The conceptual-peg hypothesis predicts that the concreteness of the cue word is the critical element for determining recall; whereas the constructive view contends that the essential factor for recall is the capacity of the cue word to elicit the context in which the image was constructed. These two variables were factorially manipulated to determine which is prepotent.

Preliminary Study

The primary variables in this study involved scaled attributes of the cue words. For example, suppose *Ss* were to form an image for the words, DRESS, RING, and CANDLE, in the context of WEDDING. If CANDLE were to be the cue word for recall, it would be essential to know the *I* of CANDLE and the likelihood with which it would elicit the context, WEDDING, at the time of recall. Therefore, imagery and associative norms were compiled on the materials. The noun triplets were selected by *E* such that the three words were obviously related to a common setting or context. Two of the items were common to all experimental conditions and were concrete nouns which could be readily imaged in the contexts. The third member of the triplet, the cue word, varied on the two scaled dimensions of imagery and association value. The latter dimension assessed the capacity of the cue word to elicit its context. To scale the cue word for each context, several candidates for the four-fold classification of concrete–abstract and high–low association value of cue word to context were selected by *E* for the two norming exercises.

Associative Rating Task

A particular type of associative norming procedure was developed to assess the degree to which the cue words would elicit the context words in this experiment. It was imperative that the measure reflect the likelihood with which a particular cue word (one of the members of the triplet) would elicit the particular context word used for the formation of the image of that triplet. In this sense, the present norming task was developed to reflect the processes proposed to take place at the time of recall. A list of potential stimulus terms was selected, and each term was paired with its context for presentation to a group of *Ss*.

Method

Subjects. The *Ss* were 36 male and 40 female volunteers from an introductory psychology course at the University of Minnesota. Each *S* received course credit for participating.

Procedure. The associative rating task was conducted in one session. Table 1 shows the format for the exercise in which several pairs of words (cue words with contexts) were grouped under their appropriate contexts. The *Ss* were told to interpret the pairs from the frame of reference of the context word which preceded each group of pairs. The *Ss*' task was to estimate for each pair what proportion of a large group of people would respond with the right-hand member of each pair (context) when presented the left member (cue word). The *Ss* made their responses by circling a number from 1 through 4, where 1 indicated that a low proportion and 4 indicated that a high proportion of the population would give the member on the right when presented with the member on the left. Each *S* was given a booklet with 90 pairs grouped under 22 appropriate contexts. The *Ss* were given an explanation of free-association procedures as well as what was required of them in this task. They were told to work rapidly but carefully and were allowed to proceed at their own pace.

Imagery Rating Task

Method

Subjects. Forty males and 60 females from an introductory psychology class at the University of

volunteered to participate in this Each *S* received course credit for ng.

e. The left members of the pairs used sociative norming exercise were presented ... an imagery rating task similar to that of , Yuille, and Madigan (1968). Each word red beside a 7-point rating scale, with 7 ring the high end of the scale and 1 anchoring w end. The *S*s were given imagery rating ctions similar to those of Paivio et al. and allowed to work at their own pace.

ined Results

he two norming tasks yielded two values for each cue word, (*a*) a mean ion value between itself and its con- nd (*b*) a mean imagery rating. For h context, the cue word candidates were oss-classified on the association value and magery dimensions to obtain an item in each cell of the four-fold classification. The members of the classification were determined by selecting words from the extremes of the two dimensions. For the association value dimension, a word was classified as high if it had a mean of approximately three or better and low if its mean was two or less. On the imagery dimension, words with a mean of six or better constituted concrete words, while words with a mean of four or less constituted abstract words. Of the 22 contexts appearing in the norming exercise, 13 yielded candidates fulfilling these cross-classification requirements. Table 2 displays the means in a four-fold array for the 13 target triplets.

TABLE 2

CELL AND MARGINAL MEAN CLASSIFICATIONS OF TARGET ITEMS ON IMAGERY (*I*) AND ASSOCIATION VALUE (AV) DIMENSIONS

Association value	Imagery: Abstract	Imagery: Concrete	Mean AV
Low			
AV	1.68	1.39	1.53
I	2.73	6.23	
High			
AV	3.29	3.57	3.43
I	3.57	5.93	
Mean *I*	3.15	6.08	

MAIN EXPERIMENT

Method

Subjects. Thirty-two males and 32 females from an introductory psychology course at the University of Minnesota served as *S*s. Each *S* volunteered and received course credit for participating.

Design. A 2 × 2 × 2 randomized block design was used, with *S*s being blocked on sex. The other two between-*S*s variables were imagery (concrete and abstract) and association value (high and low). All three variables were crossed, and *S*s were assigned to the various combinations of imagery and association value by their order of appearance at the laboratory.

Materials. The list consisted of 20 triplets and contexts. The first 3 and last 4 groupings were filler items, while the middle 13 triplets were the target items resulting from the preliminary study. Each target triplet consisted of a context and two items that remained constant under all experimental conditions. The third member of each triplet varied according to the particular combinations of imagery and association value. For example, for the context WEDDING, the two constant items were DRESS and RING and the four cue words were as follows: concrete–high association value (AV), BRIDE; concrete–low AV, CANDLE; abstract–high AV, VOWS; and abstract–low AV, BEAUTY.

Procedure. The *S*s were run in groups of 4–10. They were read instructions regarding the nature of imagery and given an example of how they might form compound images for word triplets. In addition, they were told to use the provided context as a setting in which to form the image and to try to remember the triplet, such that when they were given one of the members of the triplet later, they would be able to recall the other two words. The *S*s were then given four examples for which they practiced forming images. The triplets were read to *S*s at a rate of one triplet every 15 sec., followed by a 1-min. subtraction task. After this, *S*s were read one word from each triplet and allowed 30 sec. to write the other two words.

Results

The first 3 and last 4 triplets on the list were fillers; therefore, only the remaining 13 triplets were included in the analysis. A 2 × 2 × 2 analysis of variance was performed on the recall scores, with the three between-*S* variables being imagery (abstract and concrete), association value (low and high), and sex (female and male).

The recall means for the four groups are shown in Table 3. The analysis of variance on these scores revealed two significant main effects: association value, F (1, 56) $= 58.43$, $p < .0001$; and sex, F (1, 56) $= 4.51$, $p < .04$. None of the other main effects or interactions was significant. The

TABLE 3

Mean Recall (*SD*s in Parentheses)

Association value	Imagery	
	Abstract	Concrete
Low	12.50 (5.06)	12.75 (5.50)
High	21.81 (2.86)	20.75 (4.65)

mean recall for the high-AV condition was 21.28 as compared to 12.62 for the low-AV condition, while the means for the two imagery conditions were quite similar (abstract = 17.16, concrete = 16.75). The mean recall for the females was 18.16 and for the males, 15.75. Interactions involving sex were not significant; therefore, this variable was not analyzed any further.

Discussion

The results of this experiment were quite unambiguous: Differences in recall were due solely to the association value of the cue word to the context, and the imagery value of the cue words had no effect. This finding would not be predicted from the conceptual-peg hypothesis, but it is entirely consistent with the constructive process view of imagery.

The important point to be realized from these results is that the critical factor for recall was not the concreteness of the cue words per se; rather, it was the function that the cue words served. In other words, in most of the studies demonstrating the importance of the concreteness of the stimulus term in cued recall (e.g., Paivio, 1965; Yarmey & Paivio, 1965), it is quite possible that the concreteness of the cue word was confounded with the term's capacity to elicit the context used to construct the image. In these studies, the concrete stimulus terms may also have been high in likelihood of eliciting the context used to construct the image, thereby yielding positive results. The present experiment did not confound these two factors and consequently demonstrated that the critical factor was the stimulus term's capacity to elicit the context.

Context is quite vaguely defined here and is meant to refer to the general setting from which the image can be reconstructed. When the statement "eliciting the context" is used, it is meant to refer to the act of restoring the setting used to construct the original image. Nothing is offered here as to how the process actually takes place; instead, the results demonstrate the importance of the reinstatement of the context.

The facilitatory effect of context or themes on the recall of prose is well known (cf. Bartlett, 1932; Bransford & Johnson, 1972; Dooling & Lachman, 1971). Generally, the position taken is that the context or theme is recalled along with a few details, and the remainder is reconstructed. The results of the present experiment indicate that the reinstatement of a context is also a critical element in recall through imagery, and they are consistent with the argument offered for the role of contexts in prose recall.

Both fourth-grade children and adult Ss searched faster for target letters through common words than nonwords (scrambled collections of letters), through third-order pseudowords than nonwords. In fact, both fourth-graders and adults reduced their search time by nearly the same proportion: 10% through common words, 3% through third-order pseudowords. Better readers tended to be faster searchers, but there was no consistent relationship between reading ability and the ability to use the redundancy in words to speed letter research.

Adults can exploit their knowledge of word structure in a letter search task. Krueger's (1970b) undergraduate *S*s searched faster for target letters through real words and third-order pseudowords than through nonwords (scrambled collections of letters). In the present study, Experiment I examined whether fourth-grade children, whose knowledge and fam... ...ty with words is much more ..., yet has had some opportunity to ...velop, also would search faster through words than nonwords. Experiment I also examined whether fourth-grade children would follow the pattern shown by adult *S*s, by searching faster through repeated than nonrepeated letter strings (Krueger, 1970a) and searching faster through coherent sentences than the same words in scrambled lists (Krueger, 1970b).

Experiment I

Method

Subjects. Twenty City College of New York undergraduates, all paid volunteers, served as the adult *S*s. Ten pupils from Public School 192 in Manhattan served as the fourth-grade *S*s (median age: 9 yr., 7 mo.). English was the native language of all *S*s. All *S*s had 20/40 vision (corrected) or better.

Apparatus and materials. Stimuli were presented at 4 mL. intensity on a Gerbrands Model T-3B-1 tachistoscope. The exposure field was illuminated when *S* pressed a foot pedal at the beginning of a trial, and was extinguished immediately upon *S*'s response.

In Sets 1 and 2, each card contained a single (target) letter, centered above a column of five six-letter words or nonwords, typed in all-capitals, one to a line on a 4 × 6 in. white index card, in 10 pitch, IBM Courier 72. All typed lines were double-spaced.

In Set 1, the five six-letter items on each card were either all words or all nonwords. From the 140 common words used by Krueger (1970b, Experiment I), 14 words were chosen in a quasi-random manner so as to match as closely as possible the letter frequency distributions at each letter position in the 140-item set. Fourteen nonwords likewise were drawn from the corresponding 140-item nonword set. The 14 items chosen in each case served as repeated items; 120 of the 126 remaining items were selected for one-time use. A total of 192 cards were constructed: 72 with repeated words, 24 with nonrepeated words, 72 with repeated nonwords, and 24 with nonrepeated nonwords. The same item never appeared twice on a card. Each repeated item appeared on an average 25.7 cards. On 27 of the 72 repeated cards, and 9 of the 24 nonrepeated cards, the target letter at the top was not present in any of the five items below. When the target letter was present, it appeared equally often in either Line 1, 2, 3, 4, or 5, and always appeared in either Letter Position 2, 3, 4, or 5, but never 1 or 6. Each letter position was used equally often for words and nonwords and for repeated and nonrepeated displays. The 192 cards were divided into three equivalent subsets of 64 each, which were

TABLE 1

EXPERIMENT I: RELATIVE REDUCTION IN SEARCH TIME FOR ADULTS AND FOURTH-GRADE *S*s

Group	Repeated vs. nonrepeated words and nonwords (Set 1)	Common words vs. corresponding nonwords[a] (Set 1)	Third-order pseudowords vs. corresponding nonwords (Set 2)	Coherent vs. scrambled passages (Set 3)
Adults	2.2%	8.4%	3.1%	1.0%
Fourth graders	8.5%	10.9%	2.5%	4.2%

[a] Based only on repeated-item displays.

randomized differently for each *S*; the order of the subsets also was rotated across the *S*s.

In Set 2, 16 cards contained five third-order pseudowords and 16 contained corresponding nonwords, selected from a set used by Krueger (1970b). No items were repeated. In each subset of 16 cards, the target letter was not present in 6 cards, and in the remaining 10 cards appeared twice in each of the five rows. The 32 cards were presented in a different random order for each *S*.

In Set 3, the card contained an extended passage, either in its original (coherent) version or in a randomly rearranged (scrambled) version (for further details, see Krueger, 1970b). The single letter was triple-spaced above the set of five lines, which were double-spaced, flush left. The 36 cards were presented in a different random order for each *S*; 18 contained coherent passages and 18 contained scrambled passages. In 6 of the 18, the target letter did not appear at all in the passage; in two cases each, it appeared in Lines 1, 2, and 4, and in three cases each, it appeared in Lines 3 and 5.

Procedure. The *S*s were told to search down the card for the letter shown at the top. Half of the *S*s were told to press the left hand button ("yes") upon finding the target letter, and the right hand button ("no") after searching the entire array without finding the target; for the other half of the *S*s, the hand assignment was reversed. The *S*s were told to search as quickly as possible, but to keep their errors to a minimum. A buzzer sounded when *S* pressed the incorrect button; all errors were excluded before search time was averaged.

Eight practice cards containing rare words or corresponding nonwords were presented first, followed by Set 1, then Set. 2 The *S*s next rated 56 items (a randomized list of 14 repeated words, 14 nonrepeated words, 14 repeated nonwords, and 14 nonrepeated nonwords) as to whether they had been presented more than once in Set 1. The adult *S*s next received the Nelson-Denny Reading Test, Form A, which measures vocabulary, reading comprehension, and reading rate. Eighteen of the 20 adult *S*s subsequently received Set 3, on either the same or a later date.

Each child received Set 3 at a later date, followed by the Gates-MacGinitie Reading Test, Survey D, Form 1M. Scores also were available on the Metropolitan Achievement Test, Elementary Level, Form H, administered at the child's school two to four months previously. Data from one child on Set 3 were excluded because of failure to follow the instructions properly.

Results

Search performance. The adults searched about twice as fast as the fourth-grade *S*s; to scan down an average 3.75 items in the Set 1 nonrepeated-nonword displays, for instance, took an average 3.38 sec. for adults and 6.75 sec. for fourth-grade *S*s. In Set 1, mean search time was significantly lower for adults than fourth graders, F (1, 28) = 49.62, $p < .001$, for word than nonword displays, F (1, 28) = 49.26, $p < .001$, and for repeated-item than nonrepeated-item displays, F (1, 28) = 18.30, $p < .001$. Significant interactions were found for Adults vs. Fourth-graders × Words vs. Nonwords, F (1, 28) = 5.11, $p < .05$, and for Adults vs. Fourth Graders × Repeated vs. Nonrepeated, F (1, 28) = 11.04, $p < .01$, reflecting the fact that search time decreased more for fourth graders than for adults when word or repeated-item displays were presented. When the decrease in search time is expressed not in absolute, but in relative terms, that is, as the percent reduction of baseline nonword or nonrepeated search time (see Table 1), fourth-graders still differed significantly from the adults on repeated vs. nonrepeated, t (28) = 2.86, $p < .01$, but not on words vs. nonwords.

In Set 1, the error rate was significantly lower for adults than fourth graders, 7.1% vs. 12.6%, F (1, 28) = 12.14, $p < .01$, and for word than nonword displays, 5.1% vs. 11.2%, F (1, 28) = 14.06, $p < .001$. Although the repeated vs. nonrepeated main effect (8.5% vs. 9.3%) was not significant, the Word vs. Nonword × Repeated vs. Nonrepeated interaction was significant, F (1, 28) = 6.21, $p < .025$, reflecting the fact that the repeated-nonrepeated difference was larger among nonword than word displays. No other interaction was significant.

The *S*s rated 56 words and nonwords from Set 1 as to whether they had occurred

once on the search displays. liott's (1964) table, d' values were d, based on the frequency with s answered "yes" to repeated items ite) and nonrepeated items (false rate). The mean d' value was significantly greater than zero, both for adults, 1.21, t (19) = 9.64, $p < .001$, and rth-grade *S*s, $d' = 1.00$, t (9) = 4.15, $< .005$; the difference between adults and rth graders was not significant. Mean was significantly greater for words than nwords, F (1, 28) = 14.79, $p < .001$, and word-nonword difference was virtually ie same, for adults, 1.51 vs. .91, and graders, 1.28 vs. .71.

In Set 2, the decrease in search time for third-order pseudowords (vs. corresponding nonwords) was significant for adults, t (19) = 2.29, $p < .05$, but not for fourth graders. The relative reduction in search time, shown in Table 1, was significantly smaller for the third-order pseudowords in Set 2 than the common words in Set 1, F (1, 28) = 20.10, $p < .001$. This factor did not interact significantly with adults vs. fourth graders. The mean error rate did not differ significantly between third- pseudowords and nonwords, for ther adults (3.1% vs. 4.7%) or fourth-grade *S*s (13.8% vs. 13.8%).

In Set 3, search was faster, but not significantly so, through coherent passages than scrambled ones, among both adults and fourth graders (see Table 1). Similarly, error rate was slightly, but not significantly lower for coherent passages, for adults (18.3% vs. 18.9%) and fourth graders (20.6% vs. 21.1%).

Correlations between search and reading measures. The various reading measures were highly and usually significantly ($p < .05$) intercorrelated. The correlations ranged from $r = +.47$ to $+.96$ among the children's measures (Metropolitan: word knowledge, reading; Gates-MacGinitie: speed, accuracy, vocabulary, comprehension), and $r = +.35$ to $+.89$ among the adult measures (Nelson-Denny: reading rate, vocabulary, comprehension). The high correlations indicate that there was a good spread in reading ability, both among the children and the adults. Thus, on the vocabulary test for the adults, the scores ranged from the 1st to the 93rd percentile, based on Grade 16 norms, with the median score at the 51st percentile. For the children, on the total reading ability measure of the Metropolitan Achievement Test, the scores ranged from the 18th to the 92nd percentile, based on Grade 4 norms, with the median score at the 48th percentile.

Search time invariably correlated negatively with the various reading measures, indicating that poor readers generally took longer to locate the target letter than did good readers. (The correlations were computed separately, and yielded quite similar results, for search time through repeated common words and search time through repeated nonwords.) Among fourth graders these correlations were significant ($p < .05$) for all four Gates-MacGinitie measures, ranging from $r = -.63$ to $-.73$, but not for either Metropolitan measure, ranging from $r = -.36$ to $-.56$. Among adults the correlations, ranging from $r = -.14$ to $-.32$, were not significant.

No trend was apparent at all, however, in the correlations between reading measures and the absolute or relative reduction in search time for various types of material (i.e., words, repeated items, coherent passages). The correlations were generally quite small, and were negative about as often as positive. The only significant correlations were between reading rate in adults and absolute ($r = -.55$, $p < .02$) and relative ($r = -.49$, $p < .05$) reduction in search time through coherent passages.

Discussion

As the significant d' scores indicate, both adult and fourth-grade *S*s discriminated rather well between the repeated and nonrepeated items. Schulman (1971) obtained similar results when he tested *S*s on their recognition memory of words they had scanned through for the letter A. Neisser (1964), on the other hand, reported that *S*s usually could not distinguish words that had appeared on a list from words that had not, when tested immediately after a scan. Neisser proposed a

hierarchical model in which nontarget letters are analyzed only so deeply that they may be discarded from further consideration. Neisser's well-practiced *S*s reported that they did not even "see" nontarget letters during search for a target letter. The present findings, based on the performance of relatively unpracticed *S*s who were set for accuracy as well as speed, indicate that nontarget letters not only are seen, but may even be organized and remembered as entire words or nonwords.

The adults searched about twice as fast as the fourth graders, which confirms previous work with third graders (Forsman, 1967) and fourth graders (Leslie & Calfee, 1971). The present finding that in the fourth grade the better readers search faster than do poor readers, though, contradicts two recent studies: Leslie and Calfee (1971), using second, fourth, and sixth graders, found no relationship between reading level and search rate for target words, and Katz and Wicklund (1972), using second and sixth graders, found no difference between good and poor readers in letter-search rate through nonsense items. On the other hand, Spring (1971), using third, fourth, and fifth graders, found longer latencies for poor than normal readers on the "same"-"different" judgment of two adjacent letters.

Since older *S*s and better readers exhibited superiority on the general skill of visual search, one would have expected them to exhibit an even greater superiority on the specific skill of exploiting their knowledge of English word structure to speed search for letters. As it turned out, however, reduction in search time through words was as great for children as for adults, as great for poor readers as for good readers. This result will be discussed more fully after Experiment II has been presented. Experiment II, in which 40 adult *S*s participated, provided another test of whether the exploitation of word structure in letter search is related to reading ability.

Experiment II

Method

Subjects. Forty City College of New York undergraduates served as paid *S*s.

Apparatus and materials. Search displays were presented in a light-tight wooden box containing a semitransparent (one-way) mirror (12 × 15 in.); *S* could see into the box whenever four 40-w. lamps inside were lit. On each trial, *E* first slid a plank containing the 8½ × 11 in. stimulus sheet into the box, and then closed a switch which illuminated the lamps and started a Standard Electric, Model S-1 timer (calibrated to .01 sec.). The *S*'s response extinguished the lamps and stopped the timer.

The sets of 140 common words and 140 corresponding nonwords used were the same as in Experiment 1. Each stimulus sheet contained either 25 six-letter words or 25 six-letter nonwords, typed in one column, single-spaced, in 12 pitch, IBM Prestige Elite 72. Sampling of items was random, except that no word or nonword appeared twice on a given list of 25. Each *S* saw 22 word and 22 nonword displays, which were randomly intermixed. The target letter was actually present in 15 of the 22 displays, appearing once each in Item Positions 2 and 4, and in all odd-numbered positions from 1 to 25 (for further details, see Krueger, 1970b).

Procedure. On each trial, after *S* saw the target letter and indicated he was ready, *E* turned on the timer and lamps. The *S* was told to press the right-hand ("yes") switch as soon as he found the target letter, or, if it was not present, to press the left-hand ("no") switch. The *S* received three practice trials. The *S* was informed when he pressed the incorrect switch, in which case his search time was discarded for both the word and nonword displays having a target at the particular location. After completing the letter search task, *S* received the Nelson-Denny Reading Test, Form A, and the Wellesley Spelling Scale, Form 1.

Results

Search performance. Mean search time, through an average 15.8 items, was 8.48 sec. for word displays and 7.71 sec. for nonword displays. The 9.1% relative reduction in search time for words (vs. nonwords), was significant, $t\ (39) = 4.8$, $p < .001$. The error rate was somewhat, but not significantly, higher for nonword (11.3%) than word (9.2%) displays.

Correlations between search and reading and spelling measures. As in Experiment I, the reading and spelling measures were highly and usually significantly ($p < .05$) intercorrelated (range: $r = +.26$ to $+.73$), indicating again a good spread in reading ability. Thus, on the vocabulary test, the scores ranged from the 2nd to the 99th percentile, based on Grade 16 norms, with the median score at the 72nd percentile. Also as in Experiment I, reading and spelling measures generally correlated negatively with search time for words and nonwords, $r = +.03$ to $-.34$. That is, better readers tended to search faster than poor readers. The only significant correlation, though, was that between reading rate and mean

se..h time through words, $r = -.34$, p...

...Experiment I, the correlations ...the reading measures and the ...ion in search time for words (vs. ...ords), were all positive, both for ...lute reduction ($r = +.03$ to $+.32$) and f.. relative reduction ($r = +.09$ to $+.39$). ..at is, better readers tended to take more ..dvantage of the familiar contexts of words ..n reducing search time. The only signifi...ant correlations, though, were those be...veen reading comprehension and relative ...duction in search time for words, $r = +$ ..39, $p < .02$, and reading comprehension ..d absolute reduction, $r = +.32$, $p < .05$.

General Discussion

Perhaps the most striking finding of the present study is that fourth-grade children made as much use of the redundancy in English and near-English letter sequences as did adults. Both adults and fourth-grade children speeded their search for letters by about 10% when nonwords were replaced by common words, by about 3% when nonwords were replaced by third-or..er pseudowords (see Table 1). These resul.. ..e in very nicely with the findings of ...nd Smith (1970), who found that the ..ility to use intraword redundancy in the identification of letters increased only up to the fourth grade, where adult-level skill was achieved.

The mastery of letter and word recognition skills by the fourth grade is very important, because the child is thereby freed to develop more complex skills in reading. Singer (1970) reported that the "system for attaining Speed of Reading undergoes a developmental shift from a predominance of visual perceptual abilities at the third grade to a more equitable organization of visual perceptual and word meaning factors at the sixth grade level [pp. 215–216]."

Of course, the visual perceptual component in reading may continue to improve to some extent well past the fourth grade, and better readers may ever surpass poor readers, as shown, for instance, by the fact that even among adults, the better readers tended to search faster for target letters. Among adults, however, reading ability accounted for no more than about 10% of the variation on search time. Among the fourth graders, by contrast, reading ability, as variously indexed, accounted for about 15–50% of the variation on search time.

THE LOCUS OF THE RETENTION DIFFERENCES ASSOCIATED WITH DEGREE OF HIERARCHICAL CONCEPTUAL STRUCTURE [1]

BENTON J. UNDERWOOD,[2] JOHN J. SHAUGHNESSY, AND JOEL ZIMMERMAN

Northwestern University

Constant-order paired-associate lists were used in which the numbers 1 were stimulus terms, and 24 nouns were response terms. The order of t nouns was varied across five lists to produce a different number of hierarchi conceptual levels in the lists. There were two degrees of original learning a three types of retention tests after 24 hr. The study–test method was us Learning rate was related directly to the degree of conceptual structure, retention was uninfluenced by structure. A further experiment showed th the direct relation between recall and structure found in an earlier study is t be attributed to the anticipation method in which information at recall is i an amount that is directly related to the conceptual structure.

In a previous study (Underwood & Zimmerman, 1973), 16 words were ordered serially so that a three-level conceptual hierarchical structure resulted. If *S*, in learning the list, followed the rules implied by this structure, placement of each word in its appropriate position within the list was possible. Other lists were constructed from the same words in a way such as to violate the appropriateness of successive conceptual levels. The purpose of this previous study was to determine the role of conceptual structure on the learning and retention of the lists. Two findings emerged. First, learning rate was related directly to degree of conceptual structure up to a point, and second, recall after 24 hr. was related directly to degree of structure. This latter finding conformed in general to the notion that associations learned in the laboratory which are compatible with already established associations will show less rapid forgetting than will be the case for associations which are in conflict with established habits. In the previous study, this latter case was represented at the extreme by the 16 words presented in random order. It was presum that for such a list the long-established onceptual habits would interfere with th propriate ordering of the words at re In fact, however, the overt-error da gave no evidence that the poorer recall the random list than of the structural list was due to such interference. Thus, the reasons for the differences in recall remained obscure.

The intent of the present study was identify more precisely the characteristic of the memory for structured and unstructured lists. By so doing it was believed that the characteristic or characteristics responsible for the differences in retention might be isolated. Two different levels of learning were used as a means of varying the degree to which the conceptual structure had become a part of the memory for the lists. Since the utilization of a conceptual structure to mediate item placement at the time of retention may be critically time dependent, three different types of retention tests were used, namely, paced and unpaced recall, and unpaced associative matching.

Main Experiment

Method

Lists. Five different lists were constructed, all from the following 24 words: *robin, owl, bobolink, trout, guppy, sturgeon, apple, lemon, fig, rose, lilac, marigold, beer, rum, sherry, milk, soda, cocoa, diamor*

[1] This research was supported by the Personnel and Training Research Programs, Psychological Sciences Division, Office of Naval Research, under Contract N00014-67-A-0356-0010, Contract Authority Identification No. NR 154-321.

opal, sapphire, iron, brass, tungsten. These 24 words, presented as in the order listed above, formed the most highly structured list, to be called List 5. It will be noted that at the lowest conceptual level in List 5 there are three instances of each of eight concepts, birds, fish, fruit, flowers, alcoholic beverages, nonalcoholic beverages, precious stones, and metals. At the next conceptual level there are four concepts, animals, plants, beverages, and minerals. At the third level, living and nonliving things divide the list in half.

In List 5 the three instances within each concept were ordered serially (as above) such that the first instances had high frequency in the Battig–Montague (1969) norms, the second medium frequency, and the third, low frequency. Given this ordering the *S* could, in a manner of speaking, run off the three instances within a concept according to a frequency rule. In the previous study (Underwood & Zimmerman, 1973), this variable, with two instances of each concept, did not influence learning. However, there were reasons to believe that the earlier lists were not entirely satisfactory for a test of the frequency rule and so this variable was included again in the present experiment.

The nature of the other four lists may now be described. For List 4 the conceptual structure remained the same as in List 5, but the order of the three instances within each of the eight concepts was randomized to neutralize any influence of a word-frequency rule. In List 3 the order of the animal names was arranged so that the concepts birds and fishes were not appropriate for three successive items, but the concept animal was appropriate for a block of six words (*robin, trout, sturgeon, owl, guppy, bobolink*). The same was true for plants, beverages, and minerals. Therefore, the four intact concepts in List 3 could mediate placement only within a block of six positions. For List 2 only the living–nonliving distinction was maintained so that the implementation of this distinction by the *S* would restrict placement to halves of the list. Finally, in List 1, the ordering was random so that no conceptual mediation of placement of groups of words was possible.

The lists were presented as constant-order paired-associate lists with the numbers 1–24 in order as stimuli and with the words as response terms. In the previous experiment, this procedure gave results which were essentially equivalent to those found when the words were presented as a true serial list.

Conditions. One variable, of course, was defined by the five lists as explained above. A second variable was the degree of learning prior to the 24-hr. retention interval. Half of the *S*s learned to a criterion of 12 correct responses on a single trial, half to a criterion of 20 correct responses on a single trial. A third variable was the nature of the retention test. Half of the *S*s were given a paced-recall test, the rate being the same as used during learning. For these *S*s, recall was followed by relearning to one perfect recitation but with a minimum of three relearning trials after the recall trial. Half of the *S*s were given unpaced retention tests consisting of two steps. Initially, a sheet was provided the *S* on which the numbers 1 through 24 were listed with a blank after each. The *S* was given unlimited time to write down all of the appropriate response terms he could, guessing being encouraged. Following this step, a list of the 24 response words was provided the *S* on a second sheet and he was asked to match each word with a number, using each only once. He was required to fill each blank with a word even if it involved guessing.

The five lists, two degrees of learning, and two types of retention tests resulted in 20 different conditions. Four further conditions were added to provide controls for possible differential performance on the postcriterial trials of learning. The study–test method was used during learning, and although the use of this method is normally expected to minimize differences on postcriterial trials as a function of rate of learning, it was believed necessary to provide some minimal information about the matter. Consequently, four groups were given immediate retention tests after achieving the criterion of 20 correct responses on a single trial. Two of these groups learned List 1, and two learned List 5. For each list, one group was given paced recall and relearning, one unpaced recall, followed by matching.

There were 24 groups of college-student *S*s, one corresponding to each of the 24 unique conditions, with 18 *S*s in each group. Assignment to a particular group was made from a schedule containing 18 blocks of conditions, with each condition occurring once within each block. A different random order was used for the conditions within each block.

Procedure. All lists were presented for alternate study and test trials at a 1.5-sec. rate for both. When the appropriate criterion was achieved, the *S* either was dismissed from the laboratory (to return 24 hr. later) or was given an immediate retention test. On the immediate paced tests the experimenter stopped the memory drum, told the *S* that he would now have another test trial, with further study and test trials to follow, and that he should try to get as many correct as possible. For the unpaced tests (both immediate and delayed) the recall sheet was given the *S* and he was asked to follow the printed instructions on the sheet as the experimenter read these instructions aloud. He was given a second sheet (described earlier) for the matching test. All *S*s having 24-hr. tests were reminded that they had learned a list of words the previous day and that a test of their memories for this list was the purpose of the present session.

Finally, all *S*s having the 24-hr. retention tests were given an open-ended questionnaire concerning rehearsal activities they might have engaged in over the 24 hr. They were asked to describe any experiences they had with the words during the 24-hr. period, whether they had rehearsed or thought about the words, and so on. Honesty and accuracy were emphasized since (the *S* was told) such replies were valuable in helping to understand the nature of memory.

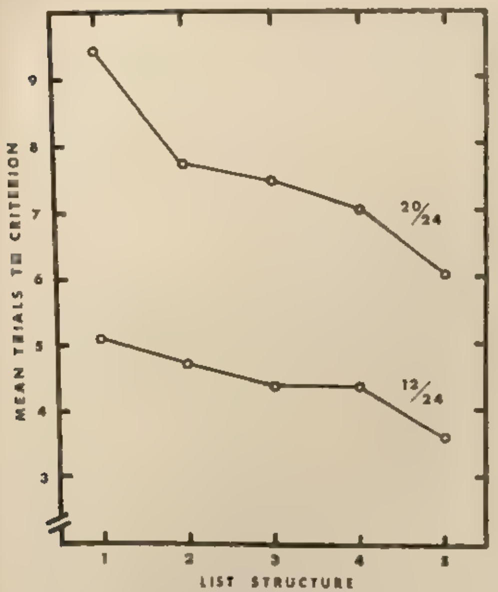

FIGURE 1. Mean number of trials to reach two different criteria of learning (12 correct on a single trial, and 20 correct), for lists varying in conceptual structure from low (List 1) to high (List 5).

Results

Original learning. For an examination of learning as a function of list structure, the *S*s who would subsequently receive different retention tests were combined to provide 36 *S*s having had each of the five lists at each criterion of learning. The data are plotted in Figure 1 in terms of the mean number of trials required to reach the two criteria. For convenience, the five lists are equally spaced along the baseline, indicating increasing structure from List 1 to List 5. It can be seen that as list structure increased, trials to learn decreased. This is true for both criteria, and summed across the two, the effect is significant statistically, F (4, 350) = 8.08, $p < .01$. Although the influence of list structure appeared to be somewhat greater for the higher criterion of learning than for the lower criterion, the interaction was not reliable, F (4, 350) = 2.14, $p > .05$. In the previous study (Underwood & Zimmerman, 1973), learning rate increased from List 1 through List 3 with no further increase for Lists 4 and 5. It is not known whether this difference is due methods of learning (anticipation vers dy-test, or to list differences. The was some evidence in the earlier study some of the instances defining the low level concepts were not always unders by the *S*.

It will be remembered that 5 differed from List 4 only in terms of ordering of the three words within ea the eight concepts. For List 5 th rds were ordered from high to low in ns of the frequency with which the i ces were produced to the concept nam the Battig and Montague (1969) normati tudy. In List 4, the three words wer domized. As seen in Figure 1, List 5 was ned more rapidly than was List 4, and was true for both criteria. An analysis variance with Lists 4 and 5 as one varial , and the two criteria as the other, showe he difference between the lists to reliable, F (1, 140) = 5.45, $p < .05$.

The effect of word frequency r all lists was also examined. Three score were obtained for each *S*, these repre nting the number of times the eight hig frequency instances were given correctly, the number of times the eight medium-frequency instances were given correctly, and the number of times the eight low-frequency instances were given correctly. Across all lists combined for the lower criterion of learning the three means were 13.99, 11.02, and 9.84, for the high-, medium-, and low-frequency instances, respectively (F = 87.59). These differences essentially disappeared at the higher criterion of learning for Lists 4 and 5, but were still quite evident for the other three lists. It appears, therefore, that one of the characteristics of initial learning of these lists by the study–test method was that either because of ease of learning of words with high frequencies, or because of priority effects, or both, the *S* acquired the high-frequency instances initially regardless of the conceptual structure of the list.

Still another finding could be interpreted as a word-frequency effect. Some observations of the experimenters suggested that the learning of the concepts differed fo men and women. The learning of List

d 5 was evaluated to see if these ob- ns had validity. The 144 *S*s (both of learning) consisted of 77 men 7 women. The number of correct re- nses within each of the eight concepts determined for each group. These are tted in Figure 2 for two reasons. First, hey show the nature of the serial-position urve which obtains even for the highly structured lists. Second, they indicate differential learning of certain concepts by men and women. Overall, the learning of the two groups did not differ ($F < 1$), but the interaction between concepts and sex was reliable, F (7, 994) = 3.13, $p < .01$. Three concepts produced substantial differences in learning between men and women, namely, *flowers*, *alcoholic beverages*, and *precious stones*. It may be that cultural experiences have resulted in women having a greater familiarity for words representing *flowers* and *precious stones* than is true for men, and that the opposite is true for *alcoholic beverages*. In any event, these results are similar to those reported by Bousfield and Cohen (1956) when they used free-recall learning of groups of conceptually related words.

Figure 2 suggests that the words which represented the first occurrence of a nonliving concept (alcoholic beverages) caused a distinct break in the position-performance curve. However, this is primarily a function of the particular words involved. For Lists 2 and 3, where the living–nonliving break also came between Positions 12 and 13, there was no evidence of discontinuity between the two positions.

Overt errors. The first overt error analysis to be presented dealt only with the number of errors across lists. The 360 *S*s from whom the acquisition data were derived (as plotted in Figure 1) were used. The error measure was the proportion of times an error was produced per opportunity (number of overt errors/number of omissions plus overt errors). For the 10 groups this ratio varied between .10 and .19. The values were greater statistically for the high-criterion groups than for the low-criterion groups, F (1, 350) = 8.33, $p < .01$, the means being .16 and .12. The errors

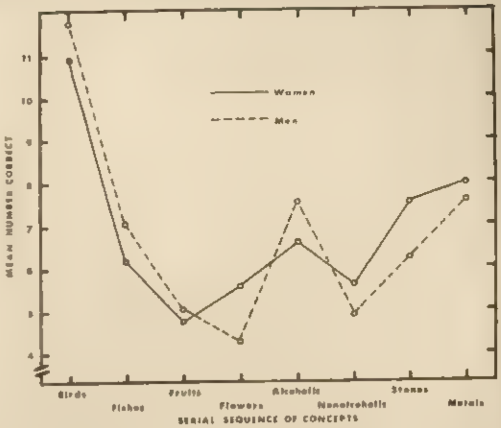

FIGURE 2. Learning of the highly structured lists as a function of the particular concepts (and their positions in the list) by men and women.

increased with list structure (.11, .11, .15, .15, .16), F (4, 350) = 4.08, $p < .01$. The F for the interaction was less than one. Undoubtedly, some correct responses resulted from guesses within concepts, particularly for the more structured lists, but in view of the relatively low proportion of overt errors to cases of not responding, it does not seem likely that mere guessing is heavily involved in the correct-response data.

For Lists 4 and 5, overt errors can be identified as having one of four levels of appropriateness in terms of the conceptual structure for these lists. These will be described and illustrated. An error may occur within the appropriate block of three instances representing the same concept. Saying "guppy" to one of the two stimuli to which it was an incorrect response in the block of three fishes was such an error, and will be called here an error at Level 1. Six words were involved in the animal block; if "guppy" was given to one of the three stimulus terms appropriate for birds, it was defined as a Level-2 error. Twelve words were included in the living block; if "guppy" was given to any of the six stimuli paired with plants, it was called a Level-3 error. Finally, if "guppy" was given as a response to any of the 12 stimuli paired with nonliving objects, it was called a Level-4 error. All errors were classified

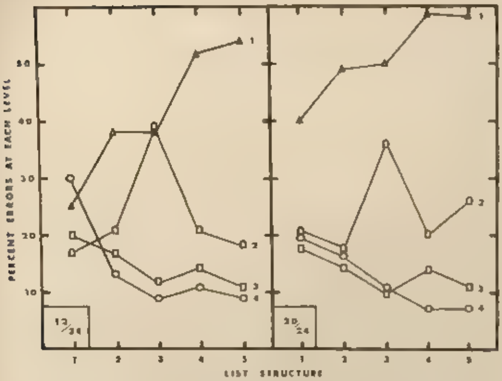

FIGURE 3. Locus of overt errors as a function of list structure and degree of learning. (The numbers 1, 2, 3, and 4 represent an increase in the discrepancy between the locus of an error and its correct position as defined by the conceptual structure of Lists 4 and 5.)

into one of these mutually exclusive categories for Lists 4 and 5. Conceptual level and position within Lists 4 and 5 are perfectly confounded. Position is also tied to stimulus number. Therefore, any analysis of the appropriateness of overt errors to the conceptual structure must consider the number of such errors which were produced by position per se. To handle this problem, the overt errors made in learning all five lists were categorized in exactly the same way as was done for Lists 4 and 5. For example, if, for List 1 (no structure), a misplaced response occurred among the first three pairs, it was classified as a Level-1 error, just as was done for List 5. Or, if an error made to the stimulus-term 9 was an appropriate response for the stimulus-term 3, it was classed as a Level-3 error. To summarize: for all lists the errors were classified as falling within one of eight blocks of 3 positions (Level 1), one of four blocks of 6 positions (Level 2), one of two blocks of 12 positions (Level 3), and, all others (Level 4).

The errors made by each *S* were allocated to the appropriate level and the percentage of errors in each level was determined. The means of these values were used to construct Figure 3. The sums of the percentages for a given list do not always equal 100 since a few *S*s produced no overt errors, and the means shown in Figure 3 were always based on $N = 18$. It should be noted that list structure is along the abscissa, with the error levels (1, 2, 3, 4) as the plotting parameter. The left panel represents the data for the *S*s who learned to a criterion of 12 correct, the right panel for those who learned to a criterion of 20 correct. Several features may be noted. For Lists 4 and 5, the greatest percentage of errors by far was that for errors falling into Level 1. Over half the errors made by the *S*s learning these lists represented errors that were approrpiate to the narrowest conceptual categories. The Level 1 values for List 1, values which should represent in relatively pure form the effects of position as such, are at 25% for the lower criterion, 40% for the higher criterion. In List 3 the narrowest conceptual category consisted of six words. If conceptual structure were used by the *S* in the placement of items in this list, he could reduce his possibilities to one of six positions. As may be seen in Figure 3, the maximum number of Level-2 errors occurred in learning List 3, these errors reflecting placement within a block of six words. For List 1, the random list, the maximum frequency of errors for the lower criterion was in Level 4, which means giving a response in one half of the list which actually belonged in the other half. There is only slight evidence that the living–nonliving distinction influenced the errors, this being shown in the fact that fewer errors at Level 4 were made by the *S*s learning List 2 than by those learning List 1. As would be expected, the major difference in the errors for the two criteria of learning was that there was an increase in Level-1 errors from the lower to the higher criterion, with the increase being the greatest for the lists with low structure. In summary, Figure 1 showed that learning was related directly to the number of appropriate conceptual levels involved in the list; the error data of Figure 3 indicate that these conceptual levels aided learning because they limited the number of possible numerical stimuli or positions for which a particular word was appropriate.

There is the possibility that with zero conceptual structure (List 1), the presence of conceptually related words actually interfered with learning. If such interference was present, it was not manifest in the error data. The errors made in learning List 1 were divided into two categories, those which were given to a stimulus for which another instance of the same concept was appropriate, and those which were not appropriate in the above sense. The concepts used were the eight with the three instances each. To illustrate: saying "guppy" to the stimulus appropriate for *trout* would be viewed as evidence for interference; giving "guppy" to the stimulus for *milk*, would not. Errors which would constitute evidence for interference constituted 7.6% of the total errors. Chance responding would be expected to yield 8.7% of such errors. This indicates that interference resulting from the conceptual relationships among the words was minimal in the unstructured list

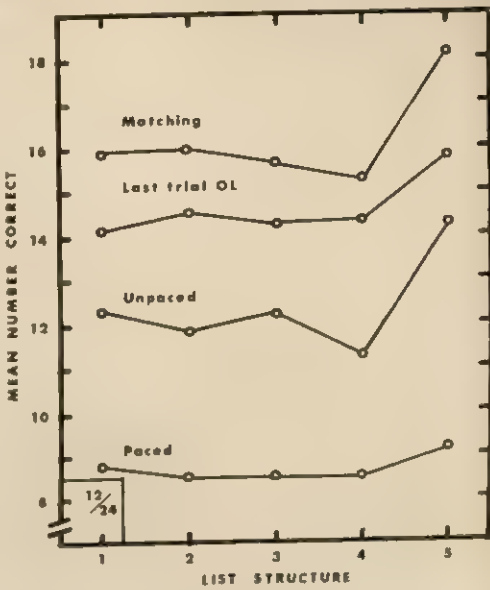

FIGURE 4. Number of correct responses on the various retention tests after 24 hr. following original learning to 12 correct responses. (Number correct on the last learning trial is also shown.)

Retention. The retention data will be presented first for the *S*s who learned to a criterion of 12 correct on a single trial. The results for all three retention tests are shown in Figure 4. To replicate the earlier study (Underwood & Zimmerman, 1973), performance should have increased as list structure increased. It is obvious from Figure 4 that list structure had little effect on retention. The means for the paced 24-hr. recall showed little variance ($F < 1$). For unpaced recall, performance was about the same for Lists 1 through 4, with an increase for List 5. However, the F for the recall for the five lists was only 1.37. It can be seen that performance on the last trial of learning was higher for List 5 than for the other four lists. It is likely, therefore, that the retention of List 5 for both paced recall and matching reflected this higher degree of learning, although it is not clear why paced recall for this list should not have been more influenced by this factor than it was. The fact that matching exceeded unpaced recall indicates that the *S*s were unable to recall some response words but could pair them appropriately when given the matching test. Again, however, the lists did not produce differential performance on the matching task ($F = 1.46$).

No immediate retention test was given to *S*s learning to the lower criterion so it is difficult to calculate the amount of forgetting which took place over the 24 hr. However, the number correct on the last trial of original learning does give some basis for a rough estimate. An immediate test would probably have shown some loss due to the fall normally found after reaching a criterion. As will be shown later, it would not be unreasonable to expect this loss to be at least one to two items. If so, the amount of forgetting was between 30% to 40% for the paced recall for the five lists. The critical fact is that list structure was unrelated to the amount lost over 24 hr

The next data to be examined are the retention scores for those *S*s who learned to a criterion of 20 correct responses. These are shown in Figure 5. For these comparisons, immediate tests are available for Lists 1 and 5 (dotted lines). It may be noted that the mean number correct on the last test trial of original learning varied between

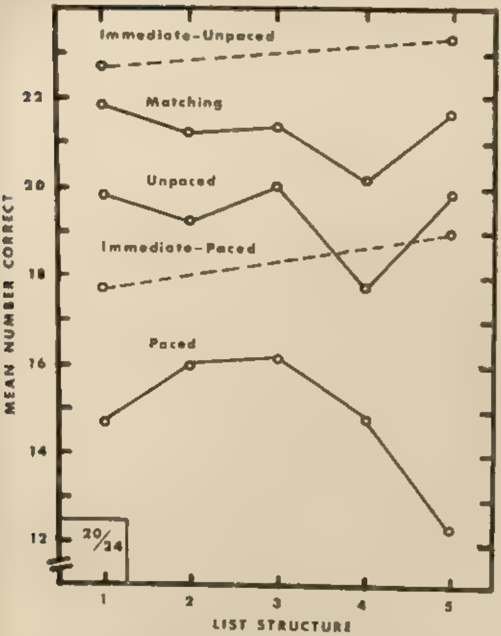

FIGURE 5. Number correct on the various 24-hr. retention tests following original learning to 20 correct responses. (Number correct on the immediate tests for Lists 1 and 5 is also shown.)

21 and 22 correct responses. Paced recall means varied between 12.28 for List 5, and 16.11 for List 3. Yet, overall the F was only 1.74. Because of the apparent difference in paced recall as a function of list structure for the two levels of original learning (Figure 4 versus Figure 5), an analysis was performed on these 10 groups. List structure was not a reliable source of variance ($F < 1$), level of original learning was ($F = 93.14$), but the interaction was not ($F = 1.66$). Thus, in spite of apparent differences when viewed graphically, both levels of original learning resulted in the same conclusion, namely, that list structure and paced recall were not related. Figure 5 suggests the possibility that there was an interaction between immediate paced recall and 24 hr. paced recall for Lists 1 and 5. A statistical analysis fails to confirm the reliability of this interaction, F (1, 68) = 3.34, $p > .05$. Using the immediate paced recall as a base, forgetting for paced recall is estimated at 25% across the lists as a whole.

It is obvious that forgetting als curred over the 24 hr. for the *S*s give paced recall. Again, however, list st re was not related to the amount of r under the unpaced procedure ($F < 1$ d the matching scores almost perfect flected the unpaced recall except the l was a little higher. In summary: th ention data for both levels of learning, paced, unpaced, and matching, all lead e conclusion that there was no syste relationship between list structure an rning using the study–test method.

The number of misplaced resp ses at recall was examined for all pac -recall groups. These numbers did not d er as a function of the criterion of learn g, but for both levels of learning the nu ber of misplaced responses at recall incr sed as list structure increased, F (4, 170) = 5.81, $p < .01$. This same relationship w found during learning and so is not a phenomenon peculiar to recall. For unpaced recall, however, list structure did not i luence the number of incorrectly-paired responses given.

As noted earlier, during learning of the constant-order paired-associate lists, very clear serial-position effects were present. These position curves were in evidence for all of the types of retention tests. Furthermore, there was a strong relationship between the number of times an item was given correctly in original learning and the number of times given correctly at recall, which is to indicate that the position effects remained essentially constant from learning to recall. For example, for the lower criterion, the correlations between number of times correct in original learning and number of times correct at recall varied between .77 and .91 for the five lists. Degree of original learning was obviously a powerful determiner of the items which were recalled.

Relearning. Differences in relearning as a function of list structure appeared on the first test trial after recall, and in terms of trials to reach a criterion of one perfect recitation, were reliable, F (4, 170) = 4.14, $p < .01$, with, of course, rate of relearning being directly related to structure. Thus,

list structure, which did not influence recall, q[illegible] reinstated during relearning the in[illegible]ce it had had during original learning.

[illegible]earsal and recall. The *S*s were given an open-ended questionnaire concerning th[illegible] rehearsal activities over the 24 hr. The replies to these questionnaires were r[illegible]ed on a 9-point scale for the amount of [illegible]earsal implied in the protocols. These [illegible]ngs were carried out independently by [illegible]e different people. Interrater reli[illegible]ities were determined for 18 subblocks [illegible]20 *S*s each. Of the 54 correlations possible, 11 were between .71–.80, 29 be[illegible]een .81–.90, and 14 were .91 or greater.

There were 20 groups of *S*s of 18 each having 24-hr. recall. All correlations between rated rehearsal activity and retention were positive, varying between .14 and .81. There was no relationship between rated rehearsal activity and list structure, and the magnitude of the correlations between rehearsal and retention did not vary systematically as a function of list structure.

The positive relationship between reported rehearsal and retention allows several alternative interpretations. For example, rehearsal may have increased retention, or, as another interpretation, *S*s with good retention may have rehearsed. The concern of the present study was whether or not rehearsal differed as a function of list structure. Since it didn't, it seems unlikely that the failure to find an influence of list structure on retention could be due to differential rehearsal. Also, if the present evidence on rehearsal can be generalized to the earlier study (Underwood & Zimmerman, 1973), it seems unlikely that the positive relationship between list structure and retention as reported for that study was due to differential rehearsal.

Discussion

In the previous study, paced recall and list structure were directly related and the forgetting over 24 hr. for the list with the highest structure was only 5%. In the present study, list structure was unrelated to either paced or unpaced recall, and the forgetting for the highest criterion of learning used was estimated at 25%. The discrepancy between these two studies is the topic of this preliminary discussion.

The contradiction in the retention results for the two studies pointed immediately to a method difference as the likely source for the contradiction. In the previous study the anticipation method was used. During the recall trial, therefore, the *S* would be informed of the particular concept whose instances were appropriate at the moment for the structured lists. If, for example, he remembered there were six animal names in succession, the appearance of the first instance would inform him that the next several positions also contained animal names. With the study–test method, the *S* would not be given this information. If he did not give the first instance of a concept at the appropriate point (to the correct stimulus), his following responses would be incorrect unless he remembered a particular response term associated with a stimulus term within the series of concept instances. There were, in fact, some cases in which *S* did give three to six correct response words in the correct order but which were scored as wrong because the initial response in the series was not paired with the appropriate stimulus. This did not occur frequently (and the data show that scoring these as correct did not change the basic conclusion), but the uncertainty felt by the *S* may have prevented him from responding overtly. List structure clearly influenced learning and relearning, but some portion of the learning which allowed the *S* to align response terms and stimulus terms correctly during learning must have been forgotten over the 24 hr. It is possible that the numerical stimulus terms were not always used as the effective stimulus terms and that the lists were treated more as serial lists than paired-associate lists, although what this means theoretically is not known. It appears that if *S* had learned, for example (for Lists 4 and 5), that number 1 was paired with the first bird instance, number 4 with the first of three fish instances, and so on, that this part of the memory was lost over 24 hr. Otherwise, there is no reason why providing this information at recall (as is done in part under the anticipation method) should result in better performance.

It seemed necessary to make a test of the notion that the discrepancy in the recall results for the two experiments was due to a difference in methods. In the auxiliary experiment, to be reported now, Lists 1 and 5 were presented for anticipation learning, with re-

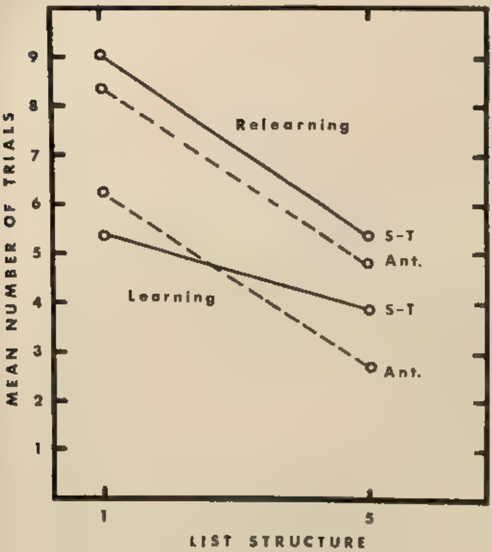

FIGURE 6. Learning and relearning scores for Lists 1 and 5 as a function of the study-test (S-T) and anticipation (Ant.) methods.

call taken after 24 hr. The expectation was that recall of these two lists would differ, with List 5 giving better recall than List 1.

AUXILIARY EXPERIMENT

Method

Lists 1 and 5 were presented at a 1.5:1.5-sec. rate for anticipation learning. The criterion of original learning was 12 correct responses on a single trial. Paced recall occurred after 24 hr. with relearning carried to one perfect trial, but a minimum of three trials beyond the recall trial. Each list was learned by a separate group of 18 *S*s assigned to one of the two lists by a block-randomized schedule.

Results

In presenting the results, comparisons will be made with the two groups of *S*s from the major experiment having the study–test method and paced recall, and who had learned Lists 1 and 5 to a criterion of 12 correct responses before the retention interval. There were 18 *S*s in each of these two groups. Since the auxiliary experiment was conducted after the major experiment, it is not known if the groups (study–test vs. anticipation) represent the same or equivalent populations. Therefore, differences in the levels of performance will not be readily interpretable, although interactions between the methods and lists should be meaningful.

The mean numbers of trials to learn to a criterion of 12 correct, and the mean numbers of trials to relearn to one perfect trial, are shown for the four groups in Figure 6. For original learning, list structure appears to have a greater influence for anticipation learning than it does for the study–test method. List structure is significant ($F =$ 25.33), as is the interaction, F (1, 68) = 4.19, $p < .05$. The interaction between list structure and method does not occur during relearning, indicating that the method's influence on learning is confined to the early stages.

It will be remembered that for the study–test method the frequency of concept instances was directly related to learning. This was quite evident at the lower criterion of learning. For List 5, under the anticipation method of the auxiliary experiment, the reverse was found. More specifically, two findings held across all eight concepts of three instances each. First, the initial word of the three (the high-frequency instance) was never given correctly more times than the second instance (the medium-frequency instance). Second, the third word in each of the eight concept triads (the low-frequency instance) was always given correctly more times than the first instance of the succeeding concept. For List 1 under anticipation learning, the effect of word frequency was in evidence just as was true for all of the lists learned by the study–test method. The above facts would indicate that item learning under the two methods would be more reliable for List 1 than for List 5. The product-moment correlations for item learning were .83 for List 1, and .58 for List 5. The positive relationship for List 5 reflects the commonality in learning by the two methods produced by serial position of the words, differences which were apparent under both methods.

Mean overt errors per opportunity were greater in learning under the anticipation method (.22) than under the study–test method (.13), and the difference was re-

lio' . , F (1, 68) = 9.24, $p < .01$. This may rep . . at a greater tendency to guess under th . . ticipation method than under the st . test method. However, of the overt er . . made under the two methods, the pe . entage of these errors within the ap- pr . riate concept position (Level-1 errors as . escribed earlier) was about the same for L . . 5, being 53% for anticipation and 54% f. the study–test method.

. he mean numbers of correct responses . ecall are shown in Figure 7, along with . mean number correct on the last learn- . trial. Under the anticipation method, . call was directly related to list structure, . (1, 34) = 4.97, $p < .05$. The inter- . tion between lists and methods for recall was also reliable, F (1, 68) = 4.44, $p < .05$. Recall for List 5 under the anticipation method was higher than performance on the last learning trial, 24 hr. earlier. To some extent, these comparisons are all in error, a matter which needs discussion.

Consider first the recall of List 1 under the two methods. A conclusion from an inspection of Figure 7 might be that recall . superior following anticipation learning . that following learning by the study– . st method. However, two factors must . considered. First, the criterion fall . ich may occur under the study–test method, and second, the learning which occurred on the last trial under the antici- pation method. This last issue can be handled directly. A multiple-entry prob- ability analysis (Underwood, 1964) was carried out to project performance to the hypothetical next trial under the anticipa- tion method. The mean expected value was 14.89. Since recall was 11.67 items, forgetting over 24 hr. was 3.22 items, or 22%. To incorporate the criterion fall into the calculations for List 1 for the study– test method requires a rough estimation of values. In the main experiment, groups were given a recall test immediately after reaching a criterion of 20 correct responses. On this immediate test under paced recall, performance fell from a mean correct of 20.89 correct on the last test trial to 17.72 correct on an immediately following test trial. This represents a loss of 3.17 items

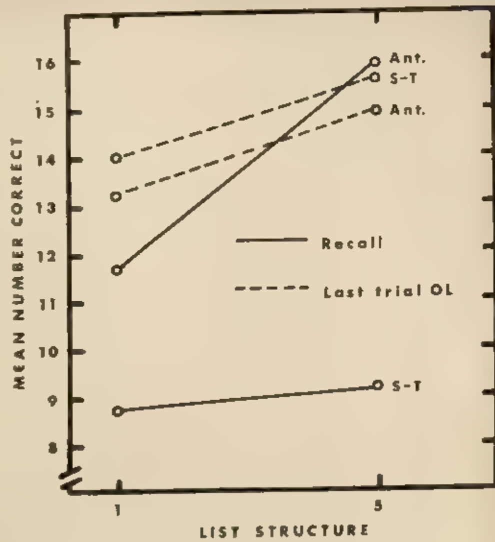

FIGURE 7. Number correct on the last trial of original learning and number recalled after 24 hr. for the study–test and anticipation methods.

which is referred to here as the criterion fall. None of the groups had an immediate test following learning to a criterion of 12 correct responses. Assume, however, that the group having the study–test method and learning to a criterion of 12 correct responses actually forgot 22%, the same as forgotten by the group having the anticipation method. This would require a criterion fall of 2.75 items. In light of the criterion fall of 3.17 items shown by the group learning to 20 correct responses, a fall of 2.75 items for those learning to 12 correct would not seem to be seriously in error. Given this assumption, the con- clusion is that for List 1, the amount of forgetting shown under the two methods is roughly the same.

Turning next to List 5, it must first be noted that it was not possible to project "next trial" performance for the Ss learning under the anticipation method because several of them learned in one or two trials. As an estimate, however, the percentage projection obtained for List 1 was used. This gives a mean expected next-trial value of 17.03 items. Since recall was 15.69 items on the average, the loss over 24 hr. was about 7%. Deriving an expected loss

TABLE 1

Comparison of Study–Test and Anticipation Methods with Regard to Concept Instance Learning and Recall for List 5

Correct responses	Anticipation		Study–Test	
	Last OL	Recall	Last OL	Recall
Three	117	162	210	102
Two

1 & 3	28	20	18	10
2 & 3	62	68	18	8
One				
1	6	2	11	16
2	13	13	2	1
3	21	12	5	9

Note. See text for complete explanation.

for List 5 following study–test learning (using the value of 2.75 for the criterion fall) gives a loss of 3.75 items from 12.92, or 29% forgetting. These values must be considered approximations, but they lead to the conclusion that the loss was about the same under the two methods for the unstructured lists, but that the anticipation method led to better recall than did the study–test method for the highly structured list. Both the estimate of loss for List 1 for the anticipation method (22%) and the loss for List 5 under the same method (7%) correspond to the findings of the earlier published experiment using this method (Underwood & Zimmerman, 1973).

The sources of the differences in the retention for List 5 following the learning by the two methods needs more detailed examination. The data which seem to aid in reaching decisions about the sources of differences are shown in Table 1. The data sheets were examined for the last trial of original learning and for the recall trial. A tabulation was made of the number of correct responses which resulted from producing all three instances of a concept, the number which resulted from producing only two instances of a concept correctly, and the number which resulted from giving only one correct response from among the three possible for each concept. When two correct responses were given, they were broken down by position within the three possible positions (1 & 2, 1 & 3, 2 & 3). When a single correct response was given, the number falling in each of the three positions was noted. All of this information is given in Table 1 for the last original learning trial, and for the recall trial, under both methods. For example, on the last learning trial under the anticipation method, there were 39 cases in which all three instances were given correctly, resulting in 117 correct responses, the latter value being shown in Table 1. For this same condition there were 13 cases in which a single correct response was given for a concept and which consisted of the second of the three instances in the series of three.

Several facts are to be noted in Table 1. First, under the anticipation method there was an actual increase over 24 hours in the number of cases in which all three instances were correctly given (117 to 162). In view of the learning which may have taken place on the last anticipation trial of learning, this increase must be viewed cautiously. Nevertheless, it is in marked contrast to the results found with the study–test method, where there was a loss of 108 (210 − 102) complete triads. The second fact to note is the difference between the two methods in both learning and recall when less than three instances were given correctly. Under the anticipation method, the most probable positions for correct responses when two were given are Positions 2 and 3, and Position 3 when a single correct response was produced. Comparable relationships do not exist for the study–test method, where there was more or less constancy among the positions. The third fact is that if the number of cases in which the first instance (by position) of a concept was given correctly was calculated (regardless of the outcome for the two following instances) for recall, the sums were found to be 198 cases for anticipation, and 146 for study–test. This seems to indicate that, (*a*) associative learning between the first instance of the concept and its position or stimulus number was greater or better during anticipation learning than during study–test learning, or (*b*), showing the *S*

the response terms during recall allowed him to "deduce" the subsequent occurrence of the first instance of a different concept. Both factors may be involved, although the latter seems more reasonable. Finally, the data in Table 1 are clear in demonstrating that failure of *S* to recall the first instance of a concept provides very little penalty under the anticipation procedure, since he can proceed to give other instances of the concept for the two following positions.

The evidence seems to point to the fact that learning under the study–test method is relatively fragile or weak with regard to positions or stimulus numbers which mark the first instance of a new concept. The same is probably true for the anticipation learning. However, on the recall trial the *S* having learned by the study–test method receives no feedback information and he has few means to apply corrective procedures based on any knowledge he had about the conceptual structure. In effect, he was reduced to responding on an item by item basis, much as is the case for an unstructured list. On the other hand, the *S* having anticipation learning could apply corrective procedures based on his knowledge about the conceptual structure of the list.

General Discussion

The higher the conceptual organization of the lists the more rapid was the learning. It is presumed that this relationship was produced because the greater the number of the conceptual levels the more precise was the placement of an item if the rules indicated by the conceptual relationships were followed. Nevertheless, this should not be taken to mean that the hierarchical structure in its totality entered into the learning of the most completely structured lists. The *S* could learn the sequence of eight concepts of three instances each without reference to the higher-order concepts present in the list (animals, plants, beverages, minerals). So also, List 3 could be learned by reference only to the four successive concepts of six instances each and without the living–nonliving distinction per se entering into the learning. The error data were clear in showing that at least one level of conceptual responding was involved in the learning of Lists 3, 4, and 5, but these error data do not speak to the question of whether two or more conceptual levels were involved in learning Lists 4 and 5. To determine if two or more levels were involved would require the use of a list in which the blocks of three instances were ordered randomly with respect to the more inclusive concepts. A list of this type was not included in the present study.

In the previous study (Underwood & Zimmerman, 1973), learning was facilitated up through the structure corresponding to List 3 in the present study. No further enhancement occurred for Lists 4 and 5. This is believed due to the fact that the present lists were made up of more obvious concepts and more obvious concept instances than were the previous lists. Unlike the present findings, frequency of the concept instance with a concept did not influence learning in the previous experiment. In view of the findings of the auxiliary experiment, it seems now that this contradiction is another by-product of the differences in the learning by the two methods.

The major purpose of the present study was to attempt to identify the component(s) in memory which had led to the increase in recall over 24 hr. as list structure increased. In an inelegant way, this study was quite successful in achieving its purpose. The use of the study–test method of learning was followed by a complete lack of any differences in the recall tests, whether paced or unpaced. Only relearning, reflecting the same relationship as was found in original learning, was related to list structure. With the study–test method the original learning was apparently based on very weak associations between stimulus number or position and words marking the conceptual changes which occurred throughout the list. The loss of these associations over 24 hr. essentially made the conceptual nature of the lists useless as a recall vehicle. The items which were recalled were apparently based upon factors specific to them.

Considering now the broader context of these studies, the question may be raised about the systematic importance of the earlier study (Underwood & Zimmerman, 1973), and the auxiliary experiment of the present report, in both of which the anticipation method was used. Recall and list structure were directly related in these studies. However, the error data from this previous study gave no support to the idea that forgetting of unstructured lists was produced by interference among the con-

ceptual associations among the words. In the present study there was no evidence that conceptual associations played any interfering role in learning the unstructured lists. It does not seem now, therefore, that these types of lists have any special or pointed use for the study of interference as a source of forgetting.

CHANGE IN SPEAKER'S VOICE AND RELEASE FROM PROACTIVE INHIBITION

JOHN M. GARDINER[1] AND PAULINE C. CAMERON[2]

The City University, London, England

Four triads of unrelated words were presented auditorily in the Brown–Peterson distractor task. Over Trials 1 to 3, half of the *S*s heard the words spoken in a female voice and half in a male voice. On Trial 4, *S*s in a control group heard the words in the same voice as on preceding trials and *S*s in an experimental group heard the words in the alternate voice. Proactive inhibition (PI) developed rapidly over Trials 1 to 3 in both groups. On Trial 4, however, *S*s in the experimental group recalled significantly more words than did *S*s in the control. It was concluded that *S*s can utilize change in speaker's voice to reduce the cumulative effects of PI in short-term memory.

Considerable interest has been shown recently in the investigation of those attributes or dimensions of verbal items which *S*s can utilize or identify in a variety of memory tasks (Underwood, 1969; Wickens, 1970). One strategy, which has yielded a considerable body of evidence on the encoding of various attributes of verbal items, has been the use of the release from proactive inhibition (PI) technique. This technique capitalizes upon the rapid buildup of PI which occurs over the first few trials in the Brown–Peterson distractor task (Keppel & Underwood, 1962) to determine the extent to which *S*s can utilize a specific change in the nature of the to-be-remembered material to reduce the cumulative effects of PI. Wickens (1970, 1972) has reviewed many studies which demonstrate that when the "category" of the material is changed after three or four trials, recall will be better than if the category remains unchanged. Wickens has argued that the amount of recovery in performance (or release from PI) on the critical trial, as a function of any particular "category shift," provides an index of the relative effectiveness of that category as an attribute or encoding dimension of memory.

A second strategy has been to examine more directly *S*s' retention of information about various attributes of verbal items, as, for example, in determining the extent to which *S*s can identify input modality following recall of a list of words presented in mixed modes (Bray & Batchelder, 1972). In this situation, there is evidence not only that *S*s are able to make accurate judgments concerning between-modality attributes (whether an item was presented visually or auditorily), but also concerning within-modality attributes (whether an item was presented in upper- or lowercase letters, or in a male or female voice). Hintzman, Block, and Inskeep (1972), for example, gave *S*s an unexpected final recognition test following several free-recall trials in which the word lists were presented in one of three mixed modes: visual or auditory; upper- or lowercase; male or female voice. In all cases, the results showed that, given recognition of the item in the final test, *S*s could identify the input mode with considerable accuracy for at least several minutes after presentation. In a rather different vein, Craik and Kirsner (in press) investigated the persistence of information about speaker's voice (male or female) using the continuous recognition paradigm of Shepard and Teghtsoonian (1961). Craik and Kirsner found that when test words were represented in the same voice as in the initial presentation, recognition performance was better than when the second presentation was in a

different voice. This "same voice" facilitation did not decline over a 2-min. lag.

There is thus good evidence that *Ss* retain various aspects of input mode information for at least several minutes following item presentation, and also that such information may in certain circumstances facilitate memory performance. These results are important in that they imply that the representational characteristics of verbal material may persist for much longer than many theorists have maintained (e.g., Crowder & Morton, 1969).

Such evidence suggests also that *Ss* might be able to utilize input modality attributes to reduce the cumulative effects of PI in the Brown–Peterson distractor task. Indeed, several recent studies (Hopkins, Edwards, & Cook, 1973; Kroll, Bee, & Gurski, 1973) have established that between-modality shifts (visual to auditory or auditory to visual presentation) can lead to dramatic release from PI effects. The results of several within-modality shift studies have also been reported. Within the visual modality, Shearer and Wickens (unpublished study cited by Wickens, 1972) found that a shift from lower- to upper-, or upper- to lowercase letters did not produce a significant release effect. Shifting slide background area (Turvey & Egan, 1969), and the color of the slide background (Reutener, 1972), were, however, found to be effective. Somewhat surprisingly, the effect of shifts within the auditory modality have not hitherto been reported. Bearing in mind the results obtained by Craik and Kirsner (in press) and Hintzman et al. (1972), it seems quite possible, for example, that change in speaker's voice would lead to a release from PI effect. The present study was designed to investigate this possibility.

Method

Design. All *Ss* received four triads of unrelated words presented auditorily in the Brown–Peterson distractor task. There was an experimental and a control group of *Ss*. Over Trials 1 to 3, half of the *Ss* in each group heard the words spoken in a female voice and half in a male voice. On Trial 4, *Ss* in the control group heard the words spoken in the same voice as on previous trials. The *Ss* in the experimental group heard the words spoken in the alternate voice on Trial 4.

Subjects. The *Ss* were 120 volunteers, mostly male undergraduate students, who were paid for their services. Sixty *Ss* were assigned randomly to each group and the *Ss* were tested individually.

Materials. Thirty unique 12-word sets were constructed by sampling without replacement from a pool of 600 common two-syllable nouns. Each set was divided arbitrarily into four word-triads. The word sets were yoked across experimental condition such that each set was used four times once for each voice condition within each group

Procedure. The word lists were recorded on a Brenell STB 2 tape recorder and subsequently presented to *S* via a loudspeaker. Each *S* was tested in a small soundproof cubicle. The trial procedure was as follows. Each trial began when the tape recorder was switched on and *S* heard a set of three words presented at the rate of one word per sec. The tape was then switched off and the "click" made by the switch was the *S*'s cue to begin the distractor task. This task was that of reporting aloud the sum of each of a series of pairs of random single digits from a sheet of these placed on a table in front of the *S*. The addition task was paced at a 1-sec. rate by the click of a metronome. After 18-sec. addition, *E* signaled with a pencil tap that *S* was to attempt oral recall of the three to-be-remembered words. The *S* was allowed 9 sec. for recall, after which a further pencil tap signaled that the next set of words was about to be presented. There was no intertrial interval, and each complete trial sequence lasted for 30 sec.

All *Ss* were instructed that the experiment involved two "unrelated" tasks, an arithmetic task and a memory task, and that performance on both tasks would be scored. The *Ss* were given an initial practice at the distractor task alone. They were then given seven lead-in trials presented in the same manner as described above. Lead-in trials comprised triads of one-syllable common words and all *Ss* received the same words. Prior to the lead-in trials the *Ss* were informed that the words would sometimes be spoken in a male voice and sometimes in a female voice, that changes in voice occurred at "random," but that all they had to do was to remember the words. The seven lead-in trials were in fact a random sequence with respect to voice. Between the lead-in trials and the four experimental trials there was an unfilled interval of about 2 min.

Results

Preliminary analyses indicated that there were no reliable differences as a function of voice (male or female) and the data were pooled over this variable. Figure 1 shows the percentage correct recall for the experimental and control groups. One point was given for each word recalled correctly, re-

gar...ss of its output position. The figure sh... that recall declined rapidly in each ...ver the first three trials. On the ... trial, however, the experimental ... showed a substantial recovery in ...mance, whereas performance in the ...ol group remained essentially the same as ... was on Trial 3.

...parate analyses were carried out on d... a from the first three trials and on data f...m Trial 4. Considering Trials 1 to 3, t... results of an analysis of variance showed ... the only significant effect was that due ... trials, F (2, 236) = 33.15, $p < .001$. ...he F ratios associated with groups, and ...oups × Trials, were less than unity. ...hese results indicate that the build-up of I over Trials 1 to 3 was reliable and did not differ with respect to groups. The result of an uncorrelated t test carried out on data from Trial 4, however, confirmed that the superiority shown by the experimental group was highly significant, t (118) = 3.95, $p < .001$.

Following the procedure suggested by Wickens (1970) the amount of release from ...I was assessed by dividing the difference between the experimental and the control ...oups on Trial 4 by the amount of loss shown by the control group from Trials 1 to 4. Use of this procedure gave a percentage recovery of 67%. Relative to previous findings (Wickens, 1972, Figure 3), this represents a substantial amount of release.

After recall of the final triad, each S was asked which voice or voices had been used over the last four trials. Somewhat surprisingly, only 33 Ss in the control group, and 29 Ss in the experimental group, reported accurately the voice in which the *final* triad had been presented. Since there were 60 Ss in each group, these figures are very close to a chance level of performance, and many Ss commented that they paid no attention to voice, or were guessing when they reported on which voices they had heard. In this context it is of interest to note how Ss' reported awareness of the change in voice relates to the release effect. Of the 60 Ss in the experimental group 22 reported the change in voice from Trials 3 to 4 accurately. Taking an increase in the number of words recalled by the S from Trials 3 to 4 as an index of "individual release," 12 of the 22 Ss who noticed the change and 16 of the 38 Ss who did not notice the change showed individual release effects. These results imply that the recovery in performance shown by Ss in the experimental group on trial four did not depend upon Ss' awareness of the change in voice.

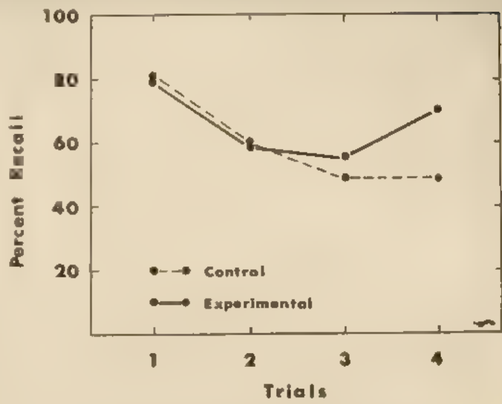

FIGURE 1. Percentage correct responses for control and experimental groups.

DISCUSSION

Clearly, the results of the present study show that change in speaker's voice lead to a dramatic recovery from the effects of PI in the Brown–Peterson distractor task. Thus speaker's voice may be added to the already large list of attributes which Ss apparently encode in short-term memory for verbal items.

The magnitude of the release effect obtained runs counter to the general finding that "physical," as opposed to semantic shifts, do not typically produce large release effects (Wickens, 1972). Why should change in speaker's voice be an exception to the more general result? One possibility is that the Ss in the present study were "set" to encode items in terms of voice. That is, the Ss were informed beforehand that the triads might be spoken in either a male or a female voice and received several lead-in trials in which they heard each of the two voices. In most previous release from PI studies, with the exception of some between-modality shift experiments (e.g., Hopkins et al., 1973), the Ss were not informed beforehand that any change in the

nature of the to-be-remembered material would occur.

However, as Underwood (1972) has pointed out release effects in general may to some extent reflect "priming" the *S*, implicitly if not explicitly, to encode the material along the specific dimension being investigated. We may well be "overloading memory" if we assume that *S*s habitually or automatically encode verbal materials along all the many dimensions so far shown to yield release effects. The more cautious conclusion, of course, is simply that *S*s can utilize such dimensions to reduce the effects of PI when given the "opportunity" to do so, and, therefore, that the dimensions may be represented, in some sense, by different memory codes. In view of Underwood's point, it may be worth emphasizing that this conclusion is independent of any conclusion with respect to the possible influence of priming the use of particular memory codes. Underwood's argument implies, rather, that the employment of such codes may, to a large extent, be "optional" rather than "automatic" (cf. Wickens, 1970). If this be so, then an urgent task for further research will be that of investigating the conditions that tend to favor the use of one encoding strategy rather than another. Reutener (1972), for example, found that shifting the color of the slide background was effective in producing release from PI when the stimulus materials were arabic numbers or spelled out numbers, but not when the materials were words drawn from a taxonomic category. On the basis of this result, Reutener suggested that a "physical" shift may be effective only when the to-be-remembered material is not words. While such a conclusion is also in line with results reported by Turvey and Egan (1969) and Shearer and Wickens (unpublished study cited by Wickens, 1972), the results of the present study do not fit into this pattern. The results of the present study, rather, suggest that *S*s may also place more reliance on "physical" codes when the to-be-remembered material consists of relatively "unrelated" words. Nevertheless, one plausible factor which may affect the extent to which *S*s utilize "physical" forms of coding may well be the degree of meaningfulness which *S*s can extract from the stimulus materials.

That the *S*s in the present study were not able to report accurately which voices they had heard in the final trials is somewhat surprising in view of the results obtained by Craik and Kirsner (in press). These authors found that *S*s could assign speaker's voice with 65–75% accuracy after a 2-min. interval. This discrepancy may be related to the fact that whereas *S*s in the Craik and Kirsner study identified presentation voice in the context of the presented words, *S*s in the present study were required to recall presentation voice in the absence of the words. We suggest that the inability of our *S*s to report accurately which voices they had heard in the final trials is in good agreement with the notion that the auditory information in speaker's voice was retained in some literal or representational form. Our data may thus be viewed as adding to the already substantial body of evidence (Craik & Kirsner, in press; Hintzman et al., 1972) which indicates that auditory information may persist for much longer than many theorists have maintained (e.g., Crowder & Morton, 1969). Further, the present study extends these findings by demonstrating that such information can to a large extent eliminate the effects of PI in short-term memory.

THE COMBINED EFFECTS OF STIMULUS AND RESPONSE CONDITIONS ON THE DELAY IN IDENTIFYING THE PRINT COLOR OF WORDS[1]

RAYMOND L. MAJERES[2]

Western Illinois University

The interaction between stimulus and response conditions in the Stroop interference effect was studied in two experiments. Response conditions in Experiment I required college students ($N = 36$) to identify colors by using verbal responses (color names, color associates, or single letters). In Experiment II, *Ss* ($N = 36$) identified the colors by writing the first letter of the responses used in Experiment I. Stimulus conditions in both experiments were color only, color names in nonmatching print colors, and color-associated words in unrelated print colors. In line with predictions from Morton's word recognition model, the Stimulus × Response interaction was significant in both experiments ($p < .01$). Differences between the experiments indicate that the type of response (verbal or motoric) influences the delaying effect of the words.

Naming the color of printed words (e.g., such as *friend*, *sky*, or *run* printed in red) takes more time than naming the color of colored patches (Fox, Shor, & Steinman, 1971; Klein, 1964). This effect is especially strong when the words are color names (Stroop, 1935). It is as if the highly developed systems involved in reading operate autonomously and interfere with simple color naming.

Klein (1964) used different kinds of verbal material in addition to color names as potential sources of distraction. It was found that a variety of verbal materials, including nonsense syllables, could delay color naming. The nature of the words in terms of their semantic relationship to the colors (other color names, color-related words) and their familiarity (word-count frequency) influenced the degree of delay. These particular results have been replicated, and a variety of word characteristics have been found to influence the delay (Dyer, 1973). Both Stroop (1935) and Klein emphasized the role of response competition, involving central as well as peripheral aspects. Implicit in their emphasis was the initial parallel processing of both color and word, with interference arising from difficulties in response selection (see also Dyer, 1973).

Studies by Treisman and Fearnley (1969) and Hock and Egeth (1970) have questioned this assumption, pointing out that the task as used confounded stimulus and response effects. They attempted to eliminate this confounding by devising tasks that did not require the overt naming of colors, but rather involved judgments of perceptual match or a match with "target" stimuli held in memory. Treisman and Fearnley suggested that the critical feature of the Stroop effect is that a comparison must be made across hypothesized word and color "analyzers," and such comparisons are less efficient than those comparisons made within an analyzer. Also, "across-analyzer" comparisons were believed to be more susceptible to interference effects from values of the irrelevant attribute. However, Egeth, Blecker, and Kamlet (1969) found that an interference effect can be obtained in "within-analyzer" comparisons. In their task the responses were verbalized and the response words (*same* and *different*) were printed in the different ink colors. That is, the identity of the set of words used in the stimuli to the set of response terms did produce a delay, even though the task involved within-attribute matching.

A few other studies have provided data

[1] This research was carried out while the author was a postdoctoral fellow supported jointly by Educational Testing Service and National Institutes of Health Grant MH-08260.

on the mutual effects of both stimulus and response variables. Most of these studies were designed to investigate language organization in bilinguals (Dalrymple-Alford, 196… Preston & Lambert, 1969). Preston and Lambert considered initial identification as one of the factors in the observed interference effect, but output processes were considered to be the major factor in producing the interference effect. Dalrymple-Alford, in a study using Arabic–English bilinguals, introduced the possibility that the stimulus word primes all words associatively related to it. That is, not only does the stimulus word prime the wrong response, but it also primes associatively related responses. There is more recent evidence that this priming may extend beyond simple associational processes and probably involves the word's semantic category as well (Warren, 1972). This is in contrast to Hock and Egeth's (1970) interpretation, where the responses were considered to sensitize *S*s to the stimulus word. It may be that the stimulus word and the response both alter the availability of some central linguistic unit.

Morton (1969) has suggested that the availability of such mediational units, called logogens, is affected by stimulus information (seeing a color, seeing a word, hearing a word, etc.) and by the experimental context. In the Stroop (1935) paradigm, the experimental context refers primarily to the instructions to identify colors, which presumably increases the availability of (primes) color names, color-related words, and perhaps entire color categories (Warren, 1972). A third factor affecting the availability of the logogen to a serial output buffer is the response. Response repetition (overt or covert) is believed to lower the thresholds of the respective logogens. Hence, in the Stroop task, both stimulus and response conditions should influence logogen availability.

For example, the use of color names both as stimulus words (printed in incongruent colors) and as response terms (as names of the print colors) should provide the greatest competition in terms of the greatest number of incompatible logogens reaching threshold: color identification is required, which influences availability of color names in general; color names are irrelevant sources of stimulus information, which increases the availability of incompatible color names; and color-name responses are required, which lowers the thresholds for color names. Likewise, using color associates as response terms, such as saying *fire* for red, should have a direct priming effect on color associates and not on the color names. If color associates are in the stimulus card as irrelevant, incompatible information and are also used as responses, the logogens for color associates should be highly available (via stimulus information), and their thresholds should be lowered (via response requirements). Such conditions should produce a dramatic delaying effect analogous to the original Stroop (1935) task. However, since the context is still color identification, which has its primary effect on the availability of color names rather than of color associates, the effect may be somewhat reduced.

Using single letters as vocal responses should not alter the threshold for color-associate or color-name logogens. However, stimulus words (color names and color associates) and context conditions should produce delaying effects similar to those found in the original Stroop (1935) task, with color names producing more delay than color associates. But the magnitude of the delay may be reduced, since single-letter responses should not alter logogen thresholds, except possibly by verbal mediation.

Experiment I

An initial experiment was designed to demonstrate the joint influence of both stimulus and response conditions on the delay in color naming, using procedures directly comparable to those used by Stroop (1935). Both the kind of words in the stimulus (color names, color-related words, and color only with no verbal distraction) and the kind of color-identifying responses (conventional color names, color-associated words, or arbitrary letters) were

systematically varied to investigate their joint influence.

Method

Subjects. Thirty-six students (18 males and 18 females) from a private and a state college in New Jersey volunteered to take part and were paid $2 for a 1-hr. session.

Materials. Three sets of stimulus cards were prepared, as described below.

Card 1. The words *red, green, blue,* and *orange* were printed in lowercase letters (pica) by a multilith-offset process on 8½" × 11" sheets with eight rows of five words each. The words were printed in incongruent ink colors (words never congruent with ink color) with each color appearing 10 times in a quasirandom order (doublets were avoided within rows). Each word appeared about the same number of times (4 times) in each of the three possible incongruent colors. This was the color-names stimulus condition.

Card 2. Using the same format as in Card 1, the words *fire, sky, grass,* and *juice* were printed in colors incongruent with the colors suggested by these words: red, blue, green, and orange, respectively. This card was the color-associates stimulus condition. The color-associated words and the color-names were quite comparable in terms of Thorndike–Lorge (1944) word-count frequency, with all rated AA except *orange* (A) and *juice* (37).

Card 3. Sets of five asterisks (approximating the average length of the words) were printed with each set in one of the four colors in the same format as was used on Cards 1 and 2. This was a noninterference or color-only stimulus condition, in that no words were printed on this card. There were two different forms of each of these three stimulus cards.

Procedure. Equal numbers of male and female *S*s were assigned to three different experimental groups. In the first group, Group N, *S*s [illegible] the colors on the three stimulus cards usi[illegible]ventional color names (red, blue, green, and orange). In the second group, Group A, *S*s identified the colors by using color-associated words, saying *fire* for red, *sky* for blue, *grass* for green, and *juice* for orange. In the third group, Group SL, the identifying responses were single letters: *v* for red, *x* for green, *y* for blue, and *z* for orange. All *S*s were given practice trials in serially naming the 40 color-only items using their particular set of identifying responses to a performance criterion of 60 sec. This practice was designed to ensure that the responses were sufficiently familiar to permit smooth and accurate responding. No *S* in the N or A groups required more than two practice trials to reach criterion. Of course, *S*s in the single-letter (SL) group typically required more extensive practice to reach the criterion since the labels they used were novel and arbitrary.

After the initial training trials, *S*s in all three response groups identified colors on the three different stimulus cards. There were eight trials on each of the three stimulus conditions. Presentation of each of the three stimulus cards constituted a trial. The color-only stimulus condition always preceded the other two stimulus conditions on each trial. The order of the color-associates and color-names cards was alternated between trials. Half of the *S*s began with a color associates-color names order, and half began with the reverse order.

A stopwatch was used to obtain performance times, and a 30-sec. interval between cards provided *S*s with a brief rest and enabled the recording of *S*s' performance times. The *S*s were instructed to correct all errors so that any errors would be reflected in the time score. The number of uncorrected errors was too limited to permit a meaningful analysis.

Res

Pe ·rmance times on each stimulus card were ·nalyzed using a 3 × 3 × 2 × 8 analysis ·· variance design with response conditio· (color names, color associates, and sin· · letters), stimulus conditions (color na· ·es, color associates, and color only), se· and trials (eight) as factors. Response c·· ·litions and sex were between-*S*s variab· ·s, and stimulus conditions and trials · within-*S*s variables.

·lean times to identify the colors under · different experimental conditions are ·ven in Table 1. Response conditions, F ·, 30) = 17.01, $p < .001$; stimulus condi·ons, F (2, 60) = 190.55, $p < .001$; and ·heir interaction, F (4, 60) = 13.48, $p <$ .001, were significant. There were significant trial effects, F (7, 210) = 28.11, $p <$ .001; as well as significant Trial × Response, F (14, 210) = 4.48, $p < .001$, and Trial × Stimulus, F (14, 420) = 4.56, $p <$ .001, interactions. Neither main effect for sex nor any of the other interactions were ·ignificant. Since the Stimulus × Re·ponse interaction was significant, the sig·ificant main effects are interpreted within ·at context.

Stimulus × Response interaction. The prediction of a Stimulus × Response interaction was confirmed. The degree of delay in color naming did depend on the particular combination of stimulus and response terms (Figure 1). Tests of simple effects indicated that the two interference conditions (color names and color associates) did produce significant delays in color identification, and this was the case for each of the three response groups (Newman–Keuls, ps $< .01$). Differences between the color-names and color-associates stimulus conditions were significant (Newman–Keuls, ps $< .01$) for both the color-names response group (34.6 vs. 26.0) and for the single-letters response group (47.1 vs. 42.9), but this difference was not significant for the color-associates response group (43.6 vs. 45.0).

Practice effects. With respect to the different response conditions, the practice effects were more marked for the newly learned conditions (identifying colors with color associates or with arbitrary single letters) than for the already well-learned color-names response condition (Table 1).

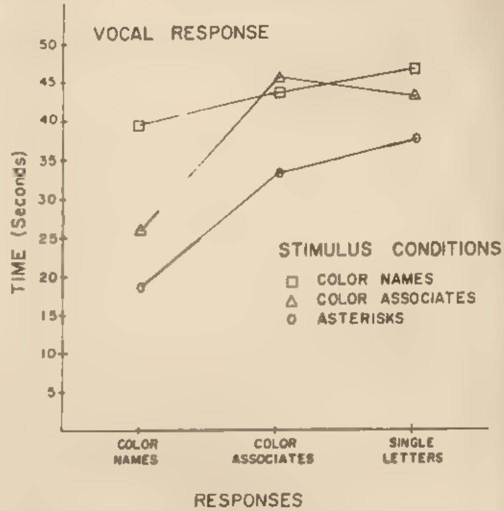

FIGURE 1. Mean vocal identification times for three stimulus conditions by three different response groups.

The effects of practice were much greater for the two interference conditions than for the color-only condition. An analysis of variance with response conditions and sex collapsed indicated that this effect was reliable, for the Stimulus × Trials interaction, F (7, 245) = 7.92, $p < .001$. Practice not only improved the speed of color identification per se, but also improved the efficiency with which the delay produced by the words was overcome. However, the nature of the Stimulus × Response interaction was not significantly affected by practice.

EXPERIMENT II

Pritchatt (1968) argued that the Stroop (1935) effect is primarily a verbal phenomenon. Using a simple motor response, tapping colored keys, it was found that the magnitude of the Stroop effect could be reduced but not eliminated. Pritchatt reasoned that sufficient practice may eliminate the Stroop effect by reducing the role of verbal mediation.

Also, according to Morton's (1969) model, vocal responses both increase the word's availability because of auditory stimulus

TABLE 2

Color Identification Times (in sec) for Three Response Groups Under Thr[illegible] Stimulus Conditions: Experiment II

Type of verbal interference	Trials				M	[illegible]crease [illegible]ontrol
	1 & 2	3 & 4	5 & 6	7 & 8		
Response Group N						
None	28.4	27.2	25.8	25.0	26.6	
Color associates	36.7	32.7	31.0	29.6	32.5	[illegible]2.1
Color names	41.9	39.0	34.6	33.8	37.3	[illegible]0 2
Response Group A						
None	37.1	36.9	35.5	32.3	35.5	
Color associates	54.9	44.9	43.8	41 3	46.2	[illegible]0.2
Color names	53.5	46.5	42.6	40.9	45.9	[illegible]9.4
Response Group SL						
None	41.2	38.8	35.4	35.5	37.7	
Color associates	46.6	42.7	40.3	36.5	41.5	[illegible]0.1
Color names	57.4	48.2	44.5	39.5	47.4	[illegible].7

Note. Abbreviations: N = color names, A = color associates, SL = single letters.

information and lower the word's threshold because of response repetition. A written and abbreviated response, such as the first letter of each of the responses of the first experiment, should eliminate the auditory stimulation and also eliminate other feedback from overt speech mechanisms, replacing them with a modest amount of visual and kinesthetic information.

Furthermore, as suggested by Pritchatt (1968), using a simple, mediated (by color names) motor response may result [illegible] a reduction or elimination of the medi[illegible]g role of the color name with practice. T[illegible]esult of such conditions should be a red[illegible]on in the interference effect. However, [illegible] context, the requirement for color id[illegible]fication, would be unchanged, and covert responding also should lower word thresholds (Morton, 1969). The net result should be a general pattern of results similar to those obtained in Experiment I (a significant Stimulus × Response interaction), however, practice may eliminate the Stroop effect by the elimination of verbal mediation. In this experiment, simple verbally mediated "motor" responses replaced the vocal responses of Experiment I. The design was analogous to the first experiment except for the response requirement.

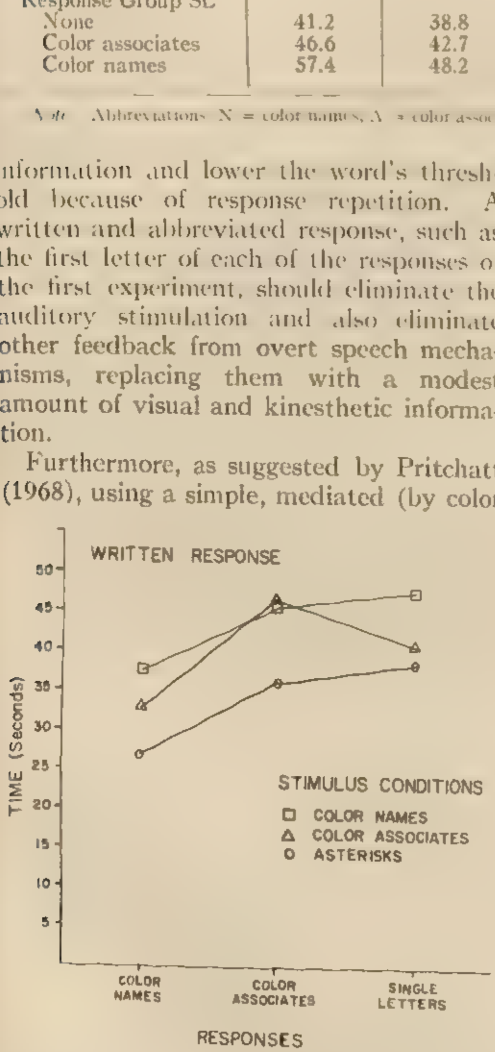

Figure 2. Mean written identification times for three stimulus conditions by three different response groups.

Method

Subjects. Thirty-six volunteers (18 males and 18 females) from a New Jersey state college served as *Ss* and were paid $2 for a 1-hr. session.

Procedure. The major modification of the procedure was to require a written response rather than a vocal one. This was done by having *Ss* in three response groups write the first letter of the identifying response that was used in the first experiment below each item.

All *Ss* were given training trials where they vocalized the correct responses just as in the first experiment. The *Ss* then were given one written practice trial of 40 responses to colors only, and then the entire experimental series was given. Each *S*

was gi... ne sheet at a time and was timed from the fir... o the last response. Errors were to be correc... by crossing out the incorrect letter. Uncorrec... errors, as in the first experiment, were rare a... insufficient for a meaningful analysis. All *Ss* w... tested individually.

R...

... in the first experiment, a 3 × 3 × 2 ... analysis of variance design was used. ...n times for the different experimental c...ditions are presented in Table 2. The ...lysis of performance times yielded sig...icant main effects for the stimulus con...tions, F (2, 60) = 101.05, $p < .001$; re...ponse groups, F (2, 30) = 7.02, $p < .01$; ...nd trials, F (7, 210) = 53.78, $p < .001$. A significant Stimulus × Response interaction was found, F (4, 60) = 5.00, $p < .01$; as well as significant Stimulus × Trials, F (14, 420) = 7.51, $p < .001$, and Response × Trials, F (14, 210) = 1.89, $p < .05$, interactions.

Unlike the first experiment, there were significant Stimulus × Response × Trials, F (28, 420) = 1.94, $p < .01$, and Stimulus × Response × Sex, F (4, 60) = 3.73, $p <$ ...01, interactions. This latter interaction was due to females in the color-names response group doing significantly better than females in the single-letters response group on the color-names stimulus condition, F (1, 30) = 11.45, $p < .01$; this was the only such difference to reach statistical significance. The sex main effect and all other interactions were not significant.

Stimulus × Response × Trials interaction. The significant Stimulus × Response × Trials interaction was the result of a general decrease in the magnitude of the differences among the groups over trials (Table 2). The effects of practice did not eliminate the delay produced by the words by the final trial (Trial 8) for the color-names (first letter of color name written) group (Newman–Keuls, $p < .01$). However, the delay produced by the color associates was not significant on the last trial. Similar results were found for the single-letters group. There was still a significant delay in color identification for the color-names stimulus condition (Newman–Keuls, $p < .05$), but the delay was nonsignificant for the color-associates stimulus condition. For the color-associates response group, there were significant interference effects for both stimulus conditions (Newman–Keuls, $p < .01$).

Stimulus × Response interaction. Again, as in the first experiment, the predicted interaction of stimulus and response conditions was found (Figure 2). Tests of simple effects indicated that the two interference conditions (color names and color associates) again produced significant delays in color identification for each of the three response groups (Newman–Keuls, ps $< .01$).

Differences between the color-names and color-associates stimulus conditions were significant (Newman–Keuls, ps $< .01$) for both the color-names and for the single-letters response groups, but this difference was not significant for the color-associates response group.

Discussion

Interference effects. For each of the three vocal response groups of Experiment I, times to identify colors on the color-word cards were significantly greater than on their respective color-only cards. Hence, the words significantly increased the time required to identify the colors under all three response conditions. An interference effect was obtained independent of the type of identifying response. However, the amount of interference appeared to be related to the type of response and to the type of verbal material on the stimulus card.

The results from the second experiment were remarkably consistent with those of the first experiment. Again, the stimulus words (color names and color associates) produced significant delays in color identification for all three response groups. The delaying effects of color associates, first reported by Klein (1964), and color names were replicated and extended to several other response conditions.

Maximum delay in color naming (78% increase over control conditions) was found when the distracting stimulus words were color names and the response terms were also color names. Similarly, in Experiment II, the analogous conditions (color-names stimulus conditions and color-names mediated response conditions) produced the greatest amount of delay, but the magnitude of the effect was reduced (only 40% increase over control condition).

The next most interfering condition was expected to be the color-associates response group under the color-associates stimulus conditions (Experiment I). This set of conditions was found to produce about the same delay as the color-names stimulus condition when using color associates as responses (color associates, 35.5% vs. color names, 31.4%). In Experiment II, the color-associates stimulus condition using the color-associates mediated responses produced similar results (30.2% vs. 29.4%). Although the effect of having color associates in both stimulus and response conditions did not result in the pronounced effect characteristic of the Stroop conditions, the effect was large enough to eliminate the usually observed difference between color-names and color-associates stimulus conditions. The results indicate that the traditional Stroop (1935) phenomenon is a product of both the particular stimulus words and the response terms.

Practice. Practice in both experiments reduced the delay in color identification produced by the words. There was improvement in color identification per se, but, in addition, there was improvement in overcoming the interference. In the color-names response condition of Experiment II, only the color-names stimulus condition still produced significant interference by the final trial. The delay for the color-associates stimulus condition was not significant. A similar result was found for the single-letters response group. This result is interpreted as evidence that context, vocal color identification, maintained the availability of color names in some sustained fashion, which is a feature of Morton's (1969) "context system."

The spoken responses in Experiment I, in contrast to Experiment II, did not result in comparable practice effects. Presumably, the activation or involvement of the speech system resulted in an attentional bias for verbal stimuli which was difficult to overcome and which produced significant interference for color-names and color-associates stimulus conditions for all three response groups. While in Experiment II, with the motor response of writing, only the delay produced by the color names resulted in sustained delaying effects, probably due to the color identification context. Since the color-associates stimulus condition only produced a sustained delay in the color-associates mediated response condition, this suggests that the thresholds of color associates were lowered by this response requirement, thereby preventing the elimination of color-associate mediation with practice. This interpretation is supported by the finding that color-associates produced no significant delay (Trial 8) in the other two response conditions, color-names and single-letters conditions.

The results support the interpretation of the Stroop (1935) phenomena in terms of verbal mediation processes (Pritchatt, 1968) which are affected by experimental context, stimulus priming (Dalrymple-Alford, 1968; Morton, 1969), and response priming (Hock & Egeth, 1970; Morton, 1969).

E[...] OF FAMILIARITY AND SEQUENCE LENGTH ON ANALOG [...]ATCHES IN THE SIMULTANEOUS MATCHING TASK [1]

GAIL A. BRUDER [2] AND WAYNE SILVERMAN [3]

State University of New York at Buffalo

The study compared the effects of string lengths and familiarity on reaction time (RT) to physical and analog matches in an attempt to determine the nature of a size variation process assumed to occur during analog matches. The results replicated prior findings that "same" RTs to familiar (word) strings were faster than to nonfamiliar strings, and that this advantage increased over string length. For nonfamiliar strings analog matches were slower but this difference was not influenced by string length. Thus, adjusting for size does not seem to occur in the matching or decision stages which appeared to be sequential. However, same RTs to analog and physical matches did not differ when familiar stimuli were used. This suggests that, if size variation is to be postulated as an early processing stage, familiarity effects must also occur quite early.

As has previous research (Eichelman, 1970), the present study used Sternberg's (1969) methodology to investigate the information processing involved in the simultaneous matching task. Posner (1969) concluded that stimuli can be matched on at least two levels, one related to physical attributes, the other dependent on past experience (e.g., the name of the stimulus). Posner and Mitchell (1967) had found *S*s would respond "same" to physically identical stimuli (AA) much faster than to stimuli identical in name only (Aa). In addition, they found matches of stimuli identical in form but not size (Cc), analog matches, to be slightly slower than physical matches, but faster than "name" matches. Posner (1969) indicated that analog matches are based on physical attributes and, in addition, involve a size variation operation.

The purpose of this research was to investigate the effects of familiarity and string length on analog matches in order to see if the size variation process is influenced by past experience (familiarity), and to explore the relationship of size variation and the matching processes. For example, if the size variation process is a global normalizing operation (Neisser, 1966) which occurs prior to any stimulus segmentation or analysis, it should be uneffected by string length or familiarity.

In addition, the study provided additional evidence relative to the effects of familiarity on physical matches. Although Posner and Mitchell (1967) found no familiarity effect on physical matches, more recent work (Eichelman, 1970) has shown that past experience does influence physical matches when letter strings (more than one letter) are used as stimuli. Eichelman (1970) found reaction time (RT) to physical matches was much faster when the letter strings formed words. Because physical matches were still faster than name matches he concluded that the increase in RT of physical matches with words did not reflect reading or naming the words. Eichelman (1970) also found the familiarity effect increased over string length. While maintaining the physical match was based on visual processing, he concluded that familiarity can effect processing stages related to the physical characteristics of the stimuli. In the present study it was hoped that the relationship of familiarity to the size normalizing operation could provide

[1] The research was supported in part by institutional funds (Biomedical Sciences Support Grant from the U. S. Public Health Service) administered by the Research Foundation of the State University of New York. The authors wish to thank Russell Ryden for his assistance in preparing the materials and collecting data, and Webb Stacy and Irv Biederman for their helpful suggestions.

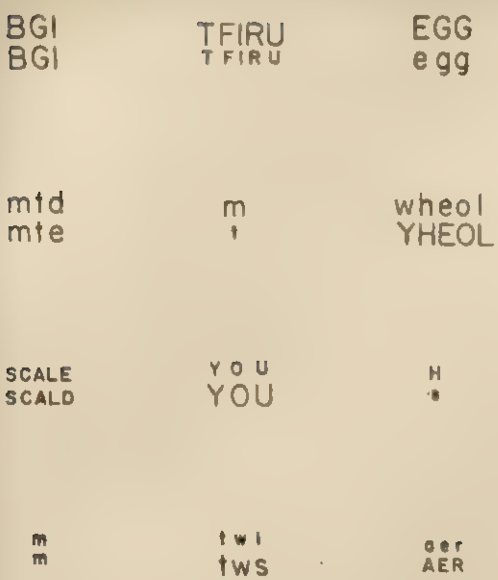

FIGURE 1. Examples of stimuli corresponding to print type and conditions as listed in Table 1.

evidence regarding how familiarity influences physical matches. For example, if the evidence from unfamiliar strings indicates that size normalizing is done separately for each unit (letter) to be matched, the effect of size variation on word matches could indicate if the units to be matched are larger than single letters.

The present study compared physical and analog matches for word and nonword letter strings of 3 and 5 letters. In addition single letter (nonword) matches were used to provide a measure of the effect of the size variation operation with single letter stimuli. In addition, name matches were included to try to replicate Eichelman's (1970) results and thus test his conclusion that physical matches of words do not include reading or naming the words.

METHOD

Design. The study used an incomplete 3 × 3 × 2 × 2 × 2 design. There were three types of matches; physical, analog, and name matches. String lengths of 1, 3, or 5 letters were used. The strings were the same or differed in one letter pair, and the letter strings were either words or nonwords. The design was incomplete because the single letter stimuli were never words. In addition separate scores were obtained for each condition for the first and second half of the test trials.

Subjects. The Ss were 12 male a[illegible] female psychology students. For half the S[illegible]eft response key was assigned to "same" r[illegible] and for the remaining half it was assigned t[illegible]rent" responses. Tray order was also co[illegible]nced across Ss.

Apparatus. The stimuli were proj[illegible] from a Kodak 900 Carousel slide projecto[illegible] h atter mechanism connected to the project[illegible] ontrol circuits controlled the stimulus durat[illegible] inter-stimulus interval. The opening of[illegible] hutter triggered a Hickock timer and the tim[illegible] opped by the depression of one of two r[illegible] keys operated by the index and middle [illegible] S's preferred hand. A Hickock printer r[illegible] d the response and the reaction time. The[illegible] were projected onto a screen 2 m. in front of[illegible]

Materials. The stimuli were lettered [illegible] k on white paper using a Leroy lettering set [illegible] tives of the stimuli were used in slides su[illegible] t the stimuli appeared as white letters on a [illegible] grey background.

There were 10 examples of stimuli for [illegible] of the conditions. Eight stimuli were used fo[illegible] test trials; two were used for the practice tria[illegible] Differences in case were used to obtain nam[illegible] tches. With the lettering set used, upper and l[illegible] case forms for the letters C, O, S, V, W, X, and [illegible] ffered only in size. These letters occasionally o[illegible] d in name match stimuli. Differences in the size of printing were used to create analog match stimuli. All conditions had stimuli printed in each of the possible cases and sizes. The four variations in printing for each of the type of matches are described in Table 1. Examples of the stimuli corresponding to print variations are shown in Figure 1. The visual angles for small lower and upper case letters were about 24′ and 36′, respectively. The visual angles for the large lower and upper case letters were about 36′ and 48′. As can be seen from Figure 1, the visual angles for letter strings depended in part on the size and case of the letters used. The range of

l angles for the three and five letter strings 1°12′ to 2°24′, and 2° to 4°, respectively. The ht of the pairs ranged from 1°12′ to 2°24′ in al angle. There were two stimuli for each iation in printing; one of these appeared in the rst half of the test trials, the other appeared in the second half. Print type for the practice stimuli were chosen in a random fashion.

For the single letter conditions, all letters of the alphabet, except A and I were used. For the different stimuli conditions the letters were randomly paired. For both the word and nonword conditions, common three and five letter words were selected (A or AA words taken from Thorndike & Lorge, 1944). For the different word stimuli condition a igle letter was changed. The letter change was ne such that both strings would be words of approximately equal frequency. The nonword strings were made by randomly arranging the letters of the words to form meaningless letter strings. The different nonword stimuli were obtained by changing a single letter. The position of the different letter was varied over the eight stimulus examples for each condition. All stimuli were randomly assigned to one of the three match conditions.

There were a total of 240 test slides which were divided into 4 trays of 60 slides each. Each tray had two examples of each condition, and the order of tray presentation was completely counterbalanced across *Ss*.

Procedure. The *S* was seated in front of a table on which were two response keys. The *S* was instructed to depress one "key" if the stimulus pairing was "same," and the other if the pairing was "different." A "same" response was defined as indicating the paired letters had the same name. That is, *S* responded "same" when the letter strings spelled the same thing. One half the *Ss* used their index finger to signal "same" and their middle finger to signal "different," while the remainder responded in the reverse manner. Each *S* was instructed as to the nature of the task and was given at least one session on the 60 practice slides. Both speed and accuracy were stressed. Additional practice was available to *S*, and a few so requested. The slides were shown in a dark room, with the slide screen about 2 meters in front of *S*. Each slide remained on the screen until the *S* responded. There was a 1 sec. intertrial interval and several seconds elapsed between each block of 60 trials while *E* changed the slide trays.

RESULTS AND DISCUSSION

Each *S* received four examples of each stimulus condition in each half of the trials. Median RTs were obtained for each *S* based on the correct responses to the four examples, and the analyses of RT were based on this data. The percent errors for each condition are shown in Table 2. It should be noted that in some conditions the median RTs were frequently based on fewer than four correct responses, but the error rates for the same responses to the physical and analog matches were low, and performance in these conditions was the basis for the major conclusions from this study.

Same reaction times. The main comparisons involved the physical and analog matches. One main analysis assessed the effects of size variation, test half, string length, and familiarity. Since there were no words of single letter length, only string lengths three and five were included in this analysis. The summary for this analysis is provided in Table 3.

Practice had no effect on RT within this study. Although RT decreased slightly over halves, the effect was not significant. None of the interactions with test half even approached significance and test half will not be considered further.

As is clear from Figure 2 and Table 4, the RTs increased with string length. In the main analysis (excluding single letter

[b] There are 15 df for all error terms.

stimuli) RTs increased with string length and decreased with familiarity. The interaction of Length × Familiarity reflects the fact that the increase in RT over length was less for words than nonwords. However, a separate analysis indicated the increase in RT over length for words alone was significant, F (1, 15) = 12.15; $p <$ .005. The analyses of nonword stimuli (including single letters) indicated a highly significant and linear increase in RT over length, F (2, 30) = 41.68; $p < .001$. The linear component accounted for 98% of the variance, and the increase was about 76 msec. per letter. The linear trend is consonant with the hypothesis that a sequential letter-by-letter matching process occurs for the nonword stimuli. With only two string lengths, the linear trend for word stimuli could not be assessed. These results support the findings of Eichelman (1970) that familiarity reduces RT and this advantage increases over string length.

Size variation effects were examined to determine the nature of any size normalizing process. According to the main analysis the size differences increased RTs, but the size difference did not interact with string length (analysis excluded single letter stimuli). For just nonword stimuli (all string lengths) the disadvantage of analog compared with physical matches did not

TABLE 4

Mean Reaction Time According to Condition

Pairs	Physical		Analog		Name	
	Word	Nonword	Word	Nonword	Word	Nonword
Different						
Single letter		762		779		763
Three letter	819	834	867	877	901	940
Five letter	952	1,056	897	1,117	969	1,042
Same						
Single letter		652		701		780
Three letter	722	766	728	837	709	1,139
Five letter	814	961	790	1,001	918	1,194

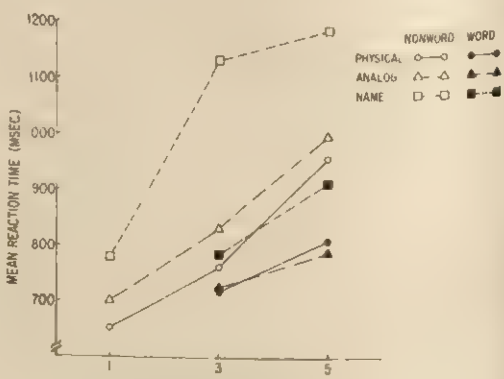

Figure 2. "Same" reaction time as a function of number of letters per string, type of match, and familiarity.

increase over string length, $F < 1$. For word stimuli alone, analog matches were not slower and the interaction, F (1, 15) = 2.91; $p < .25$.

These results provide no support for the hypothesis that size normalizing operations are done sequentially on each letter prior to or during the matching process, which seems to be sequential. However, the idea that the whole stimulus is "normalized" prior to segmentation or analysis is contradicted by the significant interaction obtained between Familiarity and Size Variation. The interaction reflects the fact that size variation only affected performance on nonword stimuli. The analysis for nonword stimuli (including single letter stimuli) showed analog matches to be slower than physical matches, F (1, 15) = 13.11; $p < .005$. There was no difference between analog and physical matches for the word stimuli, $F < 1$.

Different reaction times. The means are presented in Table 3. For all conditions and string lengths the different slides differed in only a single letter.

As Posner and Mitchell (1967) found in their study, RTs to a different single letter pair for all matches were the same and were about equal to the "same" name matches. This is in accord with the conclusion of Posner and Mitchell (1967) that *S*s must check all the way to the name level when a physical difference exists. In addition, the difference in RT between physical and analog matches was less with "different" than with "same" single letter stimuli. This supports the previous conclusion that size normalizing does not occur completely prior to any stimulus analysis.

Because only one type of different condition was used in the present study, the "different" RT data are of limited use. For example comparisons of "same" and "different" RTs with physical or analog matches are difficult to interpret since the different response may include name matching when a physical difference occurs. It was noted earlier that different single letter stimuli are probably processed to the name level in all conditions. However, it is difficult to say if the different pair is always processed to the name level in the letter strings. The position of the different pair may determine the level of processing. For example, if processing is sequential and the previous several letters have been physically identical, a physical difference may be sufficient to initiate a "different" response prior to any name analysis.

Determination of where in processing to place a size normalizing operation was more difficult than expected. The fact that size variation influenced RT to single letters and nonwords but not words precluded placing the operation prior to any stimulus analysis. The fact that size differences did not increase with string length indicates that size normalizing did not occur during the sequential matching of letters. Placing the operation later in a response selection stage is intuitively unappealing and would still leave unexplained the lack of effect of size variation on word stimuli.

Although the physical and name match data in this study replicate Eichelman's (1970) results, the analog match data suggest a complex explanation will be required to explain RT differences in matching word and nonword stimuli. The main question is whether words in a physical match condition are matched on the basis of physical characteristics and/or on some other basis, such as name information. Eichelman (1970) concluded that physical characteristics of words are involved in the matching decision. The faster RT with words could be explained by an increase in the size of the unit to be matched. However, if familiarity only increases the size of the unit to be matched (for example, making a three letter word string equivalent to a single letter) the size variation should have the same effect on words as on nonwords and single letters.

On the other hand, Eichelman (1970) argued quite effectively against the claim that words are being read and matched at the name level. He found name matches to be slower than physical matches; in the present study name matches were also slower than physical matches, for word stimuli, F (1, 30) = 14.86; $p < .005$.

The following discussion will suggest two possible approaches to integrate the effects of physical characteristics and more abstract characteristics related to words into a model of the matching process.

In order to retain a sequential stage model, it could be postulated that a word–nonword decision is made at an early stage. Subsequent processing of words might be done in a different manner (or place) from that of nonwords or letters. (See Biederman, 1972, for a discussion of contingent processing.) Kimura (1967) presented evidence that speech stimuli are processed in the left hemisphere, auditory patterns in the right. More recently, Cohen (1973) found processing differences between hemispheres with visually presented linguistic material. Johnston and McClelland (1973), comparing perception of words and letters, suggested that different systems may exist for processing letters and words. In the contingency model suggested here, physical matching of the whole word would be done with size variation filtered or ignored. If a physical match were not obtained, further processing would be done at the name level. Processing of nonword stimuli would be done letter-by-letter, with failure to obtain a physical match leading to matching at the name level. Filtering of size variation would not apply to nonword stimuli (including single letters).

On the other hand, parallel processing of physical and abstract characteristics of stimuli might be suggested. A redundancy gain between processing physical and abstract characteristics might account for RT differences between words and nonwords (Biederman & Checkosky, 1970). An alternative is an interactive parallel model.[4] In this type of model a same–different decision would be based on a composite of information from physical and abstract comparisons. If processing of abstract characteristics is faster, or takes priority, the "same" decision for physical and analog matches would be made more quickly for words than nonwords, which do not have abstract "word" characteristics. "Same" decisions might be slower for name matches because of interference from physical comparisons indicating that differences exist. One remaining problem is to specify why information about physical *size* differences would not interfere with a "same" response for words.

Clearly the development of an adequate model will require additional experimentation. The results of the present study suggest an adequate model will have to take into account the fact that physical characteristics relating to letter shape influenced word and nonword matches, while the physical characteristic of size influenced only the matching of nonwords and single letters.

[4] This model, based on Thomas (1969), was suggested by Webb Stacy.

NSFER OF ILLUSION DECREMENT AS A FUNCTION OF PERCEIVED SIMILARITY[1]

STANLEY COREN[2]
University of British Columbia, Vancouver, British Columbia, Canada

JOAN S. GIRGUS
City College of the City University of New York

Varieties of the Müller-Lyer illusion were scaled for perceived similarity to the standard Müller-Lyer configuration. Five variants differing in scaled similarity were pretested for illusion magnitude. All *S*s then received practice with the standard configuration during which illusion decrement was obtained. This was followed by a posttest on the initially tested variant. Transfer of decrement was monotonically related to perceived similarity. These data indicate central processing components in the Müller-Lyer illusion.

Since the first systematic studies of visual ·ometric illusions were undertaken by)ppel in 1854–1855, numerous theoretical explanations for these perceptual distortions have been offered. These theoretical treatments may be divided into two general classes: (*a*) theories based directly on the structural properties of the optical and nervous system; and (*b*) theories based on the way visual information is processed in he higher centers.

Structural theories contend that the il- l :sory distortions arise from physiological sources associated with the normal optical . d neural processing of visual inputs. Thus Chiang (1968) suggests that simple degradation of the optical array due to diffraction of the light as it passes through the crystalline lens may produce some intersecting line illusions such as the Müller-Lyer, Zoellner, or Poggendorff. Coren (1969) has demonstrated that this source of distortion can account for some 15% of the Poggendorff illusion with the other 85% of the illusion presumably caused by other factors. Another structural source of illusory distortion has been suggested by von Békésy (1967) and Ganz (1966) who contend that lateral inhibitory interactions operating on converging or intersecting line elements cause some of the perceived contour displacements and distortions. Coren (1970) and Girgus, Coren, and Horowitz (1973) have shown that removal of such converging line elements results in a reduction in the magnitude of several classical illusions, although significant distortions still remain in all cases.

Process theories attribute the existence of illusions to the cognitive processing of the perceptual inputs. Thus, Gregory (1963) and Gillam (1971) have shown that perspective cues which inappropriately evoke constancy scaling mechanisms contribute to the formation of some classical illusions. Coren (1971), Girgus, Coren, and Agdern (1972), Massaro and Anderson (1971), Pressey (1967), and Restle and Merryman (1968) have all found evidence that comparative judgmental components, such as cognitive contrast play a part in illusion formation, especially in configurations with unequal sized elements such as the Ebbinghaus figure. On the other hand, Carr (1935), Coren and Girgus (1972a), and Erlebacher and Sekuler (1969) have provided evidence that confusion of test with inducing elements seems to contribute to illusion magnitude in some configurations. A recently revived theoretical position maintains that some illusory distortions are based on information from scanning eye movements over the figures or information extracted to guide such movements (Binet, 1895; Coren & Hoenig, 1972a; Van Biervliet, 1896).

[1] We gratefully acknowledge the assistance of Richard Fraenkel in the collection and analysis of these data.

[2] Requests for reprints should be sent to Stanley Coren, Department of Psychology, University of British Columbia, Vancouver 8, British Columbia, Canada.

As early as 1902, Judd observed that, with free inspection over a period of time, the magnitude of the perceptual distortions in the Müller-Lyer illusion diminishes. This has since been repeatedly confirmed both for the Müller-Lyer illusion and for a number of other configurations. Although the precise mechanisms for this decrease in illusion magnitude are not fully understood, it seems unlikely that the peripheral structural components, such as optical aberrations from the crystalline lens, could be responsible for such an illusion decrement. These factors would not be expected to show changes which would lead to reduction in illusion magnitude simply as a function of inspection of the stimulus for a few minutes. There are, however, some more central structural components that have been proposed specifically to account for illusion decrement. These include cortical satiation effects (Kohler & Fishback, 1950) and adaptation of specific feature analyzers (Coltheart, 1971).

There is some evidence that these central structural components are probably not responsible for decrement. Köhler and Fishback (1950) imply maximal decrement in illusion configurations where there are converging line segments; yet, Girgus et al. (1973) have shown that the rate of illusion decrement is independent of the number of converging line elements. Both Köhler and Fishback (1950) and Coltheart (1971) predict the maximum reduction in illusion strength under fixation conditions; yet several investigators have shown that free inspection leads to a larger reduction in illusion magnitude than fixation (Coren & Hoenig, 1972b; Festinger, White, & Allyn, 1968).

There is some further indirect evidence that decrement of illusion magnitude involves process rather than structural components: (*a*) the rate of decrement responds to traditional learning variables such as the spacing of trials (Dewar, 1968; Mountjoy, 1958); (*b*) the amount of illusion decrement is cumulative over days and weeks (Judd, 1902); (*c*) direct manipulation of factors which should effect structural mechanisms of decrement such as the number of converging and intersecting line segments, do not appear to alter the rate of illusion diminution with inspection (Girgus et al., 1973).

Although these results suggest that the decrease in illusion magnitude with free inspection is due to process components, they are not conclusive. There is a technique, however, emanating from traditional learning studies, which may provide a tool for answering this question in a more convincing manner. Consider an *O* who has been inspecting an illusion configuration such as the Müller-Lyer, and has been allowed to observe it long enough for a reasonable amount of decrement to take place. If we now present him with a variant of the inspected illusion which differs in some respects from the originally viewed form, it is not unreasonable to expect some transfer of decrement to this new configuration. Some evidence for such transfer of illusion decrement may be inferred from Parker and Newbigging (1963). This transfer, or generalization, would be expected on the basis of both structural and process explanations. However, the parameters which would affect the amount of transfer are different for the two classes of illusion theories. Structural explanations would predict that the amount of transfer of illusion decrement would depend on the number of common elements in the two stimuli. Thus the greater the number of formal configurational similarities, the greater the expected amount of transfer. A process explanation would contend that the amount of decrement transferred to the new variant would depend upon the observers cognitive assessment of the similarity between the configurations. The more similar the figures appear, the greater the amount of transfer of the reduction in illusion magnitude, regardless of the number of elements in common. Thus the amount of transfer or generalization of illusion decrement seems like a useful means of clarifying the theoretical nature of illusion decrement.

METHOD

Scaling of stimuli. Since this experiment is designed to explore whether illusion decrement trans-

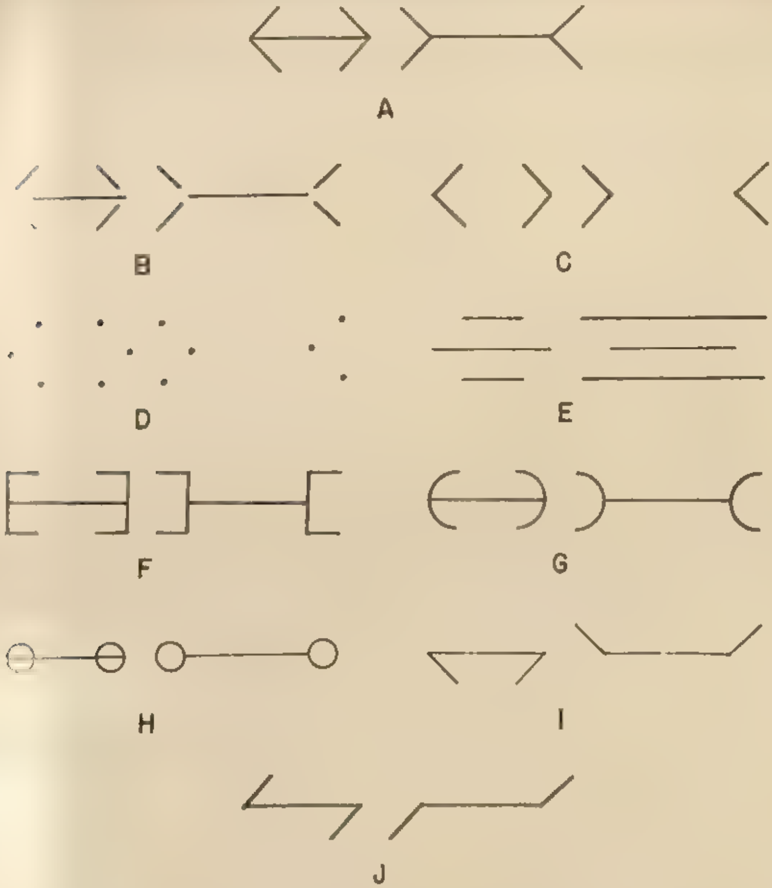

FIGURE 1. Variants of the Müller-Lyer figure scaled for similarity to the standard figure. (Forms A through E are used in the main experiment: [A] Standard form, [B] Exploded form, [C] Shafts removed, [D] Dot form after Coren, [E] Line form after Piaget, [F] Squared wings, [G] Curved wings, [H] Full circles after Parker and Newbigging, [I] Symmetrical, and [J] Asymmetrical incomplete forms after Sanford.)

fers more to perceptually similar configurations than to dissimilar ones, it is first required to establish a scale of similarity among illusion configurations. Ten variants of the Müller-Lyer figure were used to obtain such a metric. They consisted of the standard configuration (Figure 1A), a variant in which the wings are separated from the shaft by a small gap (1B), a standard configuration with the horizontal shafts removed (1C), a dot form of the illusion (1D) which was introduced by Coren (1970), an all horizontal version of the illusion (1E) introduced by Piaget (1969), a figure with squared off wings (1F), one with half circles as wings (1G), another with appended full circles (1H), after Parker and Newbigging (1963), and two configurations from Sanford (1898) that use only half of the arrowheads, either symmetrically (1I) or asymmetrically (1J) oriented. Each configuration was drawn on a 20 × 25 cm. piece of stiff paper with 1-mm. wide black lines. The horizontal shafts (or distance between the shafts when the shafts were not present) were always 8 cm. in length. Each of 15 *S*s was asked to judge the similarity of each configuration, presented one at a time, to the standard configuration (1A) which was continuously visible. Judgments were made using a 7-point rating scale labeled (1) extremely similar, (2) very similar, (3) fairly similar, (4) medium, (5) fairly different, (6) very different, (7) extremely different. The mean of the ratings per stimulus configuration can be used to indicate the perceived similarity between the configuration and the standard version of the illusion. The obtained ratings were used to select four variants of the illusion reliably rated as differing from each other in their similarity to the standard configuration. Those selected were the exploded form (1B) with a mean rating of 1.47, the configuration without shafts (1C) with a mean

rating of 3.47, the dot form (1D) rated 4.60, and the Piaget form (1E) whose rated similarity was a distant 6.53. *T* tests indicated that the mean rating of each of these configurations was significantly different from that of each of the other configurations ($p < .05$). It should be clear that this particular scaling procedure gives only a one-dimensional representation of the psychological space. However, since the theoretical issue involves only the question of the psychological distance between the standard form and the respective variants, this should be sufficient.

Subjects. Fifty undergraduate volunteers served as *S*s. Each was randomly assigned to one of the five variants of the Müller-Lyer illusion used in this study (the standard configuration plus the four variants described above).

Stimuli and apparatus. The five (Müller-Lyer) configurations—1A, 1B, 1C, 1D, 1E—served as stimuli. All of the figures were constructed with 1-mm. wide black lines. The reflectance of the lines was 5.1% and of the background was 74.3%. The test shafts (or the distance between the wings) were 8 cm. long, which corresponded to a visual angle of 12.0. When angles were present, they were 45° from the horizontal; when wings were present, they were 2 cm. long. For each configuration, the apparently longer half of the illusion was made adjustable through the use of a tongue and groove arrangement. Readings were taken in mm. from a scale affixed to the back of the adjustable half of the illusion.

Procedure. Each *S* first made two settings to apparent equality for one of the five variants of the illusion, depending upon his assigned condition. Settings were balanced as to starting position, half starting at clearly longer and half at clearly shorter. Following this, all *S*s then inspected the standard form of the Müller-Lyer figure (1A) for 5 min. with free eye movements. During this period *S*s made settings of apparent equality at 1-min. intervals. Previous investigations have shown that this procedure leads to a sizable reduction in illusion magnitude (Coren & Girgus, 1972b; Girgus et al., 1973). Following the inspection period, all *S*s made another two settings of apparent equality on the initially tested illusion variant. Any diminution in the strength of the nonpracticed illusion configuration between the pretest and the posttest may be taken as an indication of the amount of illusion decrement that has transferred from the standard configuration to that particular variant.

Results and Discussion

Since we are interested in the amount of transfer of illusion decrement from the standard Müller-Lyer configuration to other variants of the illusion, we must first verify that illusion decrement has in fact taken place. An analysis of variance performed on the judgments made during the 5-min. inspection period with the stan rd form of the illusion reveals that the ount of illusion decrement obtained acr the five groups is statistically significant. (5, 225) = 9.96, $p < .001$. However, e is no significant difference among the oups in amount of decrement and no nificant interaction. The mean amoun f decrement was 7.0 mm. This ma itude is quite comparable to values rted in other studies of illusion decre t using the standard configuration (Corer Girgus, 1972a, 1972b; Girgus et al., 1). Regression lines were fitted throug he plot of illusion magnitude against tim or each experimental group. The mea ope of these lines was 1.4 mm/min; range among the five slopes was only .4 m/min and tests on all possible paired d rences yielded no significant group d rences. These results support the conten on that the magnitude of illusion decre ent obtained on the standard figure is equ l across conditions.

The mean amount of illusion per test configuration for the pretest and the posttest is shown in Table 1. In order to assess the amount of transfer from the standard form of the illusion to the five test configurations, an analysis of variance was performed on these data. The results of this analysis indicate that there is a significant pretest–posttest difference, thus demonstrating that transfer of illusion decrement has occurred $F(1, 45) = 73.71$, $p < .01$. In addition a significant interaction between pretest–posttest differences and illusion form indicates a difference among configurations in the amount of transfer, *F*

TABLE 1

Illusion Magnitude of Five Variants of the Müller-Lyer Pre- and Postinspection of the Standard Configuration A

Illusion form[a]	Preinspection illusion (mm.)	Postinspection illusion (mm.)	Transfer (Pre-post)
A	21.9	12.4	9.5
B	15.9	8.9	7.0
C	19.2	15.4	3.8
D	6.6	4.6	2.0
E	8.8	8.5	.3

[a] Forms are labeled as in Figure 1.

(4, 45) = 10.00, $p < .01$. A significant main effect for illusion variants also exists, F (4, 45) = 12.60, $p < .01$. This main effect reflects differences in the initial magnitude of illusion obtained for the various forms, and it is correlated with the number of converging and intersecting line elements in the stimulus as has been reported elsewhere (Girgus et al., 1973). A quick glance at the table also verifies that the magnitude of decrement transferred from the standard to the test variants is independent of the initial magnitude of illusion.

The most theoretically relevant comparison is the amount of transfer as a function of the perceived similarity among the variants. A process theory would predict that as rated similarity between inspection and test figure decreases the amount of decrement transferred should also decrease. The amount of transfer from inspection of the standard is computed from the pretest–posttest differences and plotted against rated similarity of the test configuration to the standard in Figure 2A. It is clear that less transfer is found for more perceptually dissimilar stimuli. A linear trend through these points confirms this, F (1, 45) = 13.04, $p < .01$.

It is important to assess whether these results based upon perceived similarity between the test and the standard configurations predict the amount of illusion decrement transferred with any more accuracy than would a formal analysis of the contour and pattern properties of the configurations. Two methods of assessing the formal similarity of the illusion variants were used to answer this question. In the first, the standard form of the illusion was superimposed on a 40 × 200 matrix of squares, each of which subtended 1 square mm. The standard figure was found to overlap 320 units on this matrix. Each successive variant was then superimposed on the matrix. The number of units held in common between the standard and the variant then serves as an index of the similarity between the patterns. The second scoring procedure simply provides a count of the theoretically relevant pattern elements present in the illusion figures.

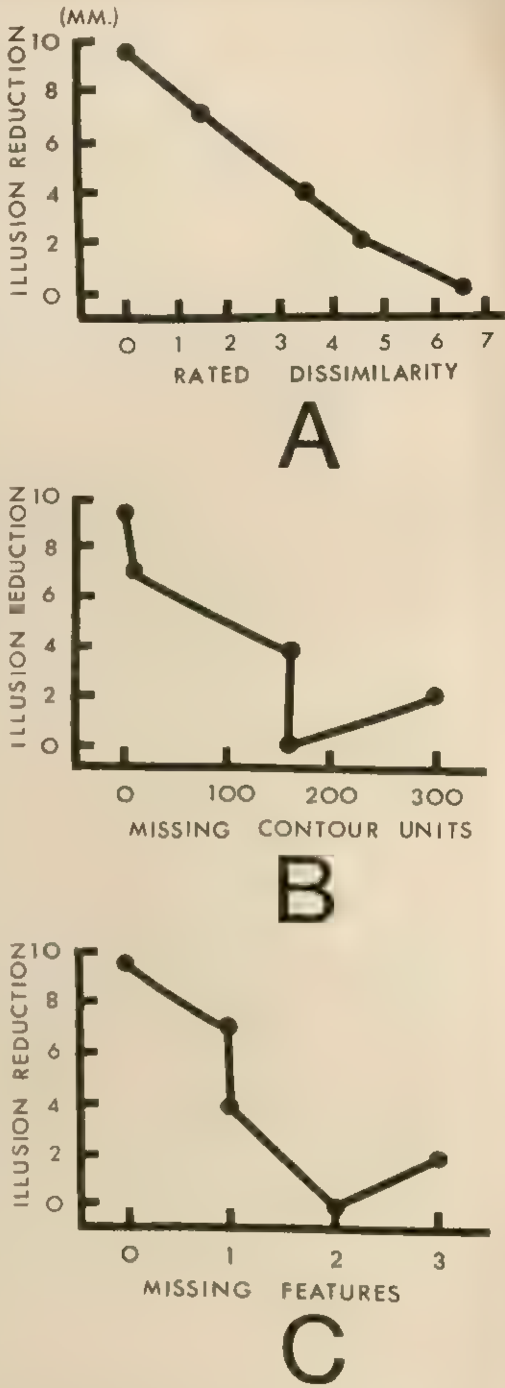

FIGURE 2. Transfer of illusion decrement, measured as illusion reduction in the test figure after practice with the standard form, plotted against (A) perceived dissimilarity of test and standard form, (B) number of missing contour units, and (C) number of missing pattern elements.

These are converging lines, horizontal shaft, and closed angles. All of these properties are contained by the standard form of the illusion, and the number contained by each variant may serve as an index of formal similarity. Figure 2B plots the degree of transfer as a function of the number of missing contour units, and Figure 2C plots the transfer as a function of the number of missing pattern elements. Visual inspection of these figures seems to indicate that neither of the two scoring schemes produces as good a fit to the data as does rated dissimilarity. This is confirmed if we compute the product-moment correlation coefficient for each method of presentation. For rated dissimilarity the correlation with transfer of decrement is $-.751$, for missing contour elements it is $-.448$, and for missing pattern elements it is $-.518$. Although each of these is significantly greater than zero with $p < .01$, the coefficient for the rating procedure is significantly greater than either of the other two procedures with $t\ (47) = 3.47$, $p < .01$, and $t\ (47) = 3.01$, $p < .01$, respectively. This result seems to warrant the interpretation that perceived similarity among configurations is a better index of the amount of illusion decrement transferred from one configuration to another than indices based upon formal properties of the figures involved.

The data presented above seem to be at variance with predictions from structural interpretations of the diminution of illusions with inspection, such as satiation (Köhler & Fishback, 1950) or adaptation of specific feature analyzers (Coltheart, 1971). These theories would predict that transfer would be a function of the formal similarity of the stimuli, such as the number of common elements in inspection and test forms. In the Müller-Lyer figure, the most theoretically important elements are the lines which define the angle between the wings. For satiation theory, this is the region in which the maximum effect is concentrated, and for specific feature adaptation models, these are the stimuli for the feature detectors which are held to fatigue with inspection. These critical angles are clearly present in Figures 1A, 1B, and 1C thus leading to the prediction that the amount of transfer should be equal among these three targets. Contrary to this, we find a decrease in the amount of transfer as the rated similarity decreases. These differences are substantiated by the statistical significance between the adjacent means ($t = 2.98$ and 3.82, respectively, $p < .01$). Since the structural effects should confine themselves to effects pertaining to angles or slanted lines, we would expect no transfer to Forms 1D and 1E since they lack any converging line elements. In addition, they are virtually devoid of any elements in common with the standard configuration. Although the Piaget from (1E), shows no significant amount of transfer, $t\ (252) = .36$, this would be expected both on the basis of missing common elements and the fact that this configuration is the lowest in perceived similarity to the standard configuration of all of the figures tested. We do, however, find significant transfer of decrement for Coren's dot form of the illusion (1D), which also contains no line elements in common with the standard form, $t\ (252) = 2.39$, $p < .01$. Taken together, these data make it unlikely that decrement of the Müller-Lyer illusion under free viewing conditions is due to satiation of cortical fields or adaptation of specific feature analyzers.

Alternatively, it might be suggested that decrement is due to a shift in the way in which the figure is judged. According to this point of view, during the decrement procedure, the O begins to pay more careful attention to the test extent and to ignore the inducing components. Such attentional restriction has been shown to reduce illusion magnitude in the Müller-Lyer (Benussi, 1912; Coren & Girgus, 1972a). If such a restriction of attention were responsible for decrement, however, one might expect that such a set would carry over equally to all alternative forms of the illusion. This would then predict an equal amount of transfer of illusion decrement for all of the configurations, rather than the generalization curve obtained. If, on the other hand, such a judgmental set was only applied as a function of the perceived

similarity of the test to the inspection figure, such a mechanism could explain these results.

The one thing that does seem to clearly emerge from these data is the fact that illusion decrement almost certainly reflects a process mechanism, responding to central cognitive factors, rather than a structural mechanism, responding only to the formal configurational aspects of the stimulus array. This is confirmed by the fact that perceived similarity between practice and test stimuli seems to act as a very accurate predictor of the amount of transfer or generalization of illusion decrement from a practice to a test form. Although this result does not serve to pin down the actual mechanism involved in illusion decrement, it certainly serves to limit the class of explanations that are most likely apt to be valid.

SHORT REPORTS

RECOGNITION LATENCY FOR A SUBJECTIVELY ORGANIZED LIST[1]

DOUGLAS J. HERRMANN[2] AND JOHN P. McLAUGHLIN

University of Delaware

A previous study showed that after *S*s memorized a list organized into category groupings, recognition latency (RL) to double-word displays (DWDs) was faster to DWDs representing the same category, HORSE–BEAR, than to DWDs representing different categories, LION–RUSSIA. This result was essentially the same when the words in a DWD were both old, one old and one new, or both new. In contrast, the present experiment showed that after learning a list of unrelated words organized into subjective groupings, the representation of groupings in DWDs affected RL only when both words in a DWD were old. Effects of subjective organization on recognition were hypothesized to differ from those of category organization because the semantic bases of subjective organization are too diverse to influence the recognition retrieval process.

Recent research has shown that organization of items during learning affects the latency of subsequent recognition. For instance, McLaughlin and Herrmann (1972) and Herrmann and McLaughlin (1973) have shown that after having memorized words in category groupings, e.g., *animals*, *countries*, *S*s recognized a double-word display (DWD) faster when the words in a DWD represented the same category, e.g., HORSE–BEAR, than when they were from different categories, e.g., LION–RUSSIA. This result was essentially the same for *old* responses (both words in a DWD from the list), *new* responses (both words not from the list), and *mixed* responses (one word in a DWD from the list).

It is often assumed that organizational processes involving relatively unstructured materials such as a list of unrelated words (Tulving, 1968) are the same as for highly structured materials, such as a categorized list. For example, a subjective grouping may be similar to a category grouping in that both list organizations reflect a semantic organization (cf. Schwartz & Humphreys, 1973). Consequently, one might expect subjective groupings to affect recognition latency in the same manner as that observed for category groupings. Alternatively, if subjective groupings are not equivalent to category groupings in organizational characteristics, a different pattern of results might be expected. The purpose of the present research was to investigate these alternatives.

Method. Twelve students participated as *S*s in partial fulfillment of a course requirement.

A three-channel tachistoscope (Scientific Prototype, Model GB) presented a white pre–post exposure field in the first channel, a fixation field in the second channel, and the DWD in the third channel. The two words in the DWD were typed in uppercase and centered one above the other. The response apparatus consisted of three levers on which *S* rested his index, middle, and ring fin[illegible] Latencies were measured to an accuracy of ±[illegible]

Each *S* was run individually in two [illegible] In the first session *S* memorized a list of [illegible] related words, each of which was printed on [illegible] × 5 in. card. Each of three lists, A, B, and C, [illegible] memorized by four *S*s. Each word on a list wa[illegible] member of a different taxonomic category in th[illegible] [illegible] and Montague (1969) category norms, and [illegible] same 18 categories were used across the thr[illegible] Before studying the list, *S* sorted the words in[illegible] groupings which were conceptually similar. At le[illegible] two and no more than seven groupings were allowed (cf. Mandler, 1967). The *S* sorted and then studied the list (for 3 min.) until he recalled all 18 words (within 1 min.) three times in succession and until there was perfect agreement in composition of sorting for three sorts in succession.

The second session, scheduled at *S*'s convenience, began approximately 24 hr. after the first session for 9 *S*s and 48 hr. later for 3 *S*s. Due to the variable delay between sessions, the *S* began the second session by restudying the list. There were no differences in performance as a function of lag between sessions. After restudying and resorting the words, *S* was seated before the tachistoscope and given recognition-test directions as described in Herrmann and McLaughlin (1973).

The recognition test consisted of two blocks of 18 DWDs each. Words for *old* DWDs came from the list which *S* memorized, e.g., List A. For *mixed* DWDs one word came from *S*'s list; the other word in *mixed* DWDs and both words in *new* DWDs came from one of the other lists in Block 1, e.g., List B, and from the remaining list in Block 2, e.g., List C. Thus, all *old* words were presented twice across the blocks, but nonmemorized words were presented only once across blocks. A different random presentation of conditions was used for each *S*.

For half of the *old* DWDs, the two words in a DWD had been studied together in a grouping during acquisition, i.e., the words in a DWD origi-

[1] The authors thank Robert M. Schwartz and Edward J. Shoben for helpful comments on an earlier draft of this article.

nated [illegible] the same study grouping (SG-DWDs). For the remaining half of the *old* DWDs, the two words of a DWD originated from different study groupings (DG-DWDs). Similarly, half of the *mixed* and *new* DWDs were SG-DWDs and half were DG-DWDs, wherein grouping origin was designated by the category to which nonmemorized words belonged and by which categories were represented in *S*'s groupings in acquisition. For example, if in memorization *S* had grouped the words WHISKEY and SUGAR, then he was considered to have grouped the categories *alcoholic beverage* and a *substance for flavoring food*. Since it was possible that *S* might organize nonmemorized items differently from memorized items, despite both kinds of items being from the same categories, a comparison was made of the groupings of List A, by the 4 *S*s who learned that list, to the groupings of List B and List C, by the 4 *S*s who learned each of those lists. It was found that there was a significant tendency for the same categories to be represented in a grouping on all three lists, $p < .001$ (see Herrmann, 1972). For example, regardless of which list he learned, *S* tended to place an *alcoholic beverage* and a *substance for flavoring foods* in the same grouping.

Results and discussion. The latency data for correct recognition responses (96.3% of all responses) are shown in Table 1. The table presents the mean of median correct reaction times (RTs) for the three response types as a function of the grouping origin of DWDs, i.e., SG and DG. The medians were based on the three RTs per condition within a presentation block. The latencies in the table have been averaged over blocks, since the analysis of variance indicated that blocks did not significantly affect latency or interact with the other experimental variables, $ps > .05$. Thus, the repetition of *old* words and the lack of repetition of *new* words across blocks did not differentially alter the effect of subjective organization on *old*, *mixed*, and *new* latencies.

Inspection of Table 1 suggests that grouping origin of words in a DWD affected *old* latencies but did not affect *mixed* and *new* latencies. The analysis of variance and simple effects tests confirmed that *old* RT to SG-DWDs was less than RTs for all other kinds of DWDs ($p < .01$), but that all other RTs did not differ significantly from each other. Thus, these data show again that the relationships used during learning affect recognition (cf. Herrmann & McLaughlin, 1973).

The results for subjective organization differ from the effects of category organization on recognition latency. Herrmann and McLaughlin (1973) found latency was faster to same-category DWDs than to different-category DWDs for *new* and *mixed* DWDs as well as for *old* DWDs. In contrast, in the present study, latency was faster to same-grouping DWDs than to different-grouping DWDs for *old* DWDs but not for *new* and *mixed* DWDs. This contrast in results for category groupings and subjective groupings is somewhat surprising since both types of organization have a semantic basis. Apparently, the semantic organization in subjective

TABLE 1

Mean of Median Correct Reaction Times (in msec.) for *old*, *mixed*, and *new* Responses as a Function of Grouping Origin

Response type	Grouping origin	
	Same grouping	Different grouping
Old	1,584	1,797
Mixed	1,945	1,906
New	1,835	1,861

groupings, in the absence of learning, was not sufficient to affect recognition latency. For subjective groupings to affect latency, it seems necessary that the grouping be memorized, i.e., contiguity during learning is crucial for the subjective-organization effect on recognition latency.

Regardless of contiguity's role in the effect on *old* latencies, it is puzzling that the semantic information alone in subjective groupings did not have some effect on mixed and new latencies. Models of semantic memory, e.g., Collins and Quillian (1969), predict that successive retrieval of related items will take less time than retrieval of unrelated items. The lack of an effect from the semantic basis of subjective groupings suggests that subjective groupings differ qualitatively from common taxonomic categories. Subjective groupings in the present study were apparently based on several semantic factors, in contrast to the single categorical basis of category groupings. For example, many *S*s placed *alcoholic beverages*, *substances for flavoring foods*, and *kitchen utensils* in a "foods" grouping. Note that the group included "things to eat" as well as "things to eat with." Thus, a grouping was based on both taxonomic relationships and use relationships. Because of the diverse semantic bases of subjective groupings, semantics may have no influence on recognition retrieval processes when a subjectively organized list is involved. This conclusion does not deny that semantics may influence the formation and initial storage of subjective groupings.

THE EFFECT OF CUE–CRITERION FUNCTION FORM ON SINGLE-CUE LEARNING[1]

L. F. W. DE KLERK[2] AND A. G. VROON

University of Leiden, Leiden, The Netherlands

This investigation is concerned with the effect of the form of the function relating cues to a task criterion upon single-cue learning. Three function forms were used (one in each condition): a J-shaped, a reversed J-shaped, and a U-shaped function form. The results indicated that (*a*) performance gradually improves with training; (*b*) a U-shaped function is more difficult to learn than a reversed J-shaped function, and the latter is more difficult than a J-shaped function. This result is in agreement with the *progression hypothesis*; and (*c*) the relative variances decrease as a function of training. This result does not support the view that single-cue learning is to be conceived of as a two-process theory, which would predict that the relative variance first decreases and then increases.

A single-cue learning experiment requires the S to infer a value of a criterion variable, Y_i $(i = 1 \ldots n)$ from that of a cue variable X_i $(i = 1 \ldots n)$. In fact, S has to learn to utilize the (real valued) function which determines the assignment of Y_i to X_i. The dependent variable for learning is S's prediction of Y_i, say $\hat{Y}_i$, when confronted with X_i.

It has been commonly assumed that S actually processes information in reaching a solution. The underlying assumption is that S is sampling and testing hypotheses in acquiring the function relating criterion to cue values. There is abundant evidence that the universe of hypotheses from which S is sampling is hierarchically structured. Studies in single-cue learning have shown that nonlinear functions are more difficult to learn than linear functions (e.g., Brehmer, 1971; de Klerk & Oppe, 1972). Positive linear functions are easier to learn than negative linear functions (e.g., Björkman, 1965; Brehmer, 1971; Eisler & Spolander, 1970).

According to the theory of single-cue learning, proposed by de Klerk and Oppe (1972), S starts constructing "simple hypotheses" and progresses—if necessary—towards more "complex hypotheses." Their study provided preliminary evidence for this so-called progression hypothesis. The results indicated that when the task required the S to learn a quadratic cue–criterion relation, linear processing preceded quadratic processing. This effect appeared to be highly influenced by the criterion variance.

The present investigation examines the effects of three different quadratic cue–criterion function forms upon single-cue learning. The cue which Ss had to learn to depend upon was related to criterion in either (*a*) a J-shaped manner; (*b*) a reversed J-shaped manner; or (*c*) a U-shaped manner. If the above mentioned results are valid, they will lead to the following predictions. When the cue–criterion function form is a J arc, then it is [illegible] able to assume that S starts constructing a p[illegible] linear function. When a reversed J-shaped [illegible] form is to be learned, S is assumed to sta[illegible] zing a negative linear function. Since it is e[illegible] to learn a positive linear function than a ne[illegible] linear function, it is to be expected that a J-[illegible] d arc is more accessible and easier to learn tha[illegible] eversed J-shaped arc. When the cue–criteri[illegible] function form is U shaped, S is supposed to start [illegible] ucting two linear functions. Therefore, this [illegible] of task function is expected to be more difficult to learn than the other two forms.

Method. The paradigm used in the present study comprised three events that occurred in the learning trials: a stimulus derived from the function cue (X), the S's response $\hat{Y}$, and feedback of the correct value of Y to the subject. The cue values were presented on a scope display. On this display, two marks were present which indicated the endpoints of an imaginary horizontal line. On every trial a dot was presented on this scale. This dot designated the value of X. The values of X could vary from 0 (i.e., the origin of the scale) to 100 (i.e., the right end point of the scale).

Following each presentation of the cue, Ss had to respond by turning a special knob to the estimate ($\hat{Y}$) of the function value, the scale being graded from 0 to 100.

The Ss received feedback after each setting of the knob by presentation of the correct value of the criterion, Y, as a number on a special number display. The value of Y was computed according to $Y = f(X) + e$, in which e is a random component, the value of e being obtained by random sampling from a normal distribution with a mean of 0 and a variance of 16. This variance is referred to as the criterion variance, s_e^2.

Three different experimental conditions were created by using three different functions. These functions were:

$$Y = .015X^2 - .8X + 21, \qquad [1]$$

$$Y = .015X^2 - 2.2X + 91, \qquad [2]$$

[1] This research was supported by a research grant from The Netherlands Organization for the Advancement of Pure Research (Z. W. O.).

[2] Requests for reprints should be sent to L. F. W. de Klerk, Department of Psychology, Stationsplein, 10, 2e Etage, Leiden, The Netherlands.

and

$$Y = .032X^2 - 3.2X + 91. \qquad [3]$$

Th[illegible] criterion function form represented by Eq[illegible] 1 is a J arc, the form that is represented by [illegible]ation 2 is a reversed J arc, and the form of Fun[illegible]on 3 is a U arc.

D[illegible]ing learning, S was sitting at a table in front of the scope display. On this table were mounted the response knob (provided with a scale), the nu[illegible]ber display, and a microswitch. Each learning tr[illegible] started with the presentation of the cue. Then [illegible]s requested to turn the response knob into the [illegible]ed scale position. After this response S could [illegible]t the presentation of a number on the number [illegible]play (i.e., feedback) by depressing the micro[illegible]itch. Twenty such learning trials constituted a [illegible]rning run. The test, which followed upon each [illegible]arning run, consisted of seven different cue values which were equally spaced along the X continuum. During every test, the same seven cue values were presented 10 times without feedback. In every test the cues occurred in different random orders.

Presentation and recording was done automatically by means of punched tape. The output tape contained the specific values of X that were presented during testing and the corresponding values of $\hat{Y}$.

The Ss were told that Y was a function of X plus or minus a random deviation, and that it was their task to discover this function and to use it as accurately as possible during testing. Each S worked under one condition. The Ss made 10 learning runs alternating with 10 test runs. The whole experiment took about 2 hr. per subject. The Ss were paid.

Twenty-four Ss participated in this study. They were randomly divided into three groups with eight Ss in each. The Ss were unfamiliar with this type of experiment.

Results. For each S and for each run the value of D was computed according to $D = \sqrt{\Sigma(Y_i - \hat{Y}_i)^2/n}$, where n is the number of trials.

An analysis of variance was performed on these D scores. The results showed significant main effects of function form, F (2, 23) = 10.86, $p < .001$, and run, F (9, 23) = 25.31, $p < .001$. The interaction between function and run was not significant.

The results of this analysis of variance indicated that Ss' performance improved as a function of learning. In Figure 1, mean D scores are plotted against the number of test runs for each of the three conditions. Performance gradually increased as training progressed and the overall performance was largely dependent upon the function form.

For each S the variance in the responses for each of the seven cues was computed per test. These response variances, s_y^2, were then divided by the criterion variance, s_e^2.

The overall analysis of variance that has been carried out on these relative variances indicated significant main effects of function, F (2, 108) = 132.50, $p < .001$; run, F (9, 108) = 24.20, $p < .001$; and cue, F (6, 108) = 9.09, $p < .001$. Of the interactions only those of Function × Run, F (18, 108) = 6.53, $p < .001$; and Run × Cue, F (54, 108) = 2.05, $p < .01$, were significant.

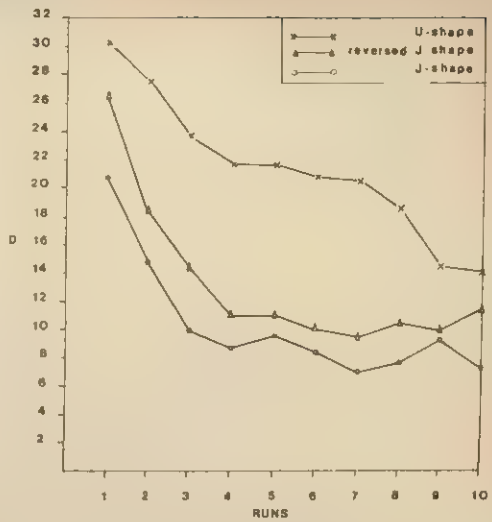

FIGURE 1. Plot of D as a function of test runs for each experimental condition.

The mean relative variances are presented in Table 1. Within every condition the mean variance in Ss' response system exceeded the criterion variance.

Discussion and conclusions. The present results provide several conclusions. First, the data clearly show that performance gradually improved over test runs. The rate of learning was approximately the same for all three functions. The D measures, which reflect the accuracy with which the functions are used, demonstrate that the extent to which Ss learn and utilize relations depends largely upon the task function form. A U-shaped function is more difficult to learn than a reversed J-shaped function; a reversed J-shaped function is more difficult to learn than a J-shaped function. These findings are in agreement with the conjectures that were derived from the progression hypothesis

A second conclusion is that the above mentioned differences between functions remain approximately constant over the range of test runs. Thus, the differences between functions do not decrease as training progresses. This is in agreement with the results of Brehmer (1971), who found that S's skill in using a function depends largely upon the particular function form S has to use. Especially when the task requires S to learn a U-shaped function form, performance appeared to be rather poor.

A third conclusion is that the relative variances, expressed by the s_y^2/s_e^2 ratios, decrease with training. The results indicate that the extent to which these ratios decrease is significantly influenced by the form of the function that is to be learned. Within every condition, the variance in S's response system exceeds the variance in the task system.

TABLE 1

MEAN RELATIVE VARIANCES PER RUN FOR EACH FUNCTION

Function	Run									
	1	2	3	4	5	6	7	8	[illegible]	10
J shaped	10.9	6.2	2.4	1.9	[illegible]	2.2	2.0	1.8	[illegible]	1.7
Reversed J shaped	20.0	11.5	7.5	3.6	5.4	4.5	2.5	3.7	[illegible]	7.1
U shaped	25.6	18.4	16.1	13.1	10.3	10.3	13.5	13.3	[illegible]	9.3

This finding is inconsistent with the results of Bjorkman (1968), who found s_a^2/s_e^2 ratios which were below unity, especially at the end of training.

Bjorkman (1968) suggested that a single-cue probability learning task required the S to learn (a) the function relating criterion to cue values (i.e., functional learning) and (b) the distribution around this function (i.e., cue probability learning). This two-process theory predicts that the relative variance should first decrease (as S learns the function) and then increase (as S learns the distribution of feedback values). Since the present results show only that the relative variances decreases, they do not offer support for this theory. This might be due to two different factors. First, it is possible that 10 successive runs of 20 learning trials only cover the first stage of the learning process and not the second stage (i.e., cue probability learning).

Second, due to S's inability to use a quadratic function correctly, there always will remain a certain amount of (error) variance in S's response system, even when a sufficient number of learning trials is given. The minimum value of s_a^2 [illegible] depends upon the function form that is to [illegible] ned. If this asymptotic value of s_a exceed[illegible] e of s_e, then the relative variance will only [illegible] se as a function of learning. Since in the pr[illegible] dy the value of s_e^2 is relatively small [illegible] derably smaller than in Bjorkman's, 1968, st[illegible] s might be the case here.

EFFECTS OF TWO TEMPORAL VARIABLES ON THE LISTENER'S PERCEPTION OF READING RATE

FRANÇOIS GROSJEAN

Département d'Anglo-Américain, Université de Paris VIII, Paris, France

HARLAN LANE [1]

Institut d'Études Linguistiques et Phonétiques, Université de Paris III, Paris, France

Apparent rate grows much more rapidly for the speaker than for the listener as words per minute increase (exponents 2.6 vs. 1.6). The rate of speaking comprises three variables, however: the number of pauses, articulation rate, and the durations of the pauses. When a speaker doubles his rate (as it seems to him) he halves the number of pauses, altering the other variables only slightly. Conversely, the listener is much more impressed by changes in articulation rate than in pausing (exponents 1.5 and −.23). Thus, the perceptual processes of speaker and listener are somewhat complementary, and changes in the two variables have more comparable effects on the listener when expressed in units of apparent magnitude for the speaker. The net effect of mapping autophonic into extraphonic magnitudes in the transmission of speech rate is one of compression, both for overall rate (exponent .6) and for the component articulation rates (.44) and pause frequencies (.21).

A speaker may alter his rate by changing the number of pauses, the articulation rate, or the durations of pauses, in various degrees. The autophonic scale that describes the speaker's perception of his own rate has a slope of 2.6 when expressed as a function of words per minute (in log–log coordinates) and slopes of −1.1, 3.4, and 4.3 when plotted as a function of the respective components of these overall rates (Lane & Grosjean, 1973). It follows that when a speaker varies his rate of reading a known passage, he primarily adds or subtracts pauses (at strategic syntactic locations); he alters articulation rate and pause duration much less. The same is true for spontaneous speech: "Increase of speed in talking is due largely to the closing of gaps and to the heightened continuity with which movements performed at relatively constant rate succeed each other [Goldman-Eisler, 1968, p. 26]." An equivalent way of describing the relative importance of these variables for autophonic rate is to point out that as reading rate increased by a factor of 2.7 (close to the total operational range for reading sentences), the three component variables changed by factors of 10.3, 2.1, and 1.6, respectively.

How the three components of rate control the listener's perception is unknown. We do know from the autophonic study (Lane & Grosjean, 1973), in which a representative speaker's productions were also played back to listeners for numerical estimates, that apparent rate grows much more slowly for the listener than the speaker as words per minute (wpm) increase (slopes of 1.5 vs. 2.6). This difference in slopes indicates that the speaker's perception of his own rate is not based solely on auditory cues. Therefore, pause frequency, articulation rate, and pause duration may not have the same relative importance for the listener's perception of rate as they do for the speaker; it may matter a great deal whether it is your own tongue that is wagging. In the present experiment, then, the two variables that proved most salient in the perception of autophonic rate were decoupled, and each was varied systematically in a 5 × 5 array of rates presented to listeners. We examined the relative contributions of pause frequency and articulation rate to the listener's extraphonic perception of rate, the invariance of the cue hierarchy across

modalities, and the reproducibility of the extraphonic scale with somewhat different procedures and stimulus ensembles.

METHOD

Seventeen graduate students, native speakers of English with no reported speech or hearing defects, served in groups of three or four, while seated in an audiometric room for 1½ hr. They wore Opelem binaural headsets supplied in parallel by an Opelem 2M-70 studio tape recorder.

The method of magnitude estimation (Stevens, 1956) was used to measure the perception of speech rate. The *E* played a recording of the experimental passage, read with a midvalue of number of pauses (7 pauses or 9.4 syllables/run) and of articulation rate (4.5 syllables/sec). The *E* assigned the numerical value 10 to this standard rate (146 wpm). Next, he played 100 recordings of the passage, and the listener assigned to each a number proportional to its apparent rate. In all, 25 rates of reading by the same speaker, ranging from 85 to 225 wpm, were presented four times, in irregular order. Each rate corresponded to a combination of a level of articulation rate and a level of number of pauses, shown on the coordinates of Figure 2. (The length of the pauses was held constant, with tape splicing, at a mean value of .56 ± .01 sec. Each articulation rate was constant within 1% over the five levels of pause frequency.) The same passage employed in the extraphonic study and comparable ranges of the variables measured there were adopted in the present study. However, the rates presented here are somewhat lower (average wpm 146 vs. 165), thus higher pause frequencies (9.6 vs. 6.3) and lower articulation rates (4.5 vs. 4.8 syllables/sec) are naturally encountered.

The experimental passage contained the following 51 words of text (including contractions), comprising 75 syllables (the number at each pause emplacement shows the lowest pause frequency that entailed pausing there; all higher pause frequencies also used that emplacement):

> as far /24/ as I know /7/ I'm a fairly /24/ normal /13/ fifteen year old /3/ neither a complete /13 psychological /24/ case /7/ nor a cut /13/ above /24/ the others /1/ I listen /24 [illegible] Radio /24/ Luxembourg /7/ my hair /24/ falls forward /13/ in the fashionable /24/ style /3 and I wear /13/ polo neck /24/ sweaters /7 but I don't /24/ consider myself /13/ a great /24/ pop fan.

The hierarchy of pause emplacements is that observed in the autophonic experiment of Lane and Grosjean (1973).

RESULTS AND DISCUSSION

The extraphonic scale of reading rate is shown in Figure 1. The magnitude estimations are well fit by a straight line with a slope of 1.7, in logarithmic coordinates. (The mean and *SD* of the 17 individual slopes are 1.7 and .56., respectively.) The scale is substantially the same as that obtained with five rates of reading in which pausing and articulation rate were normally coupled, not varied independently (slope = 1.5, *SD* = .37; Lane & Grosjean, 1973). A slope of 1.6 is found in the latter study over the range of words per minute employed here; moreover, moderate levels of the two variables in the present experiment (3 × 3 subensemble) yield a slope of 1.62. We conclude that the extraphonic scale of reading rate is reasonably invariant over these differences in stimulus array and procedure, with a slope (exponent in linear coordinates) of 1.6.

The contributions of pause frequency and articulation rate to perceived reading rate may be examined in three different ways, all of which give the same general picture. The perceived-rate solid in Figure 2 suggests that the two components of overall rate contribute about equally over the ranges employed (approximately those encountered by Lane & Grosjean, 1973, in actual productions). An analysis of variance of rate estimates confirms that pause frequency and articulation rate are equally important: the two mean squares are 3,255

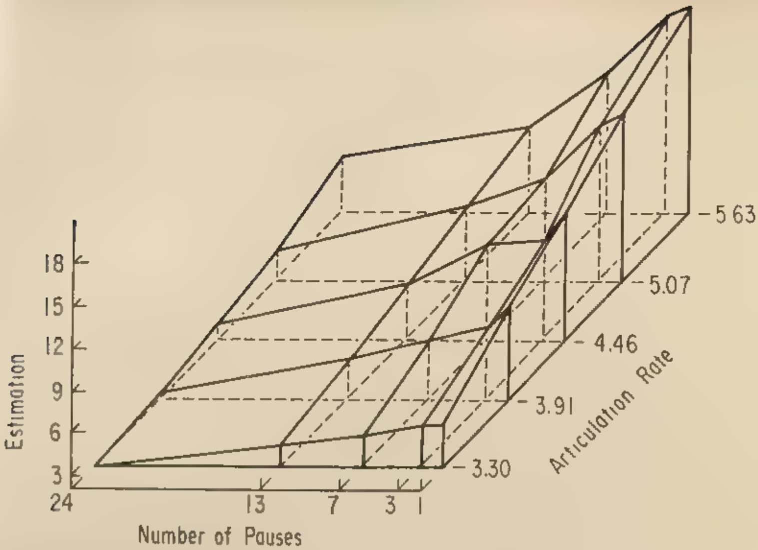

FIGURE 2. Numerical estimates of apparent rate as a function of two component variables, pause frequency and articulation rate. (The 25 line intersections plot the geometric means of 68 rate estimates, 4 by each of 17 listeners.)

and 2,919, respectively; $F(4, 64) = 98$ and 109, $p < .01$. The between-*S*s mean square is 136, *ns*. The interaction of pause frequency and articulation rate, evident in the graph, is statistically significant, mean square = 136; $F(16, 256) = 23$, $p < .01$. Eighty-four percent of the interaction sum of squares is associated with the one *df* corresponding to the bilinear component.[2] This suggests that the two cues combine multiplicatively to yield the net impression of overall rate. Thus, an increase in articulation rate may amplify the effects of pause frequency on apparent rate. The same result would be obtained, however, if the listener combines the two cues linearly under conditions in which the estimates are not linearly related to apparent rate, or if the weights assigned to the cues for integration vary as a function of stimulus magnitude.

A third way to evaluate the relative contributions of pause frequency and articulation rate, and to compare their importance for the speaker and the listener, is to examine the rates of growth of autophonic and extraphonic perceived rate as a function of the two components and overall words per minute. A speaker instructed to double his apparent rate will change pause frequency by a factor of 2, articulation rate by 1.2, and overall rate by 1.3 (since the autophonic slopes are −1.1, 3.4, and 2.6). A listener would estimate, however, that the changes were, in fact, 1.2, 1.3, and 1.5 to 1, respectively (since the extraphonic slopes found in this study are −.23, 1.5, 1.6). Consequently, equal changes in pause frequency and articulation rate have more comparable effects on the listener when those changes are measured in psychological units along the autophonic scale. Extraphonic rate grows approximately six times faster as a function of articulation rate than pause frequency, expressed in physical units. However, the rates of growth as a function of the corresponding apparent (autophonic) magnitudes are more similar: .44 and .21, respectively (absolute values). Thus, the perceptual processes of speaker and listener are somewhat complementary. The net effect is one of compression: extraphonic rate grows as the $1.6/2.6 = .6$ power of auto-

[2] The authors are grateful to Norman H. Anderson for calling this aspect of the results to our attention and for aiding us in applying his theory of functional measurement (Anderson, 1973).

phonic rate. It follows that speakers and listeners will not agree on what constitutes a doubling of rate (or halving, tripling, etc.), and that speakers will always fall short when trying to imitate the rate changes of a model.

AROUSAL AND RECALL: EFFECTS OF NOISE ON TWO RETRIEVAL STRATEGIES[1]

STEVEN SCHWARTZ[2]

Northern Illinois University

In a test of the notion that arousal affects the retrieval strategy of pigeonholing by decreasing the separation between risky and cautious criteria, 75 *Ss* heard short meaningful stories accompanied by either No, Medium, or High noise and were asked to recall the characters' names. Common names were better recalled than rare names in each noise condition. Using a decision theory analysis it was found that, in the No Noise condition, *Ss* employed a risky criterion for common names and a cautious criterion for rare names. In noise, however, *Ss* employed a similar criterion for recall of both common and rare names, but sensitivity increased for common names. The results were interpreted as supporting the hypothesis that arousal affects the accessibility of information for retrieval. A possible mechanism for arousal's action, as well as the theoretical implications of these findings, was discussed.

Drawing on his work in perception, Broadbent (1971) has identified two memory retrieval strategies—filtering and pigeonholing. According to Broadbent, filtering occurs when one adopts a "stimulus set," choosing items to be recalled on the basis of some common feature (e.g., acoustic similarity) and ignoring those items in memory without this feature. Filtering, therefore, involves the grouping of input on the basis of physical characteristics. Pigeonholing, on the other hand, occurs when one adopts a "response set" selecting from a large number of items (e.g., a list of words), those constituting a subvocabulary (e.g., the names of colors). Thus, filtering leads to stimulus selectivity, whereas pigeonholing results in response selection. When an operating characteristic is derived relating the probability of a correct response to the probability of an incorrect response (false alarm), pigeonholing produces an increase in the number of correct responses as the false-alarm rate increases, whereas filtering produces a change in the number of correct responses with a constant false-alarm rate. In decision-theory terms, filtering affects d', the difference between the correct response rate and the false-alarm rate, whereas pigeonholing affects β, the critical value of likelihood ratio above which S responds positively.

Despite recent interest in applying decision-theory measures to memory, the effects of arousal on d' and β as estimated from recall data have not been explored. On the basis of vigilance research, however, there is reason to believe that arousal affects pigeonholing but not filtering. Broadbent and Gregory (1965) found that, in a vigilance situation, arousal results in a change in the number of responses assigned to intermediate confidence levels. That is, aroused *Ss* were more certain that a signal was presented or more certain that no signal was presented than unaroused *Ss*. Such a mechanism may produce contradictory effects on pigeonholing.

Specifica hen conditions favor a cautious criterion (, ugh) a change in the number of *not sure* respons nay improve performance, whereas, when conditio favor risky responding, arousal may impede rmance.

If al's effect on recall is substantially similar to ct on vigilance, contradictory results would be ted depending on the value of β at the outset order to assess this hypothesis, it is necessa know in advance when *S*s will adopt a risky cr on and when they will adopt a conservative on o that the discrepant effects of arousal may be p ted out. Fortunately, such a situation is e established. The present study employed a m dification of a technique devised by Ingleby 9). In that study, *S*s were asked to recall the names of characters in short stories. Probe mes were suggested, and *S*s were asked to indicate he name was correct and to give a rating of confence in their judgment. Although d' was actually eater for rare names, recall for common names was superior because *S*s employed a riskier criterion (β was lower) for common names. Given a similar experimental task, the major hypothesis of the present study was that arousal would affect pigeonholing by producing a decrease in the separation of criteria (β) for rare and common names while d' remained unchanged. It was hypothesized that β for rare names would decrease, thus reducing the advantage of common names.

Method. The *S*s were 75 introductory psychology udents who received course credit for participaon. All *S*s reported having normal hearing; *S*s rticipated in groups of five. Experimental ses ns were conducted in the university language laboratory. The room was furnished with desks separated by side panels. Each desk contained a set of monophonic earphones.

Three short meaningful stories were used in the present study. The stories, which ranged in length from 375-525 words, were chosen from past issues of the *New Yorker* magazine. Each story had four characters, two of whose names were judged common and two of whose names were judged rare based on the frequency of their occurrence in the Chicago, Illinois, telephone directory. The mean frequency of common names was 920 (of about 900,000 telephone subscribers); the mean frequency for rare names was 43. The stories were recorded and presented on tape.

Upon entering the language laboratory, each *S* was seated at a booth, asked to put on his earphones, and given an instruction and answer booklet. The instructions informed *S* that the experiment was concerned with memory under various conditions. All *S*s were told that they would hear brief stories over their earphones and that a transcript of each story appeared in the answer booklet. Blanks in in the transcripts corresponded to character names. Corresponding to each blank was a suggested name and a rating scale. During the initial story presentation, the room was kept completely dark in order to discourage *S*s from making entries in their answer booklets. At the conclusion of each story, the lights were turned back on, and *S*s were required to read the transcripts and decide whether the name suggested was correct or incorrect and to give a confidence rating in their judgment on a 5-point scale ranging from 1 (certain this is the correct name) to 5 (certain this is not the correct name). For each story, two of the suggested names (one common and one rare name) were correct, while the remaining common and rare suggested names were incorrect. Each *S*, then, had three occasions to judge each of four types of suggested names: a rare name that was correct, a rare name that was incorrect, a common name that was correct, and a common name that was incorrect.

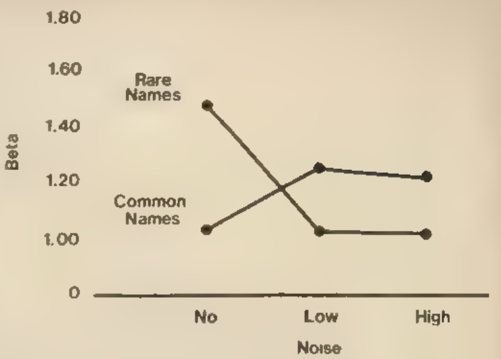

FIGURE 1. Beta as a function of name type and noise. (Each point is the mean β for the five groups in each condition.)

The *S*s were randomly assigned to one of three noise conditions (No, Medium, High). The No Noise group heard the stories on tape, recorded by a male graduate student and broadcast at about 90 db. (A).[3] (The abbreviation db. (A) refers to readings made from the A scale of a sound-level meter, where high frequencies are weighted more than low frequencies.) The Medium Noise group heard the stories accompanied by a continuous white noise, broadcast at about 65 db. (A). The High Noise group heard the stories and 85-db. (A) continuous white noise. For all *S*s, the earphones were silent during the period from the end of one story to the beginning of the next.

Results. Due to the small number of judgments each *S* was asked to make (six for each name type), there was little evidence from false positives for some *S*s in the "certain" category. For this reason, each session's data were pooled across *S*s. Since *S*s participated in small groups of five per session, each noise condition required five sessions. For statistical analyses, then, the unit was sessions and each noise condition had a sample of five.

Following the procedures described by Broadbent (1971, pp. 70–76), β for rare and common names was calculated for all rating categories combined. As Figure 1 illustrates, with increasing noise, β decreased for rare names, but increased for common

[3] Differences in the resistance of the earphones made the sound level estimate only approximate. The actual level for an individual *S* may have varied by about 3%.

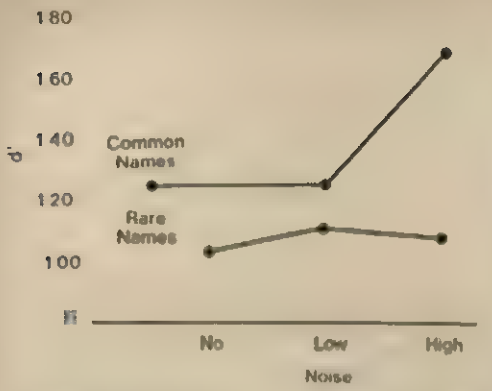

FIGURE 2. Plot of d' at most risky criterion as a function of noise and name type. (Each point is the mean for the five groups in that condition.)

names. An analysis of variance performed on these data confirmed the significant Noise × Name interaction, $F(2, 12) = 4.50$, $p < .05$. An a posteriori test on the mean β scores (Winer, 1962, pp. 309-313) indicated that although β was lower for common names in the No Noise condition ($p < .05$), β did not differ for rare and common names in the two noise conditions.

Despite the decrease in the separation of βs with noise, performance measured by hit rates did not deteriorate for common names relative to rare names. An analysis of variance of hit rates in each confidence level indicated that the hit rate for common names was higher than for rare names at each noise level, $F(1, 12) = 7.71$, $p < .05$.

Since β for rare names did not differ significantly from β for common names in noise, it seems plausible that changes in d' may have been responsible for the continued superiority of common names. Changes in d' are depicted in Figure 2. As indicated, the mean values for d' were 1.03 and 1.24 for rare and common names, respectively, in the No Noise condition, but 1.08 and 1.69 in the High Noise condition. Only the latter difference was significant, $t(4) = 3.0$, $p < .05$.

Discussion. The results of the present study were in accord with those of Ingleby (1969). In the No Noise condition, the condition most directly comparable, common names were recalled with greater accuracy than rare names, despite the fact that d' did not differ for the two types of names. The advantage of common names was due to the lower value of β for these names. The introduction of white-noise-induced arousal led to an increase in β (and pigeonholing) for common names and a decrease in β for rare names. This result supports the hypothesis that arousal improves pigeonholing when conditions favor cautious responding, but [illegible] favored.

The change in pigeonholing [illegible] in the present study, however, did not [illegible] to the predicted changes in overall responding. In [illegible] arousal condition, common names were [illegible] with greater accuracy than rare names. The superiority of common names in noise was due to [illegible] increase in d', which tended to counteract the [illegible] verse effect of noise on β. Thus, it would [illegible] that, for common names at least, arousal [illegible] filtering as well as pigeonholing.

The apparent increase in filtering with increased arousal noted for common names is in line with the results of a study by Hörmann and Osterkamp (1966). They reported a decrease in "cluster[illegible]" in free recall with noise, although similar n[illegible] of words were recalled in the quiet and noise conditions. To the extent that clustering depend[illegible] pigeonholing, noise-induced arousal operated [illegible] manner similar to the findings of the present [illegible]. That is, arousal seemed to make filtering [illegible] important than pigeonholing as a retrieval str[illegible]. Arousal, therefore, will only lead to improved [illegible] if the material may also be recalled by filt[illegible]. The actual effect of arousal on recall would be [illegible] result of the interaction of a number of facto[illegible] cluding the nature of the material to be recalled, [illegible] criterion adopted, and the efficacy of filterin[illegible].

It should be noted that the failure to find [illegible] increase in filtering for rare names in the p[illegible] study may have been due to inherent differe[illegible] discriminability. Thus, although the signal-to-n[illegible] ratio was quite good, it is possible given the [illegible] dynamic range of speech that some loss of aco[illegible] information occurred due to masking. Such [illegible] ing may have affected common and rare [illegible] differentially because common names p[illegible] phonemic characteristics resistant to mask[illegible] because such names contained common lette[illegible] features which were likely to be selectively [illegible] amined by an aroused *S* (cf. Easterbrook, 19[illegible]). In any event, an explanation based solely on [illegible] ing would be hard pressed to account for the c[illegible] in pigeonholing, since β decreased for com[illegible] names, whereas β increased for rare names.

VERBAL DISCRIMINATION LEARNING FOR BILINGUAL LISTS[1]

ROBERT M. YADRICK AND DONALD H. KAUSLER[2]

University of Missouri

The standard decrement in verbal discrimination learning for an interpair relationship between right (R) and wrong (W) items was found when the related words were bilingual translations of one another. However, the decrement occurred only when the R items were from the primary language (English) and the W items from the secondary language (German). The results were interpreted in terms of the processing tagging of different sets of features for primary language words as [illegible] items than for secondary language words as R items.

[illegible]veral studies (e.g., Eberlein & Raskin, 1968, [illegible]erson & Kausler, 1969, Zimmerman, Shaughn[illegible]., & Underwood, 1972) have demonstrated a [illegible]rement in verbal discrimination (VD) learning [illegible]ciency for lists containing interpair associative [illegible] items. The feature-tagging hypothesis of VD learning (Kausler, 1974, in press) attributes the decrement to the sharing of tagged [illegible] frequency of response cues) [illegible] the related R and W items. False recognitions of W items as being correct presumably occur when the semantic features of these items were [illegible] elsewhere in the list via the rehearsal and [illegible] of their related R items. By contrast, the same [illegible]dies failed to find a comparable decrement for [illegible]s containing intrapair associative relatedness [illegible] [illegible]mpensatory process operates in the intrapair [illegible] [illegible]ing on those features of R items that are [illegible] [illegible] graphic and phonemic features, Kausler, in press [illegible] The previously cited studies employed standard word associates as the means of manipulat[illegible] semantic relatedness. The present study tested the generality of the disparity between interpair and intrapair conditions by employing a different form of semantic relatedness, viz., [illegible] interpair and intrapair experimental [illegible] related R and W items were English-German translations of one another. For the control conditions the bilingual items were semantically [illegible] The *S*s in each condition were students nearing the completion of second year college German.

A question of further interest concerned the differential effects on VD performance of [illegible] secondary language words as R items [illegible] tance of the language variable was suggested by the [illegible] [illegible]t with Spanish-English bilingual *S*s (i.e., Spanish was their primary language, English their [illegible]

formulated within the context of a $W_1 - R_1, W_1 - R_1'$ transfer paradigm (i.e., the R items of List 2 were related to those of List 1, whereas the W items of the two lists were unrelated). Significant mediated facilitation was found, relative to a $W_1 - R_1, W_2 - R_2$ control condition, when the R_1 items were [illegible] words and the R_1' items were t[illegible] secondary language translations, but not when the interlist relationship was reversed. A [illegible] effect in the present study would in[illegible]

[illegible]

The *S*s were 80 students in fourth semester German classes at the University of Missouri. They were paid for their participation in the study, and all of [illegible]

[illegible]

with English words as R items, and 6 pairs with German words as R items) across all conditions prevented the application of the simple rule of always selecting words of one language as R items. For the intrapair condition the R–W pairings were, of course, cross-language translations of one another. For the interpair condition the R–W pairings were formed by re-pairing randomly the English–German translations within the separate sets of the intrapair condition. For the control condition either the English words or the German words of the experimental conditions were replaced by other members of the total word pool. Finally, interitem relatedness, both semantic and orthographic, other than that of direct experimental interest, was minimized as much as possible in terms of *E*'s judgment.

Each *S* received 10 trials by the anticipation method, with the first being a guessing trial. The rate of exposure was 3:3 sec., and the intertrial interval was 6 sec. Standard VD control procedures were employed. That is, the pairs were arranged in different serial orders across trials, the R items appeared equally often on the spatial right and left, etc. The experimental list was preceded by 3 trials on a short practice list conforming to *S*'s specific list condition.

Results and discussion. Means and standard deviations, respectively, for total errors summated across trials and language sets were 18.60 and 9.73, 15.65 and 6.58, and 13.10 and 5.13 for the interpair, intrapair, and control conditions, respectively. Errors were analyzed separately for the two within-list sets. Considering the English set first, the means and standard deviations, respectively, were 11.45 and 8.15, 8.10 and 4.70, and 6.40 and 2.93 for the interlist, intralist, and control conditions, respectively. Comparable values for the German set were 7.15 and 3.03, 7.55 and 3.28, and 6.70 and 3.25.

A 3 × 2 mixed analysis of variance revealed a nonsignificant main effect for list condition, F (2, 57) = 2.77, $p < .10$, a significant main effect for language set, F (1, 57) = 8.94, $p < .01$, and a significant List Condition × Language Set interaction effect, F (2, 57) = 7.76, $p < .005$. In view of the significant interaction effect, the effect of list condition was determined separately for the two language sets. For the English set the between-condition effect was significant, F (2, 57) = 4.13, $p < .02$. A Duncan test yielded a significant comparison between the interpair and control condition means ($p < .01$). Neither the interpair–intrapair comparison nor the intrapair–control comparison reached statistical significance ($ps < .10$ and $> .10$, respectively). Given the pronounced [illegible]rogeneity of variance apparent between list [illegible]ions, the between-condition effect was also analy[illegible] by means of the median test. The between-co[illegible]ion effect was again significant, χ^2 (2) = 7.93, [illegible] .02, but only the contrast between the me[illegible]s of the interpair and control conditions reache[illegible]nificance, χ^2 (1) = 4.95, $p < .05$. Finally, for [illegible] German set the between-condition effect fell [illegible] short of statistical significance, F (2, 57) < 1.

Thus, in agreement with previous [illegible]dies, the present results indicated a decrement [illegible]D learning for a list containing an interpair [illegible]tionship but not an intrapair relationship. H[illegible]ver, the generalization to bilingual relatedness [illegible]estricted by the fact that the decrement occurr[illegible]hen the R and W items were primary and sec[illegible]ary language words, respectively, but not vice [illegible]sa. One possible explanation for the bilingual [illegible]mmetry is that different sets of features are th[illegible] recipients of frequency of response cues wh[illegible] primary and secondary language words function [illegible] R items. Semantic features of primary word item[illegible]re likely to be processed and tagged via thei[illegible] rehearsal during feedback intervals. Since these [illegible]ures are shared by their secondary language co[illegible]terparts, false recognitions of the latter are po[illegible]ble when they are encountered (as W items) du[illegible]ing later anticipation intervals. On the other hand, [illegible]honemic and orthographic features of the less fa[illegible]liar secondary language words are likely to be processed and tagged when they serve as R items. Since these features are not shared by their primary language counterparts, false recognitions of the latter are unlikely to take place when they are encountered during later anticipation intervals.

.TITION EFFECTS IN ICONIC AND VERBAL SHORT-TERM MEMORY[1]

DEREK BESNER,[2] J. K. KEATING, LESLIE J. CAKE, AND RICHARD MADDIGAN
Memorial University of Newfoundland, St. John's, Newfoundland, Canada

The Sperling 1960 procedure of full and partial report was used with tachistoscopically presented arrays of 100-msec. duration in two separate experiments. A digit slide was repeated 48 times per session, with 48 slides of nonrepeated series (digits in Experiment I; letters in Experiment II) interpolated between repetitions. The results of both experiments demonstrated better recall of the repeated array. It was concluded that Turvey's 1967 observation that repetition effects differentiate verbal and iconic memory may be incorrect.

...perling (1960) viewed the difference between ...l and full report of tachistoscopic arrays as ...lecting qualitative as well as quantitative memory ...fects. That is, recall under full report was inter...reted as being from a verbal short-term store, ...hile recall under partial report was assumed to ...flect a sensory (iconic) trace. Given the existence of a separate iconic memory store, an important question concerns the kind of operations that might serve to illustrate different properties of these two memory systems.

In support of this notion Turvey (1967) reported two experiments which indicated that partial report recall of a repeated 3 × 5 digit matrix was no ...different from that of nonrepeated matrices interpolated between the successive repetitions. These ...sults were considered to be consistent with the ...ea that a sensory trace should show no effect of ...petition, since it deals with the retrieval of a relatively unencoded stimulus, while other memory ...tems yield results like the "Hebb effect" (Hebb, 1961).

It has recently been suggested however (Dick, 1971) that partial-report techniques are more a source of methodological artifact than evidence supportive of a sensory trace. Dick's findings taken in conjunction with Turvey's (1967) suggest that a more reasonable converging operation would include a full-report condition. If Turvey's results are correct, one would expect a report by repetition interaction, in which a repetition effect occurs in whole report, but not in partial.

Two experiments are reported here in which both full- and partial-report techniques have been used. The second experiment was a replication of the first, with the exception that the nonrepeated slides were composed of letters rather than digits, as in Turvey's (1967) Experiment II.

Method. The *S*s in Experiment I were five male students and one female student solicited from the Department of Psychology at Memorial University. The *S*s in Experiment II were three males and three females from the same population. All *S*s had no previous tachistoscopic experience.

Materials in both experiments were presented by means of a three-field tachistoscope, Scientific Prototype Model GB. The stimulus materials consisted of 96 slides containing three rows of five digits each. These were always dark letters on a white background. No items were repeated more than once within a single array, and never within a single row. In Experiment I the numerals 1–9 were used: in Experiment II the interpolated slides contained letters instead of digits—vowels and the letters Y and Q never appeared.

The exposures were of 100-msec. duration, followed by a 100-msec. delay, at which point a 50-msec.-duration partial-report cue appeared. Pre and post adapting fields were white light, as was the interval between array offset and cue onset. Measurements with a Macbeth illuminometer indicated that the stimulus field had a background value of 5.8 ftL., while the letters were .2 ftL. Pre and post fields were 5.0 ftL. each, while the partial-report cue field had a background value of 5.0 ftL. and the bar marker, .2 ftL. The cue for partial report was a ⅛-in. bar marker which appeared ⅛ in. to the right of the row to be reported. The total array subtended a visual angle of 1.25° horizontally and .75° vertically, while the average letter was .16° high and .14° wide. The intertrial interval was approximately 10 sec.

Each *S* received 96 preexperimental training trials on Day 1. This involved introducing *S*s to the general procedure, establishing facility with the poststimulus cuing procedure, and setting the pace which would be used throughout the experiment. Repeated slides were not used during the training phase. The *S*s were given two kinds of report, full and partial. Under full-report conditions, *S*s were told to write down as many of the items as they could remember, and to place them in the position that they occupied in the display. In the partial-report condition, *S*s were told to write down only those items that appeared in the cued row, again in their correct spatial location. The partial-report condition was a Sperling (1960) arrangement in which cues were quasi-randomly presented, indicating top, bottom, or middle rows of the display. The only constraint was that each row be cued an

TABLE 1

Mean Percentage Recall

Experiment	Whole report		Partial report	
	Repeated	Nonrepeated	Repeated	Nonrepeated
I	27.80	21.45	32.4	25.4
II	37.4	20.81	42.2	26.75

Note. Partial report scores are calculated on the basis of number correct out of 5; whole report scores are calculated on the basis of number correct out of 15.

equal number of times within a session. Type of report was counterbalanced across *S*s and testing days. Thus half of the *S*s received partial report first on Day 2, and second on Day 3. The remaining half received partial report second on Day 2, and first on Day 3.

On the second and third days, *S*s received 96 trials/day. In Experiment I the repeated slide was presented every second trial; every other trial consisted of a random digit slide. In Experiment II the interpolated slide consisted of letters. Within a daily session, *S*s received 48 presentations of the repeated slide and 48 presentations of the random slides. Under each type of slide, report was half partial, and half full.

Recalled items were scored as correct only when the items were in their exact spatial location. Recall was by means of a written response on a gridded sheet which corresponded to the 3×5 display matrix. Response sheets were turned over before the start of a new trial. Reporting five items correctly under partial report gave a score of 100%; the same number of items under whole report gave a score of 33.33%.

Results. One *S* failed to complete the second experiment—consequently, her data were not included in the analysis. The results were analyzed by a $2 \times 2 \times 6$ within-*S*s analysis of variance in the first experiment and a $2 \times 2 \times 5$ within-*S*s analysis in the second. The respective factors were report (whole or partial), treatment (repetition or nonrepetition), and *S*s. Means for both experiments can be seen in Table 1.

In Experiment I the analysis revealed a main effect of repetition, $F\ (1, 5) = 13.52$, $p < .025$, no effect of report, $F\ (1, 5) = 1.75$, $p > .10$, and no interaction ($F < 1$). The results of Experiment II mirrored those of Experiment I. Repetition was a main effect, $F\ (1, 4) = 20.45$, $p < .025$, there was no effect of type of report $F\ (1, 4) = 1.59$, $p > .10$, and there was no interaction ($F < 1$).

A check on the possibility that the repeated matrix was easier to recall in and by itself yielded negative results. This was done by taking percentage recalled on the first presentation of the repeated slide and comparing it with percentage recalled on the first random slide. In Experiment I the nonrepeated slide was recalled slightly better, although this difference was not significant, Sandler's $A\ (4) = .76$, $p > .10$, two-tailed. In Experiment II the repeated slide was recalled slightly lower than the nonrepeated one, again not significantly, Sandler's $A\ (3) = .31$, $p > .10$, two-tailed, even though the guessing probabilities favor digits over letters by a factor of better than 2:1.

Questioning after Experiment I [illegible]d that all *S*s with the exception of one fail[illegible] notice the presence of a repeated slide. A re[illegible]sis of the data excluding this one *S* left the p[illegible] of results unchanged. In Experiment II all *S*s [illegible]ted noticing that a repeated slide was prese[illegible]

Discussion. These results fail to replicate those of Turvey (1967). However, there are clear differences in methodology; in particular, the contrast ratio between pre and post fields on the one hand and the stimulus field on the other, is much less than in Turvey's. In addition, the partial-report cue was visual rather than auditory, [illegible] stimulus array was much smaller, and the full report condition was an added factor. Finally, only one delay of 100 msec. was used in contrast to Turvey's three. Some of these differences can perhaps be expected to reduce the amount of iconic memory available.

Knowing whether or not the slide was repeated did not appear to systematically influence the manner in which the input was processed, although absolute recall was slightly higher in Experiment II. That is, *S*s in Experiment I who did not know that a slide was repeated appeared to behave in the same fashion as *S*s in Experiment II who did. Furthermore, all *S*s showed the effect in Experiment I, with the exception of one tied score in full report: in Experiment II all *S*s demonstrated the effect under both report conditions.

Since type of report was not a main effect, it is unclear how these results bear on the question of whether iconic memory is susceptible to repetition effects. In general, the existence of excess sensory information is inferred from the superiority of partial over full report, thus it seems likely that these experiments show only that repetition affects a postattentional verbal component rather than an iconic one.

Finally, it may well be that the Sperling (1960) technique is an inappropriate one for this particular question. Reporting items from a visual display entails knowing the names of the items. Retrieval of such information is presumably from a long-term store—thus, in such a paradigm, it would always be possible to argue that repetition effects are dependent on previous excitation of name units in verbal memory rather than upon a precategorical sensory trace.

It is thus suggested that an uncritical acceptance of Turvey's (1967) results, and their implications, would be premature.

RELATIONSHIP OF INTERVAL FREQUENCY COUNT TO RATINGS OF MELODIC INTERVALS

THOMAS B. JEFFRIES[1]

Los Angeles City Schools, Los Angeles, California

This study tested *S*s' validity in rating the 24 ascending and descending melodic intervals of the octave, using 116 *S*s' ratings based on their judgments as to how often they had heard or experienced each of these interval types in music. (The ratings had been obtained in an earlier study.) An interval count was taken of the total number of times each of the 24 interval types occurred in the printed scores of 53 current and standard popular vocal pieces. The interval ranks determined from the total count for each interval were correlated with the interval ranks determined from *S*s' mean interval ratings. The results indicated a high degree of validity for *S*s' ratings. Other aspects of the interval count were discussed.

Several studies have provided evidence that *S*s can quite accurately judge the frequency with which words and letters appear in the English language (. . ., Attneave, 1953; Howes, 1954). The purpose of the present study was to determine if *S*s could rate the frequency of occurrence of the different melodic interval types heard in music in much the same way as *S*s rated the frequency of occurrence of words and letters in English as described in the studies cited above. The problem for the study was to determine *S*s' validity in rating the 24 ascending and descending melodic intervals within the octave. The *S*s' ratings were based on their judgments as to how often they had heard or experienced each interval type in music. These rating results were reported in an earlier study (Jeffries, 1972). The criterion measure of validity used in the present study was an interval count taken by the author of the frequency of occurrence of the 24 interval types found in several popular vocal music scores. The melodic intervals ranked according to frequency of occurrence determined from the count were correlated with the intervals ranked on the basis of *S*s' mean interval ratings as to how often they had heard or experienced each of the intervals in music in order to discover with what degree of validity *S*s had rated the intervals.

Another objective of the study was to determine if the ascending interval types occurred in significantly greater numbers in the interval count than the descending interval types.

Jeffries (1972) asked 214 college students comprising two groups to rate the 24 ascending and descending melodic intervals of the octave individually on a 10-point scale. The 98 *S*s in Group 1 rated the intervals presented on tape on the basis of how familiar each interval sounded, while the 116 *S*s in Group 2 rated the same intervals on the basis of how frequently they thought they had heard or experienced each interval type in music. Table 1 presents the familiarity and frequency mean ratings for each interval determined from the rating results.

Results of the study showed that *S*s agreed closely in their familiarity and frequency mean ratings; however, an analysis of variance disclosed a highly significant difference between the ratings, indicating that *S*s had rated the intervals on two distinctly different bases. Results also revealed that *S*s rated the ascending intervals as being significantly more familiar and frequently heard as a group than the descending intervals as a group.

In the present study the ranks for the 24 intervals determined from results of the author's interval count were correlated with the ranks for the same intervals determined from the familiarity and frequency mean ratings given in Table 1.

Method. The interval count consisted of a tally of the number of melodic intervals falling under each interval type found in the printed scores of 53 current and standard popular vocal pieces con-

tained in two song collections (*Today's Hits*, undated; *Today's Most Popular Hits*, undated). In selecting popular songs as the source material for the interval count, it was assumed that *Ss* who took part in the interval-rating experiment perhaps were more exposed to this type of music generally than to other music styles.

Ascending and descending intervals were counted from the vocal melodies, not from the piano accompaniment parts. For each song analyzed, the count began with the identification of the first interval of the melody; then successive intervals of the melody were identified and counted one by one. The songs were written in a variety of keys. Melody sections marked with repeat signs were analyzed only once. Intervals considered as enharmonics, for example, the diminished fifth and the double diminished fourth, were tabulated in the count as augmented fourths and minor thirds, respectively, for purposes of limiting the classifications to the 24 interval types. Compound intervals, those greater than an octave, were not included in the count. Repeated tones of the same pitch were tabulated as prime intervals. In all, 6,341 intervals were counted from the scores.

Each of the two song collections contained nearly the same number of songs. To determine internal consistency reliability for the count, the 25 interval types, including the prime interval ranked on the basis of the total frequency count obtained for each interval from one song collection, were correlated with the 25 ranked intervals from the other song collection ($\rho = .96$).

Results and discussion. Table 1 lists the 24 ascending and descending intervals ranked on the basis of the total count obtained [illegible] ach interval. The prime interval count is n[illegible] ded because this interval was not rated in th[illegible] iment.

The frequency interval order o[illegible] le 1 was correlated with the ranked interval [illegible] based on the frequency count ($\rho = .83$, p [illegible] The latter was also correlated with the [illegible] rity interval order of Table 1 ($\rho = .70$, $p <$ [illegible] This difference in correlation was not signif[illegible] $p > .05$).

In the experiment, *Ss* rated t[illegible] nding intervals significantly higher in famili[illegible] nd frequency than the descending intervals. [illegible] uestion now was to determine if the ascending [illegible] als occurred more frequently than the descen[illegible] intervals in the music analyzed. The data of [illegible] rearranged from Table 1 show the compari[illegible] count between the like ascending and de[illegible] intervals. A binomial test was employed to [illegible] differences in count yielding $z = 3.65$, p [illegible] indicating significantly more descending tha[illegible] nding intervals counted in the popular songs.

Ortmann (1937) reported on [illegible] dic interval count taken from 126 songs of the [illegible] mantic composers Schumann, Brahms, and [illegible] rd Strauss. In all, 15,459 intervals were counte[illegible] In Brahms's songs, 44% of the intervals counted [illegible] e ascending, while 56% were descending. In [illegible] he songs of Schumann and Strauss, 48% of th[illegible] tervals were ascending, 52% descending. For th[illegible] ounts of the three composers taken together, th[illegible] descending intervals significantly outnumbered [illegible] he ascending intervals. Here, a binomial test [illegible] $z = 7.69$, $p < .001$.

The interval counts discussed above do not agree generally with *Ss*' ratings in which the ascending intervals were rated significantly higher than the descending intervals. This difference could be attributed to many factors. In considering the interval count findings, perhaps taking more interval counts from a variety of composers' works could provide a more definitive picture regarding frequency of interval occurrence than was provided from these two counts alone. From another standpoint, it is also possible that the author's interval rating

TABLE 2

FREQUENCY COUNT FOR LIKE ASCENDING AND DESCENDING INTERVALS

Note. Abbreviations: M = major, m = minor, P = perfect, and a = augmented.

procedure lacked some sensitivity in measuring the degree of Ss' familiarity and frequency experience with the intervals. Introducing refinements into the testing procedures might produce rating results more in agreement with the interval count findings given than was found in comparing the interval count results with the mean interval ratings given in Table 1. Both the questions of interval frequency count and the interval-rating procedures need further study.

The data provide some evidence that familiarity of melodic intervals may have some bearing on interval learning. Table 1 shows the total number of errors in interval recognition for each of the 12 ascending melodic intervals made by 24 Ss, these data taken from an earlier study (Jeffries, 1967, p. 189). Table 1 lists the same ascending intervals ordered according to results of the interval count. Correlating the two interval orders produced $\rho = -.53$, $p <$ using a one-tailed test of significance, with these results indicating a significant inverse relationship between interval count and rate of error. The higher was the count for particular intervals, generally, the lower the error rate for Ss learning to identify these intervals. Although the correlation figure above is not particularly high, it does provide some basis for considering further experiments to investigate the precise effects that familiarity may have on interval learning.

In summary, the results showed a close relationship between the interval count findings and Ss' interval frequency ratings. This may point to the possibility that people can judge quite accurately the frequency with which they hear the various melodic intervals in music.

Significantly more descending than ascending intervals were counted in the popular songs as well as in the art songs. These findings are not in agreement with Ss' ratings that the ascending intervals were more familiar and frequently heard than the descending intervals.

Of course, a host of questions was not touched upon in the study, such as those relating to the resolution tendencies of tones, melodic intervals heard in cadences, and the like. No doubt many such factors in one way or another influence the recognition of tones in sequence. While such phenomena may well be of interest to this study, none was considered here because of the limited nature of the problem. Certainly many of these questions call for investigation.

THE TIME COURSE OF LATERAL ASYMMETRIES IN VISUAL PERCEPTION OF LETTERS[1]

ARNOLD WILKINS[2] AND ANNE STEWART

University of Sussex, Brighton, Sussex, England

A single letter presented at fixation was followed after a short or long interval by a second letter presented in the right or left visual field. The Ss indicated by a manual response whether or not the letter names were the same. For letter pairs with the same name and case, there were fewer errors at short intervals when the second letter in each pair was presented to the left visual field, although at long intervals right visual field presentations were more accurate. For letters with the same name and different case, there were no field differences at short intervals, but at long intervals there was a right visual field superiority. It is proposed that in the process of letter perception a preliminary nonverbal code is available in the right hemisphere until superceded by a verbal code in the left hemisphere.

Cohen (1972) and Geffen, Bradshaw, and Nettleton (1972) found that the matching of letter pairs with the same name and shape is faster when the letters are presented to the left visual field than

[1] This work was conducted while the first author held a Medical Research Council studentship.

when they are presented to the right. They also showed that matching of pairs with the same name and different shape is more rapid for presentations to the right visual field than to the left. Since each visual half-field projects to the contralateral cerebral hemisphere, the above findings suggest that letters with the same name and shape are matched in the right hemisphere in terms of a spatial code, whereas pairs with the same name but different shape are matched in the left hemisphere on the basis of a verbal representation.

Using a memory drum, Posner and Keele (1967) presented pairs of letters successively and varied the interletter interval. At short intervals pairs with the same name and shape were matched faster than those with the same name and different shape, but at intervals of 1.5 sec. the two types of letter pairs were classified at the same speed. Posner and Keele interpreted their results as indicating that at long intervals all matching was performed in terms of a verbal code, the spatial code having been allowed to decay. If their interpretation is correct, it is conceivable that a visually presented letter is available initially as a spatial code in the right hemisphere until such time as this code is translated into a verbal code in the left hemisphere. The following experiment provides evidence to support this view.

Method. Sixteen right-handed female students at the University of Sussex served as unpaid *Ss*. They were unaware of the purpose of the experiment. The Edinburgh Handedness Inventory (Oldfield, 1971) was administered after the experiment and, on the basis of this questionnaire, all *Ss* were strongly right handed.

The stimuli were presented in a three-field tachistoscope with fields of luminance 34 cd/m², 10.2 cm. high and 15.2 cm. wide, viewed binocularly at a distance of 54 cm. The fixation field, which was illuminated continuously except when one of the stimulus fields was on, contained a [illegible] gray diagonal cross, 2 mm. high, at the cent[illegible] the field. The *Ss* were instructed to fixate the cro[illegible]roughout each trial, and the importance of the[illegible]structions was stressed. The stimulus fields eac[illegible]ontained a single letter approximately 4 mm. high printed in black Letraset 14 pt. Helvetica Light. In the first stimulus field the letter was positioned in the center of the field, and in the second field the letter appeared 28 mm. (approximately 3° of visual angle) to the right or left of center.

A trial began when *E* prepared *S* by counting "Three, two, one," and, on the count of "One," triggered the onset of the first stimulus field. The tachistoscope was wired so that both stimulus fields lasted 100 msec., separated by an interval of either 50 or 990 msec. The *S* was required to respond on one key if the letters had the same name and on a second key if the names were different. Response latencies were measured from the onset of the second stimulus field, and all errors were recorded. Half the *Ss* (Group 1) used the index finger of the right hand for a *same* response and the index finger of the left hand for a *different* response. The remaining *Ss* (Group 2) used the reverse configuration.

Sixteen conditions resulted from the combination of (*a*) the two interletter intervals, (*b*) the similarity or dissimilarity of the letter names, (*c*) the similarity or dissimilarity of the letter cases, and (*d*) the two visual fields in which the second letter of each pair could appear. The experimental conditions are shown in Table 1. The letters B, D, G, H, N, Q, R, and T, or their lowercase equivalents, were used once in each condition as the first letter of a pair so that the case of the initial letter was balanced across conditions. Each cell in Table 1 is therefore based on eight observations from each of eight *Ss*. The second letter in each pair was chosen as appropriate to the condition. For the conditions in which the letter names were different, the second letter

was chosen at random from the same population as the first, with the restriction that pairs such as "Dt," with phonetic similarity, and pairs such as "rn," with similar shape, were avoided. The 128 letter pairs were presented after 10 practice trials, and the order of presentation was random and constant for all *S*s. For half the *S*s from each group the interletter interval was switched so that pairs of letters which were separated by a long interval for half the *S*s were separated by a short interval for the remaining *S*s. As a result, effects of interletter interval cannot be attributed to possible concomitant variation in stimulus discriminability.

Results and discussion. The percentage error in each experimental condition is shown in Table 1. An analysis of variance of the error scores for *same* responses over interletter interval, visual field, case similarity, and responding hand yielded a significant interaction between visual field and interletter interval, F (1, 14) = 34.3, $p < .001$, $MS_e = .311$; a significant effect of case similarity, F (1, 14) = 8.50, $p < .05$, $MS_e = .405$; and a significant three-way interaction between case similarity, interletter interval, and responding hand, F (1, 14) = 6.59, $p < .05$, $MS_e = .267$. The analysis of variance is generally considered a robust test, but in view of the highly skewed distribution of error scores, all the major effects obtained in the analysis were corroborated by individual sign tests with *S*s as *N*.

For letter pairs with the same name and case (e.g., "BB") there were fewer errors at short interletter intervals when the second letter in each pair was presented to the left visual field ($p = .004$, sign test). At long intervals there were fewer errors when the second letter was presented in the right visual field ($p = .004$, sign test). Since the first letter appeared at fixation and was therefore projected to both hemispheres, these results suggest that at short intervals letter pairs which had the same name and case were processed in the right hemisphere on the basis of a spatial representation, whereas at long intervals a verbal match was performed in the left hemisphere.

For letter pairs with the same name and different case (e.g., "bB"), there was no field difference at short interletter intervals ($p = .754$, sign test), although at long intervals fewer errors were made when the second letter was presented in the right visual field ($p = .004$, sign test). The absence of a right visual field advantage at short intervals is of interest because letter pairs with the same name and different case ostensibly required verbal processing at both short and long intervals. A right visual field advantage at both intervals might therefore have been anticipated. Furthermore, inspection of the error scores for these stimuli suggests that the significant three-way interaction obtained in the analysis of variance was partly due to the greater accuracy of the left hand at short intervals and the right hand at long intervals. Both this interaction and the absence of a right visual field advantage when the intervals were short point to the involvement of the right hemisphere. If the retrieval of the name of the first letter was not always complete by the time the second letter was presented and the retrieval of two letter names was not able to proceed simultaneously, a nonverbal code of one letter would have to have been held (possibly in the right hemisphere) while the name of the other letter was retrieved.

An analysis of variance of the error scores for *different* responses over interletter interval, visual field, case similarity, and responding hand yielded one significant effect, that of case similarity, F (1, 14) = 7.47, $p < .05$, $MS_e = .268$. Evidently more errors were made when the pairs differed in case than when their case was the same. It is therefore possible that *same* and *different* judgments involved separate mechanisms (Egeth & Blecker, 1971), and *S*s occasionally responded *different* without retrieving the letter name if the letters were the same size and did not produce a spatial match.

For each *S* the median latency of correct responses in each combination of the two levels of interletter interval, visual field, and case similarity was calculated. The eight medians in each condition were then averaged, and the resulting means appear in Table 1. Analyses of variance based on the median latencies yielded three small effects, two of which tended to contradict the clear pattern which emerged in the analyses of errors. An analysis of the latencies for *same* judgments yielded a significant interaction between case similarity and responding hand, F (1, 14) = 6.05, $p < .05$, $MS_e = 6{,}206$; a similar analysis for *different* judgments revealed an effect of case similarity, F (1, 14) = 7.78, $p < .05$, $MS_e = 2{,}188$, and a three-way interaction between interletter interval, visual field, and responding hand, F (1, 14) = 4.99, $p < .05$, $MS_e = 3{,}310$.

The effect of case similarity for *different* responses indicates that latencies were shorter for pairs of letters with the same case than for letters with different case, and this result is consistent with the view expressed earlier that letter size may have been occasionally used as a shortcut to the production of a *different* response. The interaction between case similarity and responding hand may be attributed to the faster responses with the right hand for letter pairs with the same name and case and the faster responses with the left hand for letter pairs with the same name and different case. This effect and the three-way interaction between interval, visual field, and responding hand are open to many highly speculative interpretations. Instead of discussing these here, it will simply be noted that there was no evidence for a time–error tradeoff since the correlations between residual errors and latencies were positive (.22 for *same* responses and .10 for *different* responses). Error scores were probably a more reliable index of performance than latencies, owing to the use of unpracticed *S*s and the fact that the foreperiod included the variable interletter interval. Cohen (1972) and Geffen et al. (1972), who obtained field differences for latencies but not for errors, used a constant foreperiod, a relatively large number of trials, and, in the

case of Cohen's study, near-threshold stimulus durations.

Although the apparatus did not admit observation of eye movement, presentation of the first letter at the center of the visual field was probably sufficient to secure central fixation at the beginning of each trial. Drift in fixation may have occurred during the long interletter interval and if such drift occurred predominantly to the right, it would provide an alternative account of the general superiority of the right visual field at long intervals. However, the differences in the field advantages which occurred at short intervals cannot be explained in terms of fixation drift. Furthermore, Geffen et al. (1972), who observed eye movements in a situation very similar to that of the present experiment, found that such movements were rare and that they were evenly distributed between the two visual fields. The occurrence of eye movement artifact in the present experiment was therefore unlikely. The development of consistent scanning strategies was also unlikely since *S*s could never predict which visual field the second letter wo[illegible]cupy, which interval would occur, and whethe[illegible]tters would be the same or different shape.

In conclusion, the substantia[illegible]ences in the lateral asymmetries at short an[illegible]ng intervals suggest that in the course of le[illegible] perception a nonverbal code is available in the [illegible] hemisphere until superceded by a verbal c[illegible] in the left hemisphere.

EFFECTS OF EVALUATION APPREHENSION ON MEMORY OVER INTERVALS OF VARYING LENGTH[1]

RUSSELL G. GEEN[2]

University of Missouri

In a 2 × 2 × 3 factorial design, 240 female *S*s studied a paired-associate list for a single trial after being told that it was either a test of intelligence or an evaluation of the list. The *S* was either observed or not observed by *E* during the study trial. Recall was tested after 2, 15, or 45 min. Recall was poorer after 2 min. for *S*s who had been told that their intelligence was being evaluated than for *S*s told that the list was being tested, but superior after 45 min. This finding indicates that evaluation apprehension creates a condition of arousal that facilitates long-term memory but hinders memory over relatively short intervals.

In a recently reported experiment, Geen (1973) found that female *S*s who were observed during a single study trial in a paired-associate (PA) learning task subsequently showed poorer recall after 2 min. than nonobserved *S*s, but superior recall after 45 min. Since observed *S*s also reported themselves as more "nervous" than nonobserved *S*s, the results were interpreted as being consistent with the findings of others that arousal during trace formation facilitates long-term retention, while hindering retention over relatively short periods (e.g., Kleinsmith & Kaplan, 1964). The results also conform to those of other investigators who report that the presence of observers produces increased arousal level (e.g., Cottrell, Wack, Sekerak, & Rittle, 1968). Geen implied that being observed causes increased arousal by eliciting an emotional response associated with apprehension over being evaluated by the observer. The present experiment was designed to vary observation and evaluation independently of each other in an orthogonal design. Half of all *S*s were informed that they were being evaluated and half were not. In addition, half of all *S*s were observed by *E* during the PA study trial and half were not. All *S*s were then tested for recall after either 2, 15, or 45 min.

Method. Two hundred and forty female undergraduates served as *S*s in order to earn points applicable to a final grade in a beginning psychology course. The *S*s were selected at random from class lists and scheduled by telephone. Scheduling was

arranged so that one S arrived at the waiting room every 15 min. Before meeting each S, E assigned her to 1 of the 12 conditions by referring to a table of random numbers. The E was a female approximately the same age as S.

After preliminary introductions, E led S to a table in the experimental room on which had been placed a Lafayette memory drum. After explaining that the experiment involved "single-trial learning," E informed S that a PA list consisting of six syllables and associated digits would be shown once and that recall would be tested later. To half of the Ss (evaluation condition), E then said that good recall in PA learning has been shown in several studies to be highly correlated with intelligence and that the experiment was in fact one of a number of pilot studies being carried out to assess intelligence by this means. To the remaining Ss (no-evaluation condition), E said that the experiment was designed as a test of how certain stimuli are recalled better than others and that the session in which S was being run provided for evaluation of one such list.

The E then turned on the memory drum. A period of 10 sec. elapsed before the word READY appeared in the window. Two seconds later the first stimulus term appeared. The stimuli were six syllables of 0% association value (TOV, CEF, QAP, JEX, LAJ, and DAX) first used by Kleinsmith and Kaplan (1964) paired with the digits 2–7. Each syllable appeared alone for 2 sec., followed by the syllable–digit pair for 2 sec., followed by a 2-sec. blank interval before the appearance of the next syllable. Two seconds after the final syllable–digit pair, the word STOP appeared. The S had been instructed to turn off the drum at this point. During the study trial for one half of the Ss (observation condition), E stood just to the left of S and watched as S was presented the syllable–digit pairs. With the other half of the Ss (no-observation condition), E stood beside S at about the same distance as she stood in the observation condition, but kept her back turned to S as she busied herself with some papers on a desk.[3]

When S had turned off the memory drum, E led her to the waiting area outside the experimental room and informed her that she would be called back when it was time for the recall trial. The E began timing the recall interval from the moment S was seated in the waiting room. Each S was then given a short adjective checklist on which she was asked to mark each word that described her state of feeling at that time, on the ostensible grounds that emotions have effects on learning. In addition to several distractor items, the checklist contained the words RELAXED, FEARFUL, JUMPY, and CAREFREE. This was included in an attempt to obtain an independent measure of evaluation apprehension. The E collected the checklist when S had completed it and then informed S how much longer she would have to wait before the recall trial. In order that rehearsal of the items from the PA task might be avoided during the recall interval, each S was then given a questionnaire on vocational interests, presumably as part of a pilot study for another experiment. The Strong Vocational Interest Blank for Women was used. Depending on the length of her wait, S was given either the first part, the first two parts, or the entire blank.[4] When the recall interval was over, E interrupted S, took the questionnaire, and led S back to the experimental room. The E next turned on the memory drum, instructed S to get ready, then watched S and recorded her responses. After a blank interval of 5 sec., the first syllable appeared. Each syllable appeared for 2 sec., followed by a 4-sec. blank interval during which time S responded. The syllables appeared in the same order as in the study trial. After the recall trial had ended, E interviewed each S to discover whether the experimental deceptions had been successful. The S was asked to state whether she attached any significance to whether or not E had watched her during the study trial, whether she believed that intelligence was being tested, and whether the amount of time spent waiting had any effect on recall. Evidence from S's answers that she had formed any hypotheses consistent with those of the experiment was considered grounds for classifying S as "aware" of the deceptions. The E then fully explained the true nature of the study, and included a statement of the major hypotheses being tested.

Results and discussion. No S reported being aware of the true nature of the study.

Significant differences across conditions were found in the number of Ss reporting themselves to be relaxed. No such differences were found in the case of the other adjectives. With an n of 60 in each group, the numbers of Ss in each checking the word *relaxed* on the checklist were: no observation–no evaluation, 42; observation–no evaluation, 28; no observation–evaluation, 10; observation–evaluation, 20. This pattern of responses would not have been expected on the basis of chance, χ^2 (1) = 4.96, $p < .05$, Yates's correction applied. We thus have some evidence that being evaluated made Ss less relaxed than they otherwise would have been.

Figure 1 shows the number of digits recalled by Ss in the 12 conditions of the experiment. An analysis of variance revealed that two first-order interactions were significant, the Evaluation × Time, F (2, 228) = 13.39, $p < .01$, and Observation × Time, F (2, 228) = 3.24, $p < .05$, interactions. The second-order interaction was not significant, F (2, 228) = 2.34, $p < .10$. No other interaction or main effect approached significance. Post hoc t tests further showed significant differences between the evaluated–2-min. and not-evaluated–2-min. groups,

[3] Geen (1973) found that the mere presence or absence of E either during the study trial or the test trial had no effects on S's recall. Accordingly, E was present with S during both trials in the present study.

[4] Most of the time, more than one S occupied the waiting area at one time. In order that the activities of all Ss might be relatively standardized during the recall interval, E instructed each S not to communicate with any other S during the waiting period but to concentrate on filling out the questionnaire. The Ss were also seated in the waiting room in such a way that they did not have face-to-face contact with each other.

t (38) = 2.88, $p < .01$, and the evaluated–45-min. and not-evaluated–45-min. groups, t (38) = 2.26, $p < .05$. The difference between the observed–2-min. and not-observed–2-min. groups failed to attain statistical significance, t (38) = 1.92, $p < .10$. The overall pattern of comparisons among means indicates that *S*s who believed that they were being evaluated manifested superior recall to that shown by nonevaluated *S*s after a relatively long waiting period, but poorer recall following a short period.[6] The mere fact of being observed during the study trial, independent of being evaluated, produced only a weak crossover effect of recall over waiting periods, with practically no difference as a function of being observed or not observed after 45 min. The findings thus corroborate the author's previous report that socially produced arousal promotes memory over a relatively long period but hinders it over a relatively short period, and also indicate that the important variable in the process is apprehension over being evaluated. The delineation of evaluation apprehension as the principal source [illegible] influence on memory is consistent with the fi[illegible] of others regarding the importance of th[illegible] variable (e.g., Paulus & Murdoch, 1971).

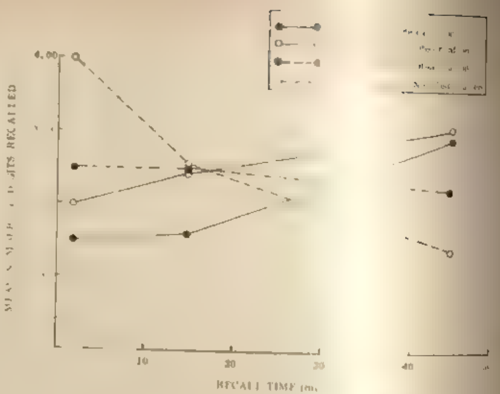

FIGURE 1. Mean number of digits [illegible] treatment groups over different recall [illegible]

[6] Of the 120 *S*s in the evaluation condition, 11 verbalized a lack of belief that they were in fact being evaluated during the postexperimental interview. An internal analysis of the data revealed that these *S*s had recall scores that deviated from those of "unaware" *S*s in the direction expected if we assume that evaluation apprehension produces arousal. Among unaware *S*s, the mean numbers of digits recalled at 2, 15, and 45 min., respectively, were 1.55, 2.19, and 3.33, thus revealing the improved recall over time characteristic of aroused *S*s. Among *S*s aware of the deception, the corresponding means were 3.50, 2.67, and 2.00, exactly what we would expect in the absence of arousal. The small *n*s of the latter three groups (n = 4, 3, and 4, respectively) indicate that the means are not sufficiently stable to warrant statistical analysis. It should also be noted that *S*s aware of the "evaluation" deception were more likely than unaware *S*s to describe themselves as relaxed. 6 of the 11 aware *S*s and 24 of the 109 unaware *S*s did so, χ^2 (1) = 4.03, Yates's correction applied. This finding indicates that *S*s in the evaluation condition were aroused primarily by evaluation apprehension and not by knowledge that they were being deceived.

RETRIEVAL BIAS AND THE RESPONSE RELATIVE FREQUENCY EFFECT IN CHOICE REACTION TIME

HAROLD L. HAWKINS,[1] KENNETH SNIPPEL, JOELLE PRESSON, STEPHEN MACKAY, AND DENNIS TODD

University of South Florida

Some investigators have obtained response relative frequency effects in choice reaction time tasks containing many:1 stimulus–response mappings, whereas others have not. Two interpretations of this seeming inconsistency have been proposed. According to one, the effect results from an anticipatory bias in response retrieval which manifests itself only when *S* is permitted the error imbalance which follows as a necessary consequence of the bias. According to the other, the effect results from frequency-related differences in associative strength across response categories whose manifestation is contingent upon the availability of a mediator (e.g., a name) that is strongly associated in *S*'s prior experiences to all stimuli within each response category. The results of the present study are consistent only with the first of these two interpretations.

Hawkins, MacKay, Holley, Friedin, and Cohen (1973) have shown that choice reaction time (RT) is inversely related both to stimulus (S) and response (R) relative frequency when these variables are independently manipulated within a 2:1 S–R mapping task. Both effects were found to increase with declining S–R compatibility. These results were interpreted in terms of an informal statistical

decision model which locates both stimulus and response relative frequency effects within the response retrieval, or selection, process. More specifically, stimulus relative frequency effects were attributed to frequency-related differences in strength of association (and thence, retrieval time) across specific S–R pairings, and response relative frequency effects were attributed to frequency-related bias in response retrieval. However, an inspection of the particular S–R codes used in the Hawkins et al. study raises a serious question regarding the appropriateness of this analysis.[2] Under all compatibility conditions, the two stimuli commonly assigned each vocal-naming response were the upper- and lowercase forms of a single letter. One of the key assumptions underlying the model proposed by Hawkins et al. was that the required response was directly associated with each of the nominal stimuli to which it was assigned. It is equally plausible, however, that this association was mediated by the familiar name common to the two stimuli forming each response category. Were this the case, the response relative frequency effect observed by these investigators may not index retrieval bias but rather frequency-related differences, across response categories, in the strength of association between mediating and required responses. Accordingly, the response relative frequency effect might be expected to attenuate or disappear under conditions where stimuli within categories do not share a common familiar name (cf. Bertelson & Tisseyre, 1966; Hawkins & Friedin, 1972; Hawkins, Thomas, & Drury, 1970). The present experiment constituted a test of this implication.

Method. The *S*s were 14 men and 10 women enrolled in introductory psychology at the University of South Florida. All *S*s had normal or normal corrected vision, and all were naive with respect to RT research. Extra course credit was given for participation.

Stimuli consisted of the letters D, d, Q, q, H, h, k, b, and p (Tactype No. 5418). The manner of stimulus presentation was as reported in Hawkins et al. (1973).

All *S*s were pretested on a 40-trial practice task in which a colored nonsense syllable, either green (p = .50) or orange, was presented on each trial. The vocal responses during practice were the common names of the two colors. Based on performance on this task, *S*s were blocked into slow (N = 12) and fast responders. One-third of the *S*s in each block were assigned on a random basis to one of three levels of S–R compatibility. The task, under all levels of compatibility, was to vocalize one of three responses to each of six perceptually distinct stimuli. Stimuli and responses were paired in 2:1 fashion. The two stimuli within one response category were presented with relative frequencies .50 and .10, respectively; those within another response category both were assigned a relative frequency of .10; and the remaining two stimuli were presented with a relative frequency of .10. These latter two stimuli, together with their respective response, were distractors, included to increase overall task difficulty and to minimize the likelihood *S*s would employ a "positive set" strategy of the type observed by Hawkins and Hosking (1969) in two-response choice RT tasks. Of primary interest were the high- (HH) and low-frequency (LH) stimuli requiring a common high-frequency (.60) response and the two low-frequency (LL) stimuli requiring a common low-frequency (.20) response.

All *S*s were tested on a total of 240 trials during a single experimental session lasting about 1 hr. and occurring within 3 wk. of the practice session. During the experimental session, the identity of, the correct relative frequency of, and the response appropriate for each stimulus were made constantly available to *S* on an index card. The intertrial interval was 3.5 sec., with a warning tone of 1-sec. duration occurring immediately prior to stimulus onset. After each correct response, *S* was informed of his RT in milliseconds. Following each incorrect response, *S* was told that an error had been committed. Stimuli to which *S* incorrectly responded were not subsequently reported. Short breaks were given following each 40-trial block. Under all experimental conditions, *S*s were instructed to respond as rapidly as possible while at the same time, minimizing errors.

Eight *S*s were tested under the high-compatibility condition where they were required to vocalize the name commonly associated with each of the stimulus letters. Each of the four stimuli, D, d, Q, and q, served as the high-frequency alternative for two of the eight *S*s. The two stimuli H and h served as distractors. Eight *S*s were tested under a low-compatibility condition where they were required to respond *Z* to stimuli D and d, *V* to Q and q, and *J* to distractors H and h. D, d, Q, and q each served as the high-frequency alternative for two of the eight *S*s. The remaining eight *S*s were tested under a low-compatibility condition where the response *Z* was required to either D or k, the response *V* was required to either Q or b, and the distractor response *J* was required to either H or p. As before, D, k, Q, and b each served as the high-frequency alternative for two of the eight *S*s.

Results and discussion. Table 1 gives the mean correct RT and percent errors (in parentheses) under each of the conditions of the experiment. These data were subjected to a mixed model analysis of variance with compatibility (high vs. low$_1$ vs. low$_2$) and blocks (fast vs. slow *S*s) treated as between-*S*s variables and S–R pairing (HH vs. LH vs. LL) and level of practice (first through fourth block of 60 trials) treated as within-*S*s variables. The overall analysis revealed that S–R compatibility, F (2, 18) = 101.99, S–R pairing, F (2, 36) = 116.51, the Compatibility × S–R pairings interaction, F (4, 36) = 34.18, practice, F (3, 54) = 29.20, the Practice × Compatibility interaction, F (6, 54) = 8.06, the S–R Pairing × Practice interaction, F (6, 108) = 7.78, and the second-order S–R Pairing × Compatibility × Practice interaction, F (12, 108) = 5.01, were all significant sources of variance (p < .001).

It will be recalled that the primary objective of the present study was to determine whether the

[2] The authors wish to thank Steven W. Keele and Lester E. Krueger who independently alerted us to this possibility.

	(.5)	(1.6)	(1.9)	(.9)	(6.6)	(17.2)	(1.7)	[illegible]	(24.6)

Note. HH and LH refer to high- and low-frequency stimuli, respectively, requiring a common high-frequency [illegible] response, LL refers to the two low-frequency stimuli requiring a common low-frequency (.20) response.

response relative frequency effect attenuates or disappears when stimuli within response categories do not share a common name in *S*'s prior experience. Two analyses were performed which are relevant to this question. First, Fisher's least significant difference (LSD) test, with the criterion of significance set at .05, was used to assess the occurrence of response relative frequency effects under each of the three compatibility levels. This analysis revealed that choice RT increased significantly between LH and LL S-R pairings under both low-compatibility, but not under the high-compatibility, conditions (LSD = 34 msec.). Second, a comparison of the magnitudes of the response relative frequency effect across the two low S-R compatibility conditions revealed that the effect was significantly *greater* under the condition in which stimuli comprising each response category did not share a common familiar name, $F(1, 36) = 7.85$, $p < .01$. These results would seem to be consistent with the Hawkins et al. (1973) view that the response relative frequency effect indexes anticipatory bias in response retrieval and that such anticipatory adjustments represent a feature of the information-processing sequence which extends across a variety of speeded recognition tasks. However, a further feature of the present data indicates that such an account cannot, in and of itself, fully characterize the findings reported here. Specifically, a subsequent partition of the variance in the original analysis revealed that the magnitude of the Response Relative Frequency × Compatibility interaction declined with practice, $F(6, 108) = 4.03$, $p <$ .005. This interaction reflects the [illegible]hat the RT difference between LH and LL pairings declined with practice under the low-compatibility condition where stimuli within response cat[illegible]s did not share a common name, but not under [illegible] remaining two compatibility conditions. The anti[illegible]patory bias interpretation implies, to the contrary, that since *S*s were given equal practice on LH and LL pairings under all compatibility conditions, the practice-related declines in RT for these two S-R pairing types should have remained equal across trial blocks, yielding no decline in the response relative frequency effect under any of the compatibility conditions.

The present results make it clear that the response relative frequency effect is a complicated phenomenon which may prove to be difficult or impossible to adequately characterize in terms of a single factor model of the type proposed by Hawkins et al. (1973).

OVERT REHEARSAL AND LONG-TERM RETENTION

GARY F. MEUNIER,[1] JANE KESTNER,[2] JO ANN MEUNIER, AND DOUGLAS RITZ[3]

Ball State University

Recall scores from intentional and incidental learning groups were compared when rehearsal was made overt by having *S* write each stimulus as it appeared. Duration of writing time was varied and the number of written replications of a stimulus was an index of rehearsal. Intentional learning *S*s were clearly superior to incidental learners even though the groups rehearsed equally often. In addition, moderate increases in rehearsal time led to improved retention, but increases in rehearsal beyond this level did not affect recall.

A central aspect of most multistore models of memory is the notion that stimulus material is both maintained in a limited capacity, temporary storage and transferred to a larger, more durable storage by a process of rehearsal. And, generally, the greater the amount of rehearsal given an item the greater is the probability that the item will be encoded into the more durable store (e.g., Atkinson & Shiffrin, 1968).

A testable implication of this conceptualization is that, all other factors constant, long-term retention of a given item should be a function of the amount of rehearsal it receives. Unfortunately, attempts to evaluate this statement have not provided consistent results: Using a variety of paradigms, previous research has yielded evidence both supportive (e.g., Rundus & Atkinson, 1970) and contradictory (Stanners & Meunier, 1969) to the implication. The present experiment, thus, is an attempt to further clarify the relationship between rehearsal and retention.

A "rehearsal" in this experiment consists of a written replication of the stimulus item. Although there is, of course, some controversy over just what a rehearsal is and how it is to be measured, this definition does not seem inconsistent with other frequently used conceptions and does have the advantage of making the rehearsal process overt.

Method. The *S*s were 130 students from introductory psychology classes at Ball State University, who received extra course credit for participation in the experiment.

Stimulus items were 24 29% association value trigrams selected from the Witmer (1935) scaling. Two additional trigrams selected from the same group served as practice items. The stimuli were projected individually by a Kodak Carousel projector onto a screen located approximately 2 m. in front of the seated *S*. Height of the individual letters on the screen was 7.62 cm., and each was presented for 1.5 sec. The *S*s were run in groups of from three to five members each. Each *S* silently viewed the trigram on the screen while it was presented. Termination of this visual stimulus was the signal for *S* to start writing the trigram on a sheet of paper from a booklet provided by *E*. Writing continued until a verbal command of "Stop" was given by *E*. This command was also the signal for *S* to turn to the next sheet of paper and get ready for the next trigram which was presented in approximately 2 sec. Following presentation of all 24 stimulus items, *S* was asked to recall as many of the trigrams as he could. This recall was written and terminated after 5 min.

The *S*s were divided into two groups dependent upon instructions given before the experiment. All were told that the intent of the experiment was to measure speed and accuracy of writing and how these changed with fatigue. In addition, *S*s in the aware (A) condition were told that they would be asked to recall the trigrams after the experiment was over. No attempt was made to emphasize the importance of this recall over the writing task. Those in the unaware (UA) condition were not told of the final recall until they had been presented each of the trigrams in the writing part of the experiment. Also, the duration of the writing task following each trigram was either 3, 9, or 15 sec. and was varied randomly with the constraint that each interval was presented equally often (eight times) within a session. All members of a given session were given either A or UA instruction, and a total of 65 *S*s served in each of the two groups.

Results. The results may best be considered in two parts, an analysis of the number of rehearsals of a trigram, and an analysis of the trigram recalls.

One rehearsal resulted when all three letters of a trigram were written in the correct serial order. These results are presented in Table 1 where both means and standard errors are given for each of the

TABLE 1

MEANS AND STANDARD ERRORS (IN PARENTHESES) OF NUMBER OF REHEARSALS PER ITEM AS A FUNCTION OF REHEARSAL INTERVAL (IN SEC.) AND S'S AWARENESS OF FINAL RECALL

Group	Rehearsal interval 3	9	15
Aware	2.42 (.05)	5.66 (.10)	8.42 (.16)
Unaware	2.48 (.07)	5.76 (.12)	8.89 (.16)

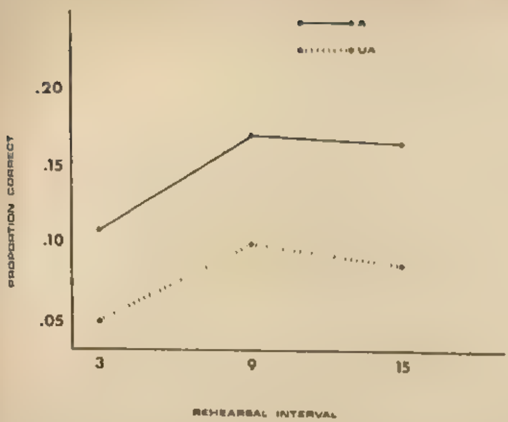

FIGURE 1. Proportion of items recalled as a function of rehearsal interval and S's awareness of final recall. (Abbreviations: A = aware and UA = unaware.)

six treatment combinations. An analysis of variance of these data confirmed the obvious conclusions from the table. The only significant effect was attributable to length of the writing interval with an increasing number of rehearsals given each item as the length of the interval increased, F (2, 236) = 115.54, $p < .001$. The *S*s in the A and UA groups did not differ in the number of rehearsals given nor in the number of rehearsals as a function of interval length. The similarity of the two groups is rather striking and implies that *S*s in the A group did not deemphasize the importance of the writing task.

In order to maintain consistency with the scoring of rehearsals, a correct recall was scored when all three letters of the trigram were recalled in the correct serial positions. The *S*s were, however, instructed to recall the whole trigrams in any order they chose, and a graphical display of these results is presented as Figure 1. An analysis of variance confirmed the suggestions from this figure: Recalls were significantly higher for A than for UA *S*s, F (1, 128) = 33.212, $p. < .001$, and recall probability changed with increasing rehearsal time, F (2, 256) = 8.530, $p. < .001$. Thus, although recall was clearly superior for A *S*s at each rehearsal interval, the same pattern of effects of the rehearsal intervals was found in both A and UA recalls. Increasing rehearsal time from 3 to 9 sec. increased recall substantially, but additional increases in this time beyond 9 sec. did not materially effect recall.

Discussion. Three aspects of these results seem particularly noteworthy. First, *S*s rehearsed equally often regardless of instructions concerning the recall task. Although it is possible tl[...] *S*s were also rehearsing covertly (and thereb[...]reasing their actual rehearsal time) this possib[...]oes not seem likely. The very short interv[...]een *E*'s command to stop writing and th[...]rance of the next trigram would not allow m[...]e for covert rehearsal, and the equality of [...]hearsals for A and UA *S*s implies that A [...] not doing something in addition to writin[...]rge number of studies indicates that perfo[...] diminishes when two activities are attemp[...] once (e.g., Monty, Taub, & Laughery, 1965

The second salient feature of [...] results concerns the relationship between an[...] of rehearsal and retention. While the numbe[r] of rehearsals increased by significant amounts [...]ch increase in rehearsal time, a correspondin[g in]crease in recall was found only when writing time [in]creased from 3 to 9 sec. The extra rehearsals allo[wed] by lengthening this time to 15 sec. did not prod[uce] increases in recall. While this breakdown in the positive relationship between memory and rehearsal appears to contradict a great deal of experimental literature (e.g., Rundus & Atkinson, 1970), it is not totally unprecedented. For example, Stanners and Meunier (1969) have also reported a limit to the beneficial effects of rehearsal on memory. Most of the studies that have reported a strong positive relationship between memory and rehearsal of individual items have not studied rehearsal intervals greater than 10 sec. or retention intervals longer than 30 sec.

And, third, some process other than simple rehearsal must be invoked to account for recall differences between A and UA *S*s. Although these two groups were nearly identical in terms of rehearsals given, A *S*s yielded consistently superior recall scores. Thus, while the present experiment does not imply what this extra process may be, it does seem to clearly indicate its existence.

EXTENDED MEDIATION IN CHILDREN'S PAIRED-ASSOCIATE LEARNING[1]

JUDITH E. SIMS-KNIGHT[2] AND LEWIS P. LIPSITT[3]
Brown University

In a study of paired-associate learning in 80 third graders, both the mediated facilitation and interference effects previously demonstrated on List III by Wismer and Lipsitt were replicated under conditions in which the stimulus words of List III were replaced either with pictures of the stimulus objects or pictures of objects in the same class as the stimulus objects. The results indicated that third-grade children apparently have the ability to make implicit associations in a mediational chain.

[illegible]mer and Lipsitt (1964) demonstrated that fi[illegible]-grade children exhibit both facilitation and interference in a mediational paired-associate study. The *S*s were presented printed word pairs on three [illegible]essive lists to arrange facilitation and interference conditions on a within-*S*s basis: (*a*) A–B, B–C, A–C for facilitation, and (*b*) A–B, B–C, A–C (re-paired) for interference. One control (C_1) involved a new word in List II, so that the sequence was A–B, X–C, A–C, and another control (C_2) instituted new word pairs on List III. Besides demonstrating the predicted facilitation and interference effects, error analyses revealed that the mechanism underlying both types of transfer was mediational in nature.

Russell and Storms (1955) showed that adults can provide their own mediational links when these are not directly administered. The present study attempted to determine whether young children can make implicit chains involving images and words. Two levels of extended mediation were studied. In the first level, pictorial presentations (designated A′) were introduced in List III in place of the printed [illegible] words, e.g., instead of the word *telephone* appearing, a drawing of a telephone would appear. For *S*s to respond to these pictures *as if* they were the printed words of List I presupposes an implicit mediational link between the image and the word.

In the second condition, the List III picture (now called A″) was of a different object from A, but was in the same class as A. For example, if the stimulus word A was telephone, a picture of a microphone (A″) was used in List III. This condition extends the mediational chain still further.

Method. The stimulus words were typed on 4 × 6 in. white cards, and the stimulus pictures were black-and-white line drawings on similar cards. Stimulus cards were presented manually, at a rate of 5 sec. per card, followed by cards containing both the stimulus and response words. On List III pairs, line drawings replaced the printed stimulus words.

Each *S* was presented eight word-pair sequences, two sequences for each experimental condition—facilitation, interference, C_1, and C_2. The eight word-pair sequences were chosen for their high A–B and B–C associative strengths and low A–C associative strength. Word-pair sequences were completely counterbalanced across *S*s. For example, a bull–cow (A–B), cow–milk (B–C) chain appears as a List III facilitation pair in Group 1, as interference in Group 2 where bull is paired with an extramediational word, and as a different type of control in Groups 3 and 4, respectively (see Wismer & Lipsitt, 1964).

The *S*s were 80 third-grade children, 40 in each implicit chain group (A′ or A″). Each counterbalancing group had 10 *S*s, who were tested individually in one session. Standard paired-associate learning instructions preceded 3 trials of List I, 3 of List II, followed by repetitions of List III until *S*s reached a criterion of 3 errorless trials (or 12 trials were completed). Presentation order was randomized separately for each trial.

Results. Table 1 shows that mean errors on List III varied with pair type. This effect was significant in a three-way analysis of variance with pair type as a within-*S*s variable, F (3, 216) = 34.96, $p < .01$. As predicted, the mediated facilitative and interfering effects were greater in the A′ condition than in the A″ condition, yielding a significant interaction, F (3, 216) = 5.44, $p < .01$. Simple tests revealed that in Condition A′ the facilitation pairs produced significantly fewer errors than C_1, t (39) = 2.82, $p < .01$, but not fewer than C_2, t (39) 1.70. Performance under the A′ condition on interference pairs was significantly poorer than performance on both controls, t (39) = 3.42 and 5.60, re-

TABLE 1

MEAN ERRORS ON LIST III FOR FACILITATION, INTERFERENCE, AND CONTROL CONDITIONS UNDER TWO LEVELS OF EXTENDED MEDIATION

Condition	Extended mediation levels: A′	A″
Facilitation	2.00	2.43
Control 2	2.30	2.45
Control 1	2.88	3.00
Interference	4.58	3.53

[1] This study was conducted at Brown University as a senior honor's thesis (Sims, 1965) by the first author under the direction of the second. TABLE 2

PERCENT FIRST-TRIAL RESPONSES ON LIST III TO A′ AND A″ STIMULI

Condition A′					
B	C	A″	C re-paired (Correct response)	A (labeled picture)	Other response (including none)
41.2	9.9	0	0	10.0	38.9
Condition A″					
B	C	A′	C re-paired (Correct response)	A (labeled picture)	Other response (including none)
6.4	1.8	3.5	0	20.2	68.1

spectively, $p < .01$. In Condition A″, facilitation pairs performance was again significantly better than performance on C_1, t (39) = 2.22, $p < .05$, but not better than performance on C_2, t (39) = .11. Interference-pairs performance was significantly poorer than C_2, t (39) = 2.66, $p < .01$, but not poorer than C_1, t (39) = 1.30.

A significant Pair Type × Counterbalancing Group interaction, F (9, 216) = 2.36, $p < .05$, was due apparently to the relatively poorer performance on Counterbalancing Group 4, particularly on C_1 and interference pairs.

Analysis of first-trial errors (Table 2) indicated that in the A′ condition the most frequent response to A′ was B, while in the A″ condition the most frequent first-trial responses were either to name the stimulus or refrain from responding. Moreover, the A′ condition elicited more than five times as many C (mediated) responses than A″, an effect which undoubtedly contributed to the greater facilitative and interference effects under Condition A′.

Discussion. Third-grade child[illegible]arently have the ability to make implicit asso[illegible] in a mediational chain. All results from th[illegible]ndition indicate that they can make associati[illegible]tween a word and its pictorial representation a[illegible] that association to complete a mediational c[illegible] Second, *Ss'* most frequent response of B to th[illegible]resentation of A′ suggests that they had asso[illegible] A′ with A, which had previously been paired [illegible] B.

The results of the A″ conditio[illegible]pected and as revealed by the Chain Cond[illegible] Pair Type interaction, indicated that as the [illegible]ional chain is lengthened, both facilitative [illegible]nterference transfer are attenuated. Further[illegible] *Ss'* first response to A″ was most often a la[illegible]he picture rather than B or C.

The difficulty of obtaining a p[illegible] control is evident. Wismer and Lipsitt's (19[illegible]ndings had suggested that C_3 more clearly d[illegible]tiates between facilitation and interferenc[illegible]he present study, however, neither condition [illegible] a significant difference between facilitation [illegible], suggesting that even in the absence of exp[illegible] A-B, B-C training *S*s may have been able to [illegible]de the implicit B link, thus facilitating A–C lea[illegible]ing. Since C_1 was significantly different from bo[illegible]acilitation and interference in Condition A′, it [illegible]ay be considered, at least in this study, the b[illegible]er control. Considering only this control, facilit[illegible]on but not interference was obtained under Condit[illegible] A″.

THE ROLE OF THE ASSOCIATION IN RECOGNITION MEMORY[1]

BENTON J. UNDERWOOD[2]

Northwestern University

The purpose of the eight experiments was to assess the role which associations between two words played in recognition decisions. The evidence on weak associations established in the laboratory indicated that the association was playing a small role, but that recognition performance on pairs of words was highly predictable from frequency information. However, the use of strongly associated words indicated that the strength of the association per se was not a critical variable in recognition performance. A post hoc expansion of frequency theory was proposed. Some unexpected findings included criterion differences in making frequency judgments as compared with recognition decisions, and criterion differences in recognition tests on homonym pairs as compared with other classes of word pairs.

At the empirical level, the present studies were concerned with the role that an association between two words plays in the recognition performance for the pair. At the theoretical level, the studies were prompted by a theory which states that recognition decisions are mediated by frequency information (Underwood, 1971). This theory has evolved from work in which the unit of analysis was the single word; the association between words has received little attention in the development of the theory. For the single word, the theory, as applied to recognition decisions between old and new words, simply assumes that these decisions are made by discriminations of phenomenal frequency differences between the old and new words. Associations enter this formulation in only a vague way. It is known that the background frequency of words (as indexed by word counts) has little if any effect on judgments of situational frequency, i.e., frequency induced in the laboratory (Underwood, Zimmerman, & Freund, 1971). This must mean that the frequency information induced in the laboratory is kept distinct from background frequency and, therefore, in the vague sense noted above, situational frequency is somehow associated with the laboratory context.

The broad perspective of memory into which frequency theory fits assumes that various types of information may constitute a memory for an event (Underwood, 1969). Frequency information is simply one of these types, but a type that assumes (by theory) the major function in recognition decisions involving single verbal units. The theory has never presumed that other types of information will always be irrelevant for recognition. Indeed, it has been concluded that when frequency information becomes invalid for recognition decisions the subject will turn to other types of information in memory to mediate his judgments (Underwood & Freund, 1970). A recent study by Broder (1973) shows a serious breakdown of the theory when frequency information and associative information are in conflict. So, then, frequency theory can only be viewed within a larger perspective; the theory deals with one type of information in memory and

its role in recognition performance. It is a part of the theoretical–empirical task to establish the limits of the theory, limits at which the theory is no longer useful in predicting the outcome of recognition studies. The studies to be reported were undertaken to determine if associative information between words leads to a breakdown of the predictions based only on frequency information.

There is a rapidly growing literature dealing with word recognition and the associative relationships among the words. These studies are often spoken of as studies dealing with associative context. The outcomes of these experiments are presumed to be relevant to the question of whether or not recognition involves retrieval. The idea is that if an association influences recognition, retrieval processes *are* involved. The central method of study, with several variations, is that of removing, on the test, the items which occurred with the target word during study. If performance falls (as compared with the condition in which the context remains on the test) it is said to implicate the loss of retrieval cues. Context may be added also, but if this influences recognition, the theoretical interpretation is not clear with regard to the role of retrieval in recognition.

An examination of the literature shows no consistency in the effect of associative context on recognition. This confusion may be sampled. Tulving and Thomson (1971) reported that both the addition of context and the removal of context degraded recognition. Subsequently, Thomson (1972) found little effect of context addition. The data of Cofer, Segal, Stein, and Walker (1969) showed that removing context caused a fall in recognition scores. Light and Carter-Sobell (1970) found that context change did influence recognition (performance fell) but in a further study Light (1972) reported that recognition for words embedded in sentences for study but tested alone gave recognition scores that were quite comparable to those obtained when the word was studied alone and tested alone. Ellis and Shumate (1973) showed no loss in recognition of stimulus terms from a paired-associate list over 28 days although the ability to recall the response terms fell over this period. Wood (196[illegible]) also concluded that the association developed in paired-associate learning did not influence recognition, although Wolford (1971) interpreted his results to indicate that the association between words in a pair was involved in recognition.

It is not the purpose here to attempt to evaluate the possible reasons for the contradictory findings. The details of some of these studies will be considered in conjunction with the specific experiments to be reported. It is merely noted here that the empirical facts concerning the role of associations in recognition decisions are far from clear.

One further background comment is required. It was noted earlier that the studies to be reported were undertaken with frequency theory as the background orientation. This theory fits nicely into the conceptual notions of signal-detection analysis. If, for example, an old and new word are given on a forced-choice test of recognition, the apparent frequency of the old item constitutes the signal, the apparent frequency of the new word, the noise. Words which have the same input frequency will constitute a distribution of phenomenal frequency for old words, and the phenomenal frequency of new words will constitute a distribution of noise. Two presumably independent measures of behavior may be obtained from signal-detection analysis. One of these is discriminability or sensitivity between the signal and noise distribution (between the phenomenal-frequency distributions for old and new words in terms of frequency theory). The measure d' is used to express sensitivity differences. The other measure has to do with the criterion set by the subject for accepting old words and rejecting new ones. Presumably the criterion represents a form of response bias which may differ among subjects and among conditions of an experiment, and it is measured by *beta* in signal-detection analysis. As will be seen, some unexpected differences in the criterion settings or response biases

were found. However, while accepting the conceptual notions of signal detection, it has seemed unnecessary to use the measures of signal detection (d' and *beta*) to reflect the behavioral manifestations of these concepts. Rather, other measures have been developed. Nevertheless, the relationships between the measures used and d' and *beta* will sometimes be reported.

The eight experiments to be described divide themselves into two subsets. The first five were concerned with transient or weak associations developed in the laboratory between the two words in a pair. The remaining three used pairs of words already strongly associated by cultural usage.

Experiment I

The first experiment was planned as an analogue of a previous study using single words (Underwood, 1972, Experiment 1). In that study, comparative recognition decisions were evaluated in conjunction with comparative judgments of frequency under exactly the same conditions. The outcomes were statistically equivalent. Furthermore, when errors were made they occurred for the same items for the group making recognition decisions and for the group making frequency judgments. The correlation between the error distributions was .74. This finding was deemed consistent with the theory that recognition decisions are based on frequency information. In Experiment I, reported below, *pairs* of unrelated words were used as the recognition unit, with frequency judgments and recognition decisions being made by different groups. The empirical question is whether or not the recognition decisions are predictable from judgments of frequency as was true when single words were the recognition unit.

Method

The general method may be described first. The *Ss* were presented a series of pairs for study, each pair being presented on a slide for 5 sec. Before presenting the pairs the *Ss* were given a booklet, and the cover sheet of the booklet contained the test instructions. These instructions were studied by the *S* before the list was presented so that he knew exactly how he would be tested. One set of instructions informed the *S* that he would be asked to make recognition decisions, both absolute recognition (*yes–no*) decisions for individual pairs, and comparative or forced-choice decisions between two pairs, one old and one new. The two types of tests were illustrated on the instruction sheet. Another set of instructions, given to other *Ss*, informed them that their memories would be tested for frequency information. These instructions further indicated that there would be two types of test items. In one case, single pairs were shown and the *S* was required to fill in a blank with a number to indicate the number of times he thought the pair had been presented. In the other case, two pairs were shown and the *S* was required to encircle the pair which had been presented most frequently. Thus, all *Ss* received the same study list, and all *Ss* made both absolute and comparative judgments, but for one group the instructions emphasized correct recognition and for the other group, correct frequency information.

Materials. The pool of words consisted of 240 five-letter words with Thorndike–Lorge frequencies falling between 11–30. This pool consisted of approximately 90% of all five-letter words falling in this frequency range.[4] From this pool, 72 pairs were formed randomly subject only to the restriction that the two words in a pair did not have the same initial letter. The 72 pairs were used in the study list, with 48 pairs presented once, 12 twice, and 12 three times. The pairs were assigned randomly to these frequency categories. Pairs presented twice were first assigned positions randomly, once in each half of the study list. Pairs presented three times were then assigned, each pair occurring once in each third of the study list. Finally, the 48 pairs occurring once were assigned randomly to the remaining positions. Two buffer pairs were assigned at the beginning of the list, and two at the end so there was a total of 112 positions in the study list.

Test booklets. The test booklet consisted of three pages plus the cover sheet of instructions. There were 84 test items, 28 on each page. Each page included 16 items containing pairs that had been presented once for study, four that had been presented twice, and four that had been presented three times. In addition, there were four pairs on each page which had not been on the study list (new pairs). Half of the items in each class (excepting the new pairs) were tested by a forced-choice procedure, half by an absolute test. Thus, across the three pages, 24 pairs that had been presented once for study were paired with new pairs to produce 24 forced-choice items, and 24 pairs were presented alone for *yes–no* decisions. Pairs presented twice and three times for study were also equally divided between forced choice and absolute judgments.

[4] This pool of words was formed by Carl P. Duncan. Its use is greatly appreciated.

For absolute recognition, the words *yes* and *no* followed the pair with the *S* instructed to encircle the appropriate response. For the judgments of absolute frequency, a blank, rather than *yes* and *no*, followed the pair with the *S* requested to write in a number to indicate the frequency with which he thought the pair had been presented during the study list. In the forced-choice items the *S* encircled the correct pair (recognition) or the pair which had occurred most frequently during study (frequency judgments).

As noted earlier, new pairs were required for the forced-choice items. The 36 new pairs required (24 for the pairs presented once for study, six each for those presented twice and three times) had been formed randomly from the pool and were paired randomly with old pairs. On a single form only half the study pairs could be tested by a given method (forced choice or absolute judgment). Therefore, a second form was constructed in which the method of testing was reversed for the pairs. As a consequence, when considered across all *S*s, each study pair was tested by a forced-choice procedure (for recognition and for frequency information) and also by an absolute test (*yes* or *no* recognition, and judgments of absolute frequency).

On each page of the booklet the type of test item was randomized. Thus, *S* might have three successive items requiring a forced-choice decision, then an item requiring an absolute judgment, then an item for a forced-choice decision, then three items for an absolute judgment, and so on. On the forced-choice items the old and new pairs were randomly assigned to the left or right position. The instructions required that the *S* respond to all items on each page, guessing if necessary.

Procedure and Subjects. The data were collected by a group procedure. As the initial step, the booklets were distributed to the *S*s with instructions not to open the booklet. The experimenter informed the *S*s that they would be presented a long list of pairs of words and that they should try to learn the pairs as pairs. They were further told that some pairs would be presented more than once. Next, they were asked to study the instructions in order to understand how they would be tested. Any questions concerning the instructions were handled individually. The list was then presented for study. After the last slide was presented the *S*s were asked to review the instructions (if necessary) and then proceed to the first test page. The testing was unpaced.

The *S*s were tested in groups of varying size, but within each group both frequency-judging instructions and recognition instructions were represented as well as were both forms. The booklets were randomized within blocks of four (two forms and two types of instructions) before they were assigned to the *S*s. A total of 152 *S*s was completed, 76 having had the recognition instructions and 76 the instructions for frequency judgments. Within each group there were 38 for each form. Since the forms did not differ in any of the analyses, no further mention will be made of this balancing variable.

Results

Pairs presented two and three times were included merely to make the frequency-judging task a reasonable one, particularly for the absolute judgments. The errors made on these pairs were few in number. The basic interest was for the pairs presented once for study. The results for the forced-choice tests will be considered first.

Forced-choice tests. There were 24 items each of which consisted of a pair presented once and a pair which was new. The *S*s were required in one case to encircle the pair which had been presented for study, and in the other case, to encircle the most frequently presented pair. For the 76 *S*s given recognition instructions the mean number of errors was 2.59 (10.8%), and for the 76 subjects given instructions to choose the most frequently presented pair the mean number of errors was 3.3[illegible] (13.8%). The difference between the two means was not reliable, $t\ (150) = 1.73$, $p > .05$. The discriminability or sensitivity, therefore, may be judged equivalent for the two groups. This result is the same as found previously with single words (Underwood, 1972). In the previous study it was found that the errors fell on the same items under both sets of instructions. In the present study the number of errors made on each of the 48 pairs presented once for study was determined for each type of instruction. The product-moment correlation between the two arrays was .43, $p < .01$.

Absolute tests. For these tests, each *S* was given 24 pairs presented once and 12 new pairs. In one case *yes–no* decisions were requested, in the other, absolute judgments of frequency. The data will be viewed in a number of ways.

The frequency estimates may be handled in exactly the same way as are the recognition decisions. If *S* indicated that a pair not presented for study had a frequency of one or greater, it would be equivalent to a false alarm for a *yes–no* recognition decision. Similarly, if *S* assigned a zero to a pair that had been presented once, it would be equivalent to a miss in recognition. Throughout the studies to be reported, it has been found that the sum of the misses

and false alarms is a simple and meaningful measure of discriminability or sensitivity. This measure and d' correlate highly. In the present experiment the correlation for the 76 *S*s given the recognition test was −.86, and for those making absolute frequency judgments, −.91. These are somewhat lower values than those to be reported in later studies. In view of these relationships, the sum of the misses and false alarms (M + FA) has been used as the basic measure of discriminability.

The mean M + FA for absolute recognition was 7.66, that for frequency judgments, 6.∴. These means do not differ statistically (t = 1.20). However, these values alone do not adequately reflect the outcome for the absolute tests. The full picture can be seen in Figure 1. This figure implicates criterion differences between those *S*s who made recognition decisions and those who made frequency decisions. The *S*s in making recognition decisions infrequently made false alarms but correspondingly had many misses. The *S*s in making frequency judgments behaved in the opposite manner; they made many false alarms (assigning a new pair a value of one or more) but had few misses.

The difference in the criterion set by the two groups is reflected directly by the interaction (F = 69.66) as seen in Figure 1. An analysis of variance of data such as Figure 1 is based upon allows conclusions about both differences in sensitivity or discriminability and differences in the criterion or response bias. If there is a significant main effect between recognition and frequency judgments, differences in sensitivity would be indicated. A main effect of input frequency would simply indicate the overall balance between the tendency to produce false alarms and the tendency to produce misses. A significant statistical interaction resulting from a convergence of the lines between input frequencies zero and one (whether a crossover or not) indicates a criterion difference.

The above technique for determining sensitivity and criterion differences seems straightforward. However, some comments should be made about other measures used

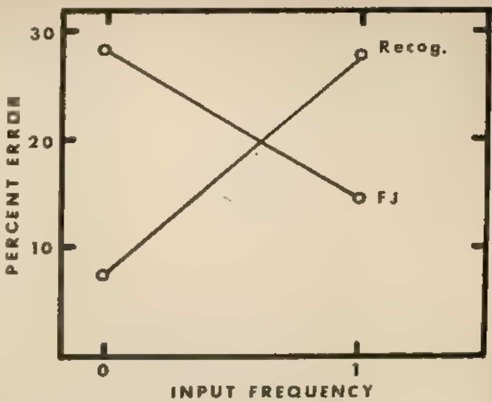

FIGURE 1. Errors on pairs of words as related to input frequency. The test included both frequency judgments (FJ) and recognition (Recog).

to reflect criterion differences. *Beta*, the measure of the criterion setting used in signal-detection analysis, is the ratio of the height of the ordinate of the normal curve for the proportion of hits and the ordinate height for the proportion of false alarms. The *beta* distributions were severely skewed for the present data. Ignoring this skewness, the mean *beta* for recognition was 4.95, and for frequency judgments, 2.44 (t = 3.59).

Another measure which could be used to reflect differences in the criterion is M − FA/M + FA. Thus, if one *S* had two misses and eight false alarms, and another *S* had eight misses and two false alarms, sensitivity is equivalent but the criterion differs for the two (−.60 for the first, and +.60 for the second). Scores may vary from −1 to a +1. For the present data the mean values were .72 for recognition and .08 for frequency judgments (t = 7.14). This measure is curvilinearly related to *beta*. If zero false alarms and zero misses are assumed to be one miss or one false alarm, the rank-order correlation between the two measures (*beta* and M − FA/M + FA) is essentially perfect. The logic of changing zeros to a positive value (the value could be less than one, e.g., .1) is to avoid too many extreme scores (−1 and +1) which result when zero scores are entered. This simulates the situation for *beta* where no ordinate value is zero.

The values for M + FA are essentially equivalent for the two groups. Therefore, the criterion difference resulting from the formula M − FA/M + FA must come from the M − FA values. In effect, this is simply another way of calculating an interaction. For the present work, therefore, any criterion difference between conditions seems given most directly by the interaction of the analysis of variance between input frequencies and type of test. However one analyzes the data, it is clear that there were differences in the criterion setting for *Ss* given the recognition task and those given the frequency-judging task. As was the case with forced-choice tests, sensitivity did not differ for the two groups on the absolute tests.

Item correlations. The number of misses for each of the 48 pairs presented once was determined for recognition and for frequency judgments on the absolute tests. The correlation between the two distributions was .63 ($p < .01$). This indicates a substantial relationship between phenomenal frequency and recognition decisions. This relationship emerges in another analysis. The mean frequency judgments for the 48 pairs presented once were correlated with the number of misses for recognition. The value was −.50 ($p < .01$).

Correlations by Subjects. A given *S* made both absolute and comparative frequency judgments, or both absolute and comparative recognition decisions. The relationship between the two types of judgments may be examined. For frequency judgments the correlation for the 76 *Ss* between M + FA for 24 items and number of errors on the 24 forced-choice items was .65. For recognition, the corresponding value was .59. Both values are reliable statistically ($p < .01$).

Each *S* under frequency-judging instructions made absolute frequency estimates for 24 pairs which had been presented once for study. For each *S* the mean and standard deviation of these judgments was determined and correlated with the number of errors made on the forced-choice frequency judgments. The correlation between the mean frequency judgments and number of forced-choice err[illegible] was −.09 but that between the stand[illegible] deviation and number of forced-choi[illegible] errors was .44 ($p < .01$). Thus, the l[illegible] the variability of phenomenal freque[illegible] for items with a constant input freque[illegible] the better the discriminability on [illegible]ed-choice decisions.

Discussion

The discussion of the finding[illegible] be brief at this point. Overall, the resul[illegible] showed that frequency judgments and recogn[illegible] decisions for pairs of words have much in [illegible]mon, and these results could be interprete[illegible] consistent with the idea that phenomenal [illegible]uency differences play a major role in re[illegible]ition performance. Alternative interpr[illegible]tions are undoubtedly possible, of course, [illegible]t such interpretations must include an a[illegible]ounting of the commonality in errors produce[illegible]by recognition and by frequency-judging in[illegible]uctions.

The finding that there was a diff[illegible]ence in the criterion set (on the average) for recognition judgments and for frequency jud[illegible]ments was quite unexpected. It was therefore decided to undertake a further study, with somewhat changed procedures, to see if the finding could be replicated.

Experiment II

Method

In this experiment all *Ss* were given exactly the same study list as was given in Experiment I. The two changes, which occurred on the test, will be described.

In Experiment I, each *S* made both absolute and comparative judgments. In Experiment II, e[illegible] *S* made a single type of judgment on all items. Therefore, there were four groups of *Ss*. One group made only absolute frequency judgments, [illegible] made only forced-choice frequency judgments. A third group made *yes–no* recognition decisions, and a fourth made forced-choice recognition decisions. Of primary interest were the judgments [illegible] on the 48 pairs presented once for study.

It will be remembered that in Experiment I only 12 new pairs were used for *yes–no* recognition and for absolute frequency judgments. In Experi[illegible] II, 48 new pairs were included. Since there [illegible] also 48 pairs presented once, the number of [illegible] rights and wrongs was more nearly equali[illegible] Experiment II than was true in Experiment [illegible] These 48 new pairs also became the new pairs on t[illegible] forced-choice tests.

The booklet for the forced-choice tests (recognition and frequency judgments) consisted of the

instruction sh... and two test sheets with 30 items on each for ... of 60 test items. These 60 items consisted ... 18 pairs presented once (each accompa... new pair) and six items in which the stud... had been presented twice and six in which i... been presented three times. Thus, only half ... items presented twice and half those presente... three times were tested. The purpose in this wa... keep the total number of pairs to which the sub...t was exposed on the test equivalent for the f... choice and for the absolute tests.

The test booklet for the absolute judgments was mad... of the instruction sheet and three test pa... items to a page, for a total of 120. These con...ed of 48 new pairs, 48 pairs presented once, 12 ...ated twice, and 12 presented three times.

...ther details of the procedure were exactly the sa... for Experiment I. The *Ss* studied the in...on sheet which described how they would be te...d, after which the list was presented for study at ... 5-sec. rate. Again, the test was unpaced. The four instructional conditions were randomized in ...ocks of four so that for each session each was about equally represented. Sessions were continued until 36 *Ss* had completed the test for each instructional condition.

Results

Forced choice. The mean number of ...rors made by the 36 *Ss* on the 48 forced-...oice items under recognition instructions ...s 5.42 (11.3%), and under instructions to choose the most frequent pair, 4.92 (10.1%). The t was .60. The correlation of errors by items was .54 ($p < .01$). These results confirm those of Experiment I.

Absolute tests. The mean frequency judgments for the pairs presented 0, 1, 2, and 3 times may first be noted. The means in corresponding order were .18, .91, 1.74, and 2.49. The relationship is linear. Again, however, in the analyses to follow, no attention will be given to the pairs presented more than once since the errors on these pairs were few in number. As was done for Experiment I, false alarms and misses were determined for the groups making absolute judgments. The results are plotted in Figure 2. The interaction, although less severe than in Experiment I, was still present, $F\ (1, 70) = 5.99$, $p < .05$. There was no appreciable effect of type of instruction ($F = 2.18$), indicating that discriminability was equivalent for both frequency decisions and recognition decisions. There was a main effect of input frequency

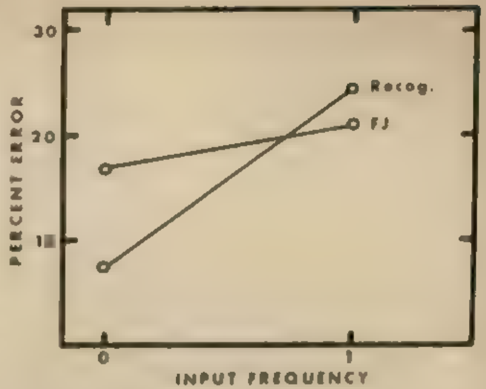

FIGURE 2. Further evidence on the errors made on pairs of words as related to input frequency for frequency judgments and recognition.

($F = 17.54$) indicating more misses than false alarms when combined across both groups.

The sum of the false alarms and misses correlated $-.93$ with d' for the frequency judgments, and $-.94$ for the recognition data. The difference in the criterion set by the two groups, as given in the interaction in Figure 2, was not reflected in *beta* differences, the F being less than one.

Item correlations. The number of misses was determined for each of the 48 pairs presented once for study. This was done separately for the 36 *Ss* making absolute frequency judgments (a miss being an assignment of zero) and for the 36 *Ss* making *yes–no* recognition decisions. The correlation between the two arrays was .55 ($p < .01$). The correlation for the number of false alarms on the 48 new items for the two groups was .42 ($p < .01$).

If frequency information is involved in recognition decisions, it should be possible to predict forced-choice recognition and frequency judgments from the absolute frequency judgments. In the forced-choice tests, two pairs were involved for each item, one old (presented once) and one new. For each of these pairs a mean frequency judgment was available from the group making the absolute frequency estimates. It would seem that the greater the phenomenal frequency difference between the two pairs in the forced-choice item, the

fewer the number of errors which should be made on that item. However, the variability of the frequency judgments should also be considered. For whatever reason, items having the same input frequency differ in the variability of the frequency estimates when viewed across the 36 estimates from the 36 *S*s. It was shown in Experiment I that *S*s having the lower variability of frequency estimates with constant input frequency did better on the forced-choice items than did the *S*s with the higher variability. The same outcome may apply to item variability when calculated across *S*s. Therefore, it would seem that the clearest prediction would be that the greater the mean difference in phenomenal frequency between an old and new pair in a forced choice item, adjusted for differences in the variability of frequency estimates for those pairs, the better should be the performance on the forced-choice test.

The mean frequency difference for each old and new pair appearing in the forced-choice items was divided by the square root of the sums of the variances of the frequency estimates for the two pairs. A high value should indicate good discriminability between the two pairs. The correlation between these values and the number of errors on the forced-choice recognition test was −.61. For the forced-choice frequency judgments, the correlation was −.79. Clearly, the phenomenal frequency of items presented once, and the variability of the estimates reflecting phenomenal frequency, predict performance on the forced-choice tests with some accuracy.

As one further bit of evidence on the relationship between frequency information and recognition performance, the absolute judgments made on the 48 pairs occurring once were combined across Experiments I and II. Therefore, there were 74 *S*s who had made absolute frequency judgments and 74 *S*s who had made *yes–no* recognition decisions. The apparent frequency of a pair was given by the mean of the frequency judgments, and for each pair a standard deviation was available. It would be expected that the higher the mean apparent frequency and the lower [illegible] variability the better should be the p[illegible]ormance on recognition. The coeffici[illegible]f variation (M/σ) was used to derive a[illegible]gle measure for each pair. A high co[illegible]ent should indicate good discriminabil[illegible] These 48 values were correlated with [illegible] number of errors on *yes–no* recogniti[illegible]or the 48 pairs. The product-mom[illegible]correlation was −.70.

Discussion

Both experiments have sh[illegible] that discriminability or sensitivity for [illegible] of words was equivalent when *S*s were [illegible]d to make recognition decisions and judgments of frequency. This outcome held for both forced-choice items and for absolute judgments. Furthermore, the particular ite[illegible] on which errors were made in recognition [illegible]nded to be the same items on which the errors were made when judging frequency and frequency differences. Mean frequency judg[illegible] for pairs combined with the variability of those judgments, predicted errors in rec[illegible]ition performance on both *yes–no* and forced-choice tests. Viewed as a whole, the results were entirely consistent with the theory which specifies that frequency information is the major attribute of memory involved in pair recognition. In short, these two studies indicate that when pairs of words constitute the unit of analysis of recognition the outcome is much the same as when the individual word is the unit.

An unexpected finding in both experiments was that *S*s making absolute frequency judgments set a more lenient criterion than did those *S*s making recognition decisions. The reason for this difference is not known. An examination of the changes in performance across pages of the tests showed only very slight decrements under any of the conditions of testing, and the differences in the criterion were present initially and remained relatively constant across pages. Perhaps background frequency influenced the frequency judgments and not the recognition decisions although, as noted in the introduction, other data would argue against this possibility. By way [illegible] looking ahead it may be noted that a later experiment will show that criterion differences were found to be present for different class[illegible] of pairs of words for the same *S*. For the time being, therefore, the problem concerning th[illegible]

reason for the criterion differences will be set aside.

The two studies reported have established nothing concerning the role of the association in recognition. They have merely shown that frequency theory does not break down when pairs of words are used, pairs which presumably have some associative relationship as a consequence of the study trial. To assess in a more analytical way the role of associations in recognition requires different types of studies. The immediately following experiments represent one of these different types.

Experiment III

Assume the *S* is presented a series of pairs of words under instructions to associate the words in each pair. Let three of the pairs be identified as A–B, C–D, and E–F. On the test of recognition he is presented A–B (intact pair) and C–F (broken pair). His instructions are to respond *yes* to all pairs providing both words in the pair had been presented for study whether paired during study or not. If the number of misses is greater for the broken pairs than for the intact pairs, the association would seem to be clearly implicated in recognition performance. If the misses are equivalent, it would be concluded that the association is irrelevant for recognition performance. The purpose of Experiment III was to make this test.

In addition to the two types of test items noted above, two others were included in order to have pairs for which the correct response was *no*. One of these types consisted of one old and one new word, and the other type consisted of new pairs.

Method

Materials. The pairs of words were from the same pool as used in the first two studies. The *S* was presented 54 pairs for study. Of these, 18 were tested as intact pairs, that is, both words were old and paired as they were for study (O–O). A further 18 were re-paired words or broken pairs (O–Ob). One word from each of the remaining 18 pairs was used in pairs in which a new word constituted the other member of the pair (O–N). Finally, the test included 18 new pairs (N–N pairs).

For purposes of balancing conditions against possible pair differences, each pair was used in all conditions equally often. Originally, 72 pairs were assigned randomly to four subgroups of 18 pairs each. Across four forms each subgroup was used once for each of the four test types as described above. Thus, there were four different lists presented for study and four different test forms. The only additional words required were the 18 used as new words for the O–N pairs. These 18 words served the same function across all forms although, of course, the old words differed for each form. The O–Ob test pairs never consisted of an interchange of the members of two pairs. In the presentation list, each type of test item (except N–N of course) was represented in each successive block of three pairs. On the test, item types were randomized within blocks and particular items within blocks were random with respect to presentation position during study.

One further variable was introduced in the test. Half of the O–O pairs were tested in the order presented for study (A–B), and half were tested in reverse order (B–A). This was also true for the O–Ob pairs and for the O–N pairs. The latter became N–O pairs when reversed. The particular nine pairs to be reversed were determined randomly.

Procedure and Subjects. The pairs were presented for study at a 5-sec. rate by a slide projector. The instructions emphasized the learning of pairs as pairs and, although the *Ss* knew their memories would be tested, the nature of the test was not specified before presenting the list. After the study of the pairs the *Ss* were given a two-page booklet, 36 pairs to a page, with the words *yes* and *no* after each pair. They were instructed carefully that *yes* was the appropriate decision if both words had been [illegible] study or not. The instructions further empha[illegible] that if one or both of the words in a test pair had not been presented for study, the appropriate response was *no*. According to these rules there were 36 pairs for which the correct response was *yes*, and 36 for which the correct response was *no*, although the *Ss* were not told this.

Subjects were tested in small groups until 18 were completed for each of the four forms. Forms did not prove to differ statistically on the test, and they did not interact with item types. The results will be considered for the 72 *Ss* combined.

Results

The overall results are shown in Figure 3, where percent errors is used as the recognition measure. An error would be a false alarm for N–N and O–N, and a miss for O–O and O–Ob. It is to be noted that there were about 7% more misses on O–Ob pairs than for O–O pairs. The overall analysis showed a significant effect of item type ($F = 37.58$). A standard error of the mean difference derived from the error term indicated that any difference as large as

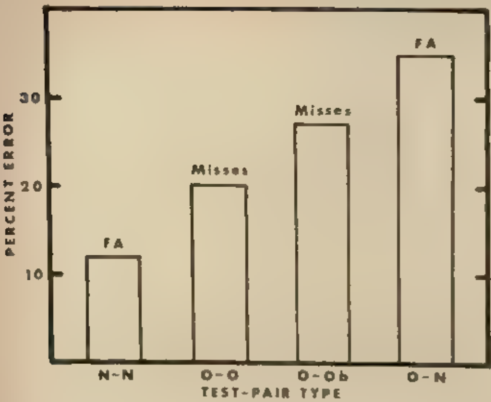

FIGURE 3. Misses and false alarms (FA) for four types of test pairs. (Abbreviations: N refers to a new word, O to an old word, and b to a broken pair.)

4.3% was reliable at $p = .01$. All differences between item types were larger than 4.3%. The fact, therefore, that type O–O results in fewer errors than type O–Ob may be taken as evidence that the association between the two words in a pair played a role in recognition.

The misses on the O–O pairs were more frequent than were the false alarms on the N–N pairs. The M + FA measure of sensitivity for these pairs correlated with d' across the four forms at the following levels: −.93, −.94, −.91, −.95.

The O–N pairs produced nearly 35% false alarms. A satisfactory accounting of this result was not found. Several subsidiary analyses were done to search for leads. The 72 *S*s were divided into two subgroups based upon the total errors made on all item types. The relative relationship among the four item types were exactly the same for these two subgroups of good and poor *S*s. There were two pages to the test form, and the *S*s completed the first page before moving to the second. It seemed possible that testing effects might have differed for item types. However, an analysis showed no difference in performance on the two pages and no interaction between pages and item types, both *F*s being less than 1.

It will be remembered that the position of the words in a pair during study was reversed for half the pairs on the test. This change had essentially no effect on the O–O pairs, the nonreversed pairs producing 20.7% errors, the reversed pairs, 19.6%. For the O–Ob pairs the corresponding values were 25.8% and 27.9%. But, for the O–N pairs the false alarms were 38.0%, and when reversed, (N–O) 31.6%. This is to say that when the old word was the first member of the pair, errors were more frequent than when the new word was the first member. However, even for the latter pairs, performance was poorer than was found on any of the three other item types.

It is difficult to see how criterion differences could exist for the various item types, since if the *S* could classify an item type he presumably could provide the correct response. Frequency theory might predict good performance on the O–N pairs on the grounds that the two words would represent a contrast in apparent frequency and this contrast would lead to a correct rejection. In one sense the results for the O–N pairs are in contradiction to the notion that an association facilitates recognition. The two words in the O–N pairs were not associated during study just as the O–Ob pairs were not associated. If the lack of an association leads to a *no* decision for the O–Ob pairs it should do the same for the O–N pairs, but in the latter case the decision would be correct. It is possible, of course, that this effect was present and kept the number of errors from being more frequent than was actually found. For the time being, the mechanisms responsible for the heavy error rate on the O–N pairs cannot be specified.

One other fact will be reported. When words are paired randomly the resulting pairs should show a distribution defined in terms of the ease with which the words within the pairs could be associated. There is a possibility that a pair which is easily associated when presented for study will also produce errors (false alarms) when it is used as a new pair on a test. This does not seem to be the case. In the present experiment, the 72 pairs were used both as old pairs (O–O) and as new pairs (N–N). The number of false alarms made on the

72 pairs when they were used as new pairs did not correlate with the number of misses which occurred when they were used as old pairs ($r = -.03$).

Experiment IV

The results of Experiment III were interpreted as demonstrating that an association between two words, developed on a single study trial, facilitated recognition of the pair. Or, as is sometimes said, associative context aided recognition performance. Experiment IV was another test of the role of associative context using a different approach, although one that is similar to those used by other investigators, particularly by DaPolito, Barker, and Wiant (1972). These investigators presented a triad of words for study. On the test, the *Ss* made recognition decisions on single words, but other items were sometimes present in the display when the decisions were being made. Essentially any change at test produced an increase in misses. The *Ss* were not instructed to associate the words in the triads during study, and since the triads were presented for only 1 sec., associative formation between the items would be minimal. Still, the results showed that when the order of the three items as presented for study was changed on the test, a decrement was observed, suggesting either that item-order information was important or that associations between the item and its position within the triad was a part of the memory. The method used by DaPolito et al. makes context (when defined as the presence of an item or items on which no recognition decisions are to be made) seemingly incidental. To some degree it would seem that *S* could ignore the context words on the test. The fact that context effects were found in spite of this seems to speak strongly that context, whether known to be associative or not, does influence recognition.

In the present experiment, *Ss* were presented pairs of words for study under instructions to associate the words in each pair. On the recognition test, either single words or pairs of words were presented. In the latter case the recognition decisions were made only on the second word in the pair. Thus, the first word in the pair need not have been involved at all in the recognition decision although the *Ss* were told that it might help them in reaching a decision on the second. Of course, the major variable was the nature of the first word in the pairs.

Method

A description of the seven classes or types of test items will be given first, expanding the symbol system used in describing the pairs in Experiment III. An old item is designated O, a new item, N, and (*a*) the test word was always the second word in a pair on the test, and (*b*) a word on the test always occupied the same position in a pair (first or second member) as it held during the study trial. The seven types of items were as follows.

- Type O: old second word tested alone
- Type N: new word tested alone
- Type O–O: intact pair
- Type N–N: new pair
- Type N–O: old second word with new first word
- Type O–N: new second word with old first word
- Type O–Ob: two old words from different study pairs

Materials. The words in the pairs were all four-letter monosyllabic words. They were drawn from a pool of 312 such words which constituted a random sample from the Thorndike Lorge tables. The change in the class of words (from the class used in the first three experiments) was necessitated by the fact that other experiments being conducted in the department were using the words from the earlier experiments.

Study and test lists. Initially, 96 words were drawn randomly from the pool and formed into 48 pairs randomly. These 48 pairs constituted the study list, hence the old pairs, for all *Ss*. A second sample of 84 words was drawn randomly and these 84 words were always used as new words on the test form.

For balancing purposes, the 48 study pairs were arbitrarily divided into four blocks of 12 pairs each. Across four test forms, each block of 12 pairs was used once for each of the four item types on the test involving old words in the second position (O, O–O, N–O, O–Ob). This means, therefore, that on a test form there were 12 items representing each of the four types. The O–Ob pairs were never constructed by interchanging the members of two pairs.

The assignment of new items to particular functions on the test forms was done randomly, with a different random assignment for each form. There were 12 Type O–N test pairs, the O words being the first words in the study pairs which on the test became Type O. There were also 12 Type N pairs

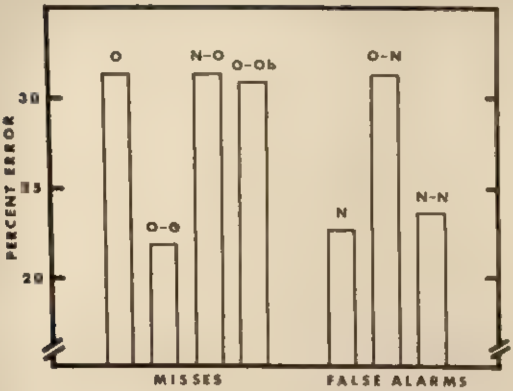

FIGURE 4. Misses and false alarms for various types of test items. (For pairs, the recognition decision was made only on the second word in the pair.)

on the test, but 24 pairs were used to represent Type N–N. This made 48 true *yes* items on the test and 48 true *no* items. On the test, the seven item types were block randomized, and test position, relative to input position, was orthogonal by halves. There were 48 items on each page of the two-page booklet.

The single items on the test always occupied the nominal second position of a pair. For example, the first four items on one of the test forms were as follows.

1.	spry–wile	YES	NO
2.	whey–ramp	YES	NO
3.	jest	YES	NO
4.	came–dell	YES	NO

Procedure and Subjects. The 48 study pairs, preceded and followed by two filler pairs, were presented at a 5-sec. rate. Prior to presenting the pairs, the *S*s were told only that pairs would be presented and that they should try to associate the words in each pair in preparation for a memory test. After the last pair had been presented, the booklets were distributed. The *S*s were run in groups of varying size but in any group the four test forms were assigned randomly to the *S*s. The instructions for the test involved five key points: (*a*) for a single word on the test form, the *yes–no* decision was whether or not the word had been shown as a member of a pair; (*b*) for a pair of words, the decision was to be made only for the second word, i.e., had it or had it not been presented as a second word in a pair on the study list; (*c*) the first word in a pair might aid in making the decision on the second; (*d*) an old word always occupied the same position on the test form as it had in the pair in which it appeared on the study list; and (*e*) all items were to be completed, guessing if necessary. The test was unpaced.

Groups of *S*s were tested until 68 *S*s had been completed, 17 for each of the four forms.

Results

The results, shown in Figure 4, are quite unambiguous. There were only two levels of errors, differing about 8–10%, and these two levels were associated with change of context and with context constancy. For the misses, omission of the first word (O), including a new first word (N–O), or repairing old words (O–Ob) all resulted in about the same increase in the number of errors when no change (O–O) is used as a reference. False alarms were correspondingly influenced when an old word was used as a first word (O–N). A number of different ways of viewing the differences statistically all produced the same conclusions. Perhaps the most direct way is to ask about the differences among the four types for the misses, F (3, [illegible]) = 7.87, $p < .01$, and among the three types for the false alarms, F (2, 134) = [illegible], $p < .01$. In both analyses, the deviation of one condition from the others is largely responsible for the conclusion that reliable differences were present.

It will be remembered that in Experiment III, Types N–O and O–N produced more errors than did Type O–Ob. In the present data, where *S* was asked to make decisions on a single word rather than on a pair as was true in Experiment III, the numbers of errors for these types were essentially equivalent. Also, in Experiment III the misses on Type O–O exceeded the false alarms on Type N–N, which was not true in the present experiment. This is to say that the two techniques (judging single words in pairs versus judging pairs) produced differences in detail, but both lead to the same conclusion. The presence on the test of the full associative context present during study facilitated recognition. Any changes made in the context caused an increase in misses.

EXPERIMENT V

Experiments III and IV gave evidence that an intact association between two words in a pair is a positive factor in the recognition of that pair. The present experiment represents a further test of the

role of an association in recognition, a test which makes use of paired-associate learning.

It was mentioned earlier that when words are paired randomly one would anticipate that some of these pairings would consist of words which would be easy to associate and others which would be difficult to associate, with the bulk of the pairs lying in between the extremes. If an association between two words influences the recognition of the pair, it might be reasoned that old pairs on which few errors were made developed stronger associations than did pairs on which many errors were made. To put this another way, during a constant period of study, the strength of the acquired association would differ for different pairs. If the strength of the association is involved in recognition, it must be predicted that pairs on which few recognition errors were made would be learned more rapidly as paired associates than would pairs on which many errors were made. Experiment V was a test of this proposition.

Method

Materials. From among the 48 pairs presented once for study in Experiment I, and tested by a *yes–no* procedure, 10 pairs on which few recognition errors were made were selected along with 10 pairs on which the most recognition errors were made. As paired-associate lists, these will be called the Easy List and the Hard List. Both lists are shown in Table 1. Although these lists were selected by using the data of Experiment I, the same pairs occurred under much the same conditions in Experiment II. Therefore, the errors made in Experiment II are also shown. The reliability of pair difficulty is by no means perfect, particularly for the pairs in the Hard List, although some regression would be anticipated. Nevertheless, the mean errors were substantially different for the two lists even when gauged by the errors made in Experiment II.

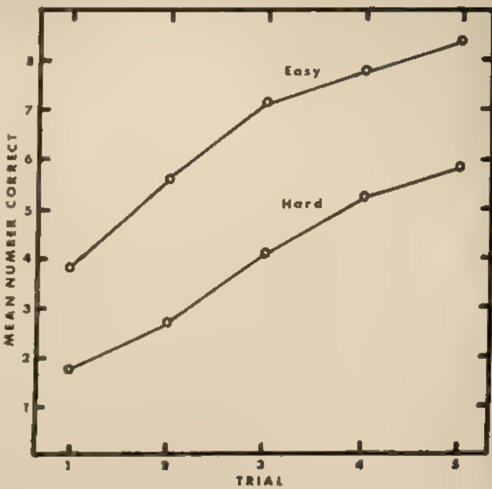

FIGURE 5. Acquisition of paired-associate lists of 10 pairs each, identified as easy and hard by the number of recognition errors made on the pairs.

Procedure and Subjects. The lists were presented for one study trial and five anticipation trials at a 2:2-sec. rate on a memory drum. There were 20 *Ss*. Half learned the Easy List followed by the Hard List, and half learned in the reverse order.

Results

As may be seen in Figure 5, the list made up of pairs defined as easy by recognition errors was much easier to learn than the list made up of pairs on which many recognition errors were made. This was true regardless of the order in which the lists were learned and the overall difference across the five trials was highly reliable ($F = 28.09$).

The mean number correct for each pair, summed across the five trials, is shown in Table 1. Only two pairs from the so-called Hard List fall within the range of number

of correct responses as shown for the pairs in the Easy List. Other information is included in Table 1. In Experiment I, 38 *S*s made absolute frequency judgments of these pairs, and in Experiment II, 36 *S*s did the same. The mean apparent frequency as derived from these 74 *S*s for each pair is shown in Table 1. The difference in the mean frequency judgments for the two lists is significant, $t\ (18) = 3.69$, $p < .01$. Thus, the pairs in the Easy List had higher apparent frequency than did those in the Hard List.

As shown earlier, prediction of recognition errors from absolute judgments of frequency was quite good when means and variability were considered simultaneously by using the coefficient of variation (M/σ). These values also appear in Table 1 and it is to be noted that the two lists differ markedly on this measure. Rank-order correlations were calculated across the 20 pairs. The M/σ values correlated .86 with recognition errors and .56 with the number of correct anticipations in paired-associate learning. The correlation between recognition errors and paired-associate learning was .72.

Discussion

The present results indicate that the ease of associating two words in a pair is positively related to correct recognition. These results support those of Experiments III and IV in showing that an association between the two words in a pair seems to be involved in recognition performance. Insofar as apparent frequency has been shown to predict recognition errors it is not surprising that apparent frequency also has some predictive value for paired-associate learning.

The evidence that an association between two words influences recognition must be kept in theoretical perspective. The major information used in recognition decisions may well be frequency information—apparent frequency of the pair as a unit and of the individual words, each as a unit. The difference between intact and broken pairs in Experiments III and IV was only 7–10%; performance did not fall to chance when associative context was removed. Thus, although the results of the experiments thus far indicate that an association plays a role in recognition, the magnitude of the role is not impressive when overall recognition performance is considered.

Experiment VI

Two of the basic findings from the preceding experiments led to Experiment VI. Experiments III and IV indicated that an association resulting from one presentation of a pair of words adds information which aids recognition performance. Experiment V showed that pairs on which few recognition errors were made were more rapidly acquired in a paired-associate list than were pairs on which many recognition errors were committed. These facts suggest that the associability of two words in a pair facilitated recognition performance, or, that facilitation of recognition of a pair by the association existing between the two words was directly related to the strength of that association. An obvious projection from these facts is that if very strongly associated pairs of words were tested for recognition, few if any errors would be observed. The present experiment deals with this possibility.

Many of the pairs used in Experiment VI were strongly associated as a consequence of cultural usage. Other investigators have approached the problem of associative context by the use of similar materials. Tulving and Thomson (1971) presented *S* strongly associated pairs of words as well as weakly associated pairs as indexed by published word-association norms. On the recognition test the *S* was asked to make a decision on each word of a pair independently. Based on the results of this procedure it would be concluded that the strength of an association had little influence on recognition. There were 12% misses on the strongly associated pairs, and 21% false alarms on new associated pairs. For weakly associated pairs the values were 15% and 16%. However, these data came from only a small part of an extensive procedure of testing which involved changing words in pairs, testing single words, adding new words to words which during study had been members of pairs, and so on. It is possible that the

TABLE 2

CRITICAL PAIRS OF WORDS: EXPERIMENTS VI–VIII

varied test context, and testing the words in a pair independently, may not have allowed differences as a function of strong and weak associative context to manifest themselves. Thomson (1972) used strongly associated pairs in one experiment (Experiment I) and pairs with no preexperimental associative relationship in another (Experiment IV). The *S*s made decisions on each word in a pair. The misses were 5% less for the strongly associated pairs than for those which were weakly associated, with the false alarms about equivalent for new pairs. These data, like the Tulving–Thomson data, suggest only a small facilitating effect of the culturally established associative relationship. Such findings seem odd if one is to assume that associative context is a powerful factor in recognition memory. Further investigation seemed necessary.

In the present experiment the *S* studied pairs of highly associated words and pairs of initially nonassociated words. Recognition decisions were always made for pairs as pairs.

Method

Materials. From a variety of sources, 100 pairs of words were brought together. As may be seen in Table 2, there were 20 pairs in each of five classes. Four of these classes were assumed to represent pairs with strong, culturally established, associative relationships. These four classes are the parallel associates, synonyms, antonyms, and conceptual associates. The fifth class, homonyms, represent a special class. There is no reason to believe that the two words in a homonym pair are associatively related in the sense that the words in pairs in the other classes are associated. The distinguishing property of the homonym pairs for the present study was that the acoustic-articulatory response to the two words in a pair would be equivalent. The consequence is that the frequency of this response would be double that for the words in the other types of pairs. It was believed that this property would yield information not only relevant for frequency theory, but also relevant to an understanding of the mechanisms of recognition in the associated pairs.

No argument is to be made for the purity of the pairs in the classes, nor that the pairs are necessarily representative of all possible pairs which might be placed in these classes. But, taken as a whole, each class is assumed to be distinctly different from each other class.

In addition to the 100 associated pairs, 100 nonassociated pairs were formed. In constructing these 100 nonassociated pairs, 100 additional words were chosen, these words varying in length, frequency, and form class. Some examples are: *assail, degree, lid, oath, worthless.* These words were paired randomly with one word from each of the 100 pairs listed in Table 2. Half the time (within each class), the first word in the pair as listed in Table 2 was retained, and it occupied the first position in the pair, the second position being held by a neutral word. For the other half of the pairs, the

TABLE 3

MEAN ERRORS (M + FA) FOR E PAIRS AND C PAIRS IN EACH OF THE FIVE CLASSES

Pair types	Parallel associates	Synonyms	Antonyms	Homonyms	Conceptual associates
E	1.14	1.15	1.70	1.42	.95
C	1.32	1.32	1.23	1.10	.83

Note. The standard deviations for these 10 distributions varied between .94 and 1.39. Abbreviations: M = misses; FA = false alarms; E = highly associated; C = nonassociated.

second word in the pair was retained, the first position being occupied by the neutral word. For example, using the pair *cup–saucer* in the list of parallel associates, the nonassociated pair became *cup–artist*, and using *bed–sleep*, the nonassociated pair became *utter–sleep*. Thus, the highly associated pairs (to be called E Pairs) and the nonassociated pairs (to be called C Pairs) always had one word in common.

Study lists and test forms. Each *S* was presented 50 pairs on the study list (plus two filler pairs at the beginning and two at the end). These 50 pairs were made up of five E Pairs and five C Pairs from each of the five classes. There were 100 pairs on the test forms consisting of the five E and C Pairs from each class presented for study plus five E and C Pairs from each class not presented for study. Of course, no word appeared in both an E Pair and a C Pair on the study list or test. For any given *S*, only half of the E Pairs and half of the C Pairs were used. Across four study lists and four test forms, each E Pair served as an old pair and as a new pair, and this was also true for each C Pair. This was accomplished by dividing the pairs in each class into four subgroups of C and E Pairs of five pairs each and rotating functions (old or new) across forms.

For the study list the 10 item types (five E Pairs and five C Pairs from each class) were block randomized across the 50 positions. The test forms consisted of 100 pairs, 50 on each of two pages, with the words *yes* and *no* appearing after each pair. The order of the pairs on the test forms was random, but with a different random order being used for each form.

Procedure and Subjects. Prior to presenting the list for study, the *S*s were fully informed concerning the nature of the test. They were told to try to associate the words in each pair on the study trial. The list was presented at a 5-sec. rate by a slide projector. After the list was presented the test booklets were distributed and the instructions for the test repeated. The *S*s were informed that they must make a decision for each pair, guessing if necessary.

The *S*s were run in small groups until 21 had completed each of the four forms. Since forms did not interact with the variables of experimental interest, the data have been summed across forms for the 84 *S*s.

Results

Data were available on 20 different types of pairs, each type represented by five pairs. These types were: old E Pairs in each of the five classes; new E Pairs from each class; old C Pairs from each class; and new C Pairs from each of the five classes. For the initial analysis, the sums of the misses and false alarms (M + FA) was determined for the C Pairs and for the E Pairs for each class. (It may be noted that d' correlated .98 with M + FA when summed across the five classes for the old and new E Pairs.) The means of the M + FA scores are shown in Table 3. It will be noted that for only two of the five classes (parallel associates and synonyms) are there fewer errors for the E Pairs than for the C Pairs. For the other three, the direction is reversed, although in none of the five classes is the difference between E and C Pairs of appreciable magnitude. Nevertheless, an analysis of variance showed the class was a significant source of variance, F (4, 332) = 7.87, $p < .01$, as was also the interaction between class and E-C Pairs, F (4, 332) = 4.18, $p < .01$, but the difference between E and C Pairs was not, F (1, 83) = 2.25, $p > .05$. These findings indicate that, overall, associated pairs are not better recognized than nonassociated pairs.

The measure of sensitivity, or discriminability, M + FA, has indicated that across the five classes the discriminability of pairs of highly associated words was not better than the discriminability for pairs with the minimal associative relationship that might have been established on a single study trial. The interaction between type of pair and class, however, indicated that discriminability differed as a function of class of pairs. An examination of the results for each class in more detail is indicated.

In presenting the results for the first two experiments, it was pointed out that criterion differences could be detected by a certain type of interaction when two conditions, both represented by old and new items, were plotted on the same graph. These requirements were met in the present

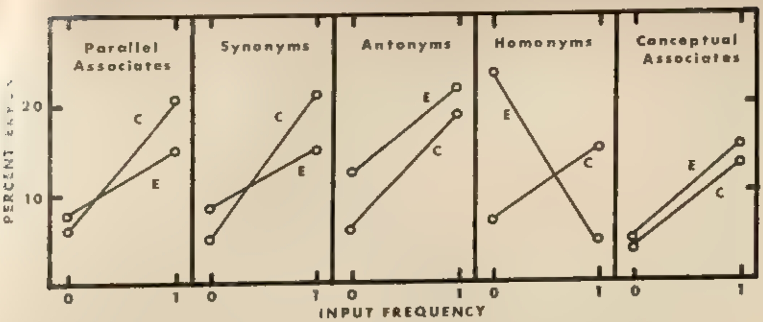

FIGURE 6. Recognition errors on experimental (E) and control (C) pairs of words as a function of input frequency and class or type of pair.

. for each class since there were old and new E Pairs and old and new C Pairs. The data are plotted in Figure 6 for each class, using input frequency (0 and 1) rather than old and new along the baseline.

The critical fact exhibited in Figure 6 is that *S* may maintain different criteria for different classes of pairs even when those pairs are intermingled on the same test form. The results for the homonyms show that *S* has a very lenient criterion for accepting pairs which were not in fact on the study list. The marked interaction between input frequency and E–C Pairs is evident. The results for each of the five classes of pairs have been analyzed separately. Each F is based on 1 and 82 *df*, and an F of 3.96 is required for the .05 level, 6.96 for the .01 level. Input frequency was significant for all classes, and except for the homonyms (which shows the smallest F, 9.51), more errors were made on old than on new pairs. The E–C difference was significant for only the antonyms ($F = 9.15$) and homonyms ($F = 4.02$). The interaction between the two variables was reliable for parallel associates ($F = 6.65$), synonyms (11.15), and, of course, for the homonyms ($F = 59.67$). The interaction for the parallel associates and for the synonyms cannot be interpreted as representing a criterion difference for the E and C Pairs, since the differences in errors are small in magnitude for new (zero frequency) items.

An examination of performance on the two test pages separately showed no systematic changes for any class of item. The differences in the criterion imposed for the different classes, therefore, was not a consequence of a gradual change or shift as the *S* made successive judgments.

It will be remembered that one word in each C Pair was tied to a word from a pair in one of the five classes. There is no reason to expect that these pairs should differ in number of errors across classes unless the words in the different classes differed in recognition difficulty in some way. Table 3 did suggest, however, that small differences were present among the C Pairs representing the different classes. Statistically, the M + FA values for the C Pairs for the five classes were reliable, F (4, 332) = 4.00, $p < .01$. The greatest number of errors occurred for the C Pairs derived from words making up parallel associates and synonyms, and the fewest from the conceptual associates.

Discussion

Four classes of natural associates have given no consistent evidence that the associative relationship facilitated recognition performance. Overall, control pairs, where the associative relationship would be minimal after a single study trial, produced no more errors than did the associated pairs. Even if it is presumed that the *Ss* rehearsed the C Pairs more than the E Pairs on the study trial, it does not seem possible that the associative strength of the C Pairs would even approach that of the E Pairs. It therefore becomes apparent that no simple conclusion about the role of associations in recognition is possible. This is not to say that an interpretation of the findings of Experiment VI as seen in Figure 6

is not possible. A tentative interpretation will be given later. Before doing this, however, it will be useful to look at the results of some additional experiments.

Experiment VII

In this experiment *S*s were again presented pairs of items from the five classes or types of pairs used in Experiment VI. On the test, only one word from each pair was tested, along with single words (control or new words) which had not been presented. The purpose of this procedure was not to test the effects of removal of associative context. Rather, the interest was centered in the relative recognition performance under these "impoverished" conditions for the five different classes. The interest was in particular directed toward the homonyms. It had seemed clear from Figure 6 that a lenient criterion was involved in the judgments on the homonym pairs. This alone could result in few misses on the E Pairs. But still another factor would also keep the number of misses to a minimum. As discussed earlier, a homonym pair should double the frequency of the acoustic–articulatory response as compared with that for any single word in the pairs of the other classes. Insofar as frequency information enters into the recognition decisions for pairs, the misses should be less for the homonym pairs than for the other types. Now, when a single word from a homonym pair (as presented for study) is presented for a *yes–no* test, the acoustic–articulatory frequency should be the major basis for the decision. In fact, it should be of little consequence whether the pair or the single word is presented if frequency is the dominant attribute. Number of misses should be small in both cases. Consider next the case of a single new word being tested, a new word which is a nominal member of a homonym pair but a pair which was not presented for study. There seems to be no reason to expect that the *S* would perceive this word as having a homonym. Therefore, there should be no criterion problem that is specific to homonyms. Or, in terms of formal predictions for the experiment, new items (from nominal homonym pairs) should not produce more false alarms than single new words representing the other classes. And, as discussed above, misses should be fewer on the old words from homonym pairs than on the old words from the other pairs.

Method

Study lists and test booklets. The *S* was presented 50 pairs for study, 10 pairs from each of the five classes. There were also two filler pairs at the beginning and end. On the test, one word from each of the 50 pairs was printed in a booklet along with 50 new words, representing one word from each of the 50 pairs remaining in the five classes. For the 50 pairs presented for study, half the time (within each class) the first word in the pair was tested and half the time the second word in the pair was tested. By using two study lists, and a single test form, each word served once as an old word and once as a new word. The study list was block randomized so that each type of pair occurred once in each block of five trials. On the test form (two pages) the 10 item types (five old and five new from each class) were block randomized and were random with respect to input order.

Procedure and Subjects. Prior to presenting the list of pairs for study, the *S*s were informed that the study list consisted of a series of pairs, and further, that on the test there would be single words, some from the pairs presented and some from pairs not presented. They would be required to make a *yes–no* decision on each word. The list was presented by a slide projector at a 5-sec. rate. Immediately following the presentation of the last slide, the booklets were distributed, and the instructions for the test repeated. As was true in all of the previous studies, the test was unpaced and the *S* was required to complete all items on the first page before going to the second. Thirty-four *S*s completed each form for a total of 68.

Results

Figure 7 shows the basic results, plotted in the same manner as Figure 6. Two facts are to be noted. First, errors on the antonyms (both misses and false alarms) were considerably higher than for the other types. Second, the fewest misses were made on the homonym pairs. The statistical analysis shows that class or type of item, based on M + FA is reliable, F (4, 268) = 18.72, $p < .01$. More errors were made on old words ($f = 1$) than on new words ($f = 0$), F (1, 67) = 6.18, $p < .05$, and the interaction between frequency and type was also reliable, F (4, 268) = 6.52,

$p < .01$. Sources of these effects are quite apparent in Figure 7.

The number of misses on the homonyms was slightly under 14%. The class of items having the next fewest misses was conceptual associates 19%. A direct-difference test showed this difference to be reliable, $t(67) = 2.84$, $p < .01$. This may be interpreted to mean that input frequency was greater on the homonym pairs than in the other types. The fact that there were only slightly more false alarms (yes to new items) for the homonyms than for the corresponding items in three of the other classes is interpreted to mean that a criterion difference for the classes was of little consequence in this study.

Recognition of antonyms was clearly inferior to the recognition of the words in the other classes. There was a suggestion of this possibility in the previous experiment for the E Pairs (see Figure 6). A part of the difference seen in Figure 7 can be attributed to heavy testing effects for the antonyms. This is to say, performance decreased in accuracy from page 1 of the test booklet through page 2. This was quantified for each class of items by using M + FA, with 10 items on each page. The errors increased for the parallel associates (15.3% to 19.3%), for the synonyms (16.9% to 22.2%), and for the antonyms (20.7% to 31.5%). All three of these changes were reliable beyond the .05 confidence level. The homonyms showed an unreliable increase (14.9% to 16.5%) and the conceptual associates showed a slight decrease (17.6% to 16.2%). The reasons for these differential testing effects in this experiment are not clear. It should be noted, however, that as pointed out earlier, there were no systematic changes in test performance over pages for Experiment VI where pairs were tested.

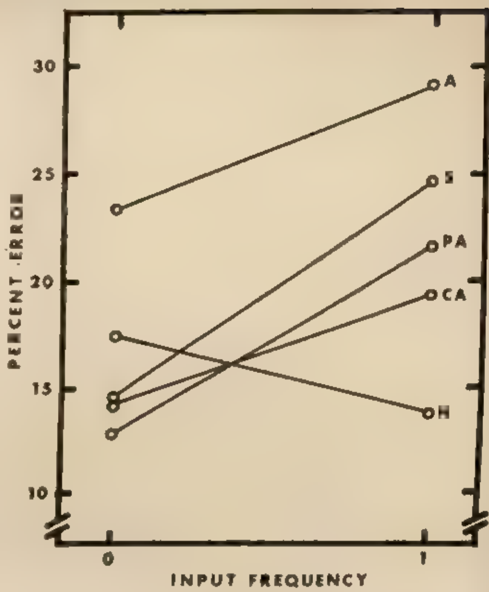

FIGURE 7. Recognition errors on single words following pair presentation for antonyms (A), synonyms (S), parallel associates (PA), conceptual associates (CA), and homonyms (H).

EXPERIMENT VIII

This experiment will be briefly reported. It had as its major purpose the examination of the possibility that some peculiarity of the words used in the homonym pairs led to the small number of misses in Experiments VI and VII. It is, perhaps, becoming apparent that some theoretical importance is to be attached to the findings reported thus far for the homonyms. The test made in the present experiment was simply to present single words from the pairs in each class for study and then test these single words for recognition along with new words from the classes. The critical question is whether or not the outcome will be the same for single words from the homonym pairs as for the single words from the other classes, particularly the classes other than antonyms. The antonyms appear to represent a special problem.

Method

The same test forms were used as in Experiment VII. The study list consisted of 50 single words (plus two filler words at the beginning and end of the series), 10 in each class, representing 10 of the pairs. These were in fact the same words as tested in Experiment VII. By using two different presentation lists, each of 20 words in each class served both as new words and as old words.

The *S*s were fully instructed concerning the study list and the method of testing. There were 24 completed records for each of the two forms for a total

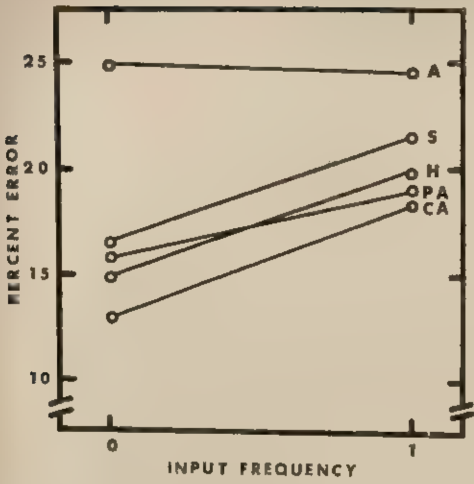

FIGURE 8. Recognition errors on single words following presentation of single words from five classes of pairs.

of 48. All procedures were exactly the same as in the previous studies.

Results

The essential results are shown in Figure 8, which is plotted in the same manner as the other recent graphs. It is to be noted that the results for the single words from the homonym pairs fall well within the limits set by the parallel associates, conceptual associates, and synonyms. This is to conclude, therefore, that there seems to be nothing peculiar about the words in the homonym pairs when recognition performance is observed for them as single words.

Figure 8 shows that the single words from antonym pairs produced many false alarms, as well as more misses than did the words from the other classes. Performance on the antonyms was largely responsible for the reliable class effect, F (4, 188) = 8.46, $p < .01$. There is a suggestion that a criterion difference might exist for the antonyms versus the other classes, but the interaction between old–new and type was less than one. It should be clear that the new items in the test were not, for any of the classes, the associated word as shown in Table 2. The false alarms cannot, therefore, be attributed to implicit associative responses elicited during the study trial which were represented in the new words on the test. If the false alarms are to be attributed to such implicit responses they arise from sources which cannot be easily identified. That some of the false alarms could be attributed to this mechanism is not to be denied, but it is not apparent why these should fall more heavily on the antonyms than on the other classes. The antonym problem will not be pursued further in this paper.

General Discussion

This research was initiated to determine the role which an association between a pair of words played in recognition. Given the knowledge of this role (if such existed) it would be possible to assess the degree to which frequency theory fails to accomodate it. The major purpose of this discussion is to make this assessment. The basic evidence from the experiments will be summarized initially.

1. Experiments I and II showed that parallel procedures in which recognition decisions were required in one case and frequency judgments in the other produced the same outcomes quantitatively. This was true for both absolute and relative judgments. Errors tended to fall on the same pairs for both types of judgments, and recognition errors were predictable from frequency judgments by combining the means and variance of the frequency judgments.

2. The paired-associate study showed that pairs on which few recognition errors were made were more easily associated than were pairs on which many errors were made. This would seem to implicate associability as a factor in recognition performance over and above frequency. Experiments III and IV supported this conclusion in showing that a pair of words, both shown on the study list but in different pairs, were less likely to be recognized than were intact pairs.

3. Experiment VI, however, in which pairs of culturally associated words were used, provided no consistent evidence that recognition performance was better for associated pairs than for nonassociated pairs. If one assumes that the association in culturally associated words is not qualitatively different from the associations established in the laboratory between initially neutral words, the findings with the culturally associated words are in direct conflict with those summarized in point 2 above.

4. Quite unexpectedly, criterion differences were found between frequency judgments and recognition decisions, the criterion being more lenient for the former. Recognition performance on homonym pairs also reflected a much more lenient criterion than was found for control pairs and culturally associated pairs.

The results of Experiments I and II make it difficult to turn abruptly away from frequency as the basic discriminative attribute for pair recognition. Therefore, the attempt has been made to develop a coherent account of the basic findings, using an expanded theory of frequency discrimination. This expansion is post hoc, and consequently must be viewed with skepticism, although the formulation as a whole does rest on frequency theory as developed in recent years. Before describing the account, it seems necessary to show how associative information or associative strength between words in a pair cannot be taken seriously as a direct explanatory mechanism for pair recognition.

Experiment VI showed that associated pairs and nonassociated pairs produced equivalent recognition performance. It would be quite possible to obtain such a result even if the recognition performance in the two cases was mediated by quite different types of information in memory. To be more specific, for the associated pairs the decisions may have been based exclusively on the associative relationship while the decisions for the nonassociated pairs may have been based on frequency information. Two considerations argue against the idea that the associative information is critical in the recognition of the culturally associated pairs of words. First, the new pairs for the associated pairs were also highly associated pairs. Therefore, some information other than associative information would be required to distinguish between the old and new pairs. Otherwise, the *S*s should have accepted any associated pair as having been included in the study list. Still, it might be argued (and this leads to the second point) that the single presentation of the associated pairs so increased the momentary situational strength of the association for the associated pairs that they were distinguishable on this basis from the control pairs even though the latter were strongly associated by cultural usage. This does not seem to be a likely possibility. In Experiment II, 12 pairs made up of unrelated words were presented twice during the study trial, and 12 pairs were presented three times. On the *yes–no* recognition test there were 5.3% misses for the former pairs, 3.5% for the latter. Although comparing error rates from experiment to experiment is risky because of many possible differences in subject samples, number of words presented and tested, and so on, these values must be considered appreciably less than the misses for the culturally associated pairs presented once. It does not seem appropriate to conclude that a neutral pair of words, presented twice, has a stronger associative link between them than does a pair of culturally associated words, such as *table–chair*, presented once. Based on associative strength alone, there is no reason to believe that the *S*s should have made any errors on the culturally associated pairs of words. Associative strength, at least as the term is understood as a consequence of multiple trials in the laboratory, does not seem to be directly involved at all in the recognition decisions. This conclusion was important in directing the explanatory efforts back toward frequency as the fundamental discriminative attribute for pair recognition.

In a recent study (Underwood & Zimmerman, in press), the evidence pointed toward the fact that each syllable of a two-syllable word gained a small amount of subjective frequency which was independent of the frequency information for the word per se. This is to say that the subunits of larger units may have frequency representation in memory. This abstractive nature of the assimilation of event frequency has long been known to be a characteristic of memory in the developmental history of the individual (Underwood, 1971). It now seems evident that this same feature obtains to some degree in the laboratory. The implication of this fact for frequency theory as applied to recognition of pairs is that the frequency information in memory will consist of information about each word, and also about the two words as a unit.

Given that frequency assimilation for a pair may involve three event frequencies, it is reasonable to ask what the optimal frequency should be for each event if recognition errors are to be minimized following a single presentation of a pair. Obviously, this arrangement would be one in which each unit has a subjective frequency of one, and the pair as a unit has a subjective frequency of one. All three sources of information would lead the *S* to respond with *yes*. A reduction in the subjective frequency for any one of the three events should reduce the likelihood of a correct

decision. Assumptions will now be made to reflect changes in the subjective frequency of each of the three events, hence changes in the likelihood of a correct decision.

It will be assumed that the stronger the association between two words *prior* to the study trial, the greater the likelihood that the subjective frequency of the pair as a unit will approach one, and the less the likelihood that the subject frequency of each word will approach one. The converse may be stated. If there is no associative relationship existing between two words prior to the study trial, the greater is the likelihood that the subjective frequency for the individual words will approach one, and the less the likelihood that the subjective frequency of the pair as a unit will approach one. In the extreme case, if no associative link is developed between the words in a pair during the study trial, the subjective frequency of the pair as a unit would be zero. The application of these notions to the data may now be examined.

1. In Experiment III, re-pairing old words on the test resulted in an increase in the errors. This would be accounted for on the grounds that a re-paired item has no subjective frequency for the pair as a pair. The decision must be made on the basis of the subjective frequency for the individual words. In Experiment IV, errors on the recognition of a single word from a pair presented for study increased (as compared with the presence of the intact pair), and the amount of increase was independent of the newness or oldness of the context word. The lack of pair-frequency information is believed responsible. In a further experiment, not reported in this series, individual words were presented for study. On the test, pairs of individual words were presented just as in Experiment IV and with *S* always making a recognition decision on the second word. Just as found by Thomson (1972), the characteristics (old or new) of the first word in the pair had no effect on the recognition of the second. Since there was no pair-frequency information induced during study, no loss of accuracy should have been found by prefixing either old or new words to the test word.

2. Pairs on which few recognition errors were made were more easily associated (in a paired-associate test) than were pairs on which many errors were made. The easy pairs were also judged to have higher frequency than were the difficult pairs. The easy pairs represent pairs which approximate as cl[illegible] as it is probably possible the maxin[illegible] frequency case. The pair was not asso[illegible]d prior to the study trial. But, for whate[illegible] reason, an association could be establishe[illegible]dily. In this process, each word will r[illegible]e a near maximum frequency (one), an[illegible] addition, the pair will approach this max[illegible]n because of the rapid formation of the as[illegible]ion.

3. Why were not cultural[illegible]ssociated words better recognized than [illegible]ssociated words? It is now presumed th[illegible]is result is a coincidence of the distributi[illegible] subjective frequency information. For [illegible]ssociated pairs, the decisions are primarily [illegible]d on pair frequency, for the nonassocia[illegible]pairs, on element or single-word frequency [illegible]It would be suspected that the small di[illegible]ences in errors among the four classes [illegible]sociates resulted from differences in the m[illegible]nitude of the subjective frequency for the s[illegible]le words.

It should be repeated that the f[illegible]lation is post hoc. However, it does have [illegible]umber of testable implications. Although [illegible]ese will not be examined here, it can be se[illegible] that the basic idea would be to evolve [illegible]cedures which would change the subjective [illegible]equency of one or more of the sources assum[illegible]d by the theory to be involved in the [illegible]ognition decisions.

The theory does not seem capable of handling cleanly the false-alarm data for N–O and O–N pairs in Experiments III and IV. All that can be said is that since subjective frequency should be present for one of the three events held important by the theory, the *S* is led to a *yes* response. This is not considered a satisfactory account for such false alarms.

Finally, the result for the homonym pairs provided a special case for frequency theory, a case that touches on several issues. Frequency theory makes no assumption concerning the awareness of the *S* that he is using frequency information in recognition decisions. In response to questioning, *S*s will sometimes respond that the correct item looked familiar, but more frequently given is the response: "It looked right." It will be remembered that the only distinctive difference found between recognition decisions and frequency judgments in Experiments I and II was that the *S*s set a more lenient criterion in making frequency judgments than in making recognition decisions. Now, when the *S* is presented homonym pairs he may, with some level of intention, make his decisions on the basis of the frequency

of the acoustic–articulatory responses he produced to a pair during the study trial. If this is the case, then whatever leads the S to set a lenient criterion for frequency judgments may likewise lead him to do the same in recognition of pairs of homonyms. That frequency of the acoustic–articulatory response is implicated seems clear by the results of Experiment VII. This study showed that relatively few misses were made on a single word from a homonym pair, a result that was not due to a lenient criterion. The S, in effect, had a subjective frequency of two for the single acoustic–articulatory response; for the other classes of items, the frequency would be appreciably less.

This series of experiments was initiated with the expectation that associative information in memory would cause a serious breakdown in the usefulness of frequency information as an explanatory mechanism. The evidence as viewed has led to the conclusion that it would be premature to abandon frequency theory in attempts to account for recognition performance for associatively related verbal units.

Journal of Experimental Psychology

CONTENTS

ARTICLES

(Continued on inside back cover)

American Psychological Association

Vol. 102, No. 6 June 1974

Beginning in 1975 the *Journal of Experimental Psychology* will appear as four [illegible] edited and distributed sections.

The Journal of Experimental Psychology: Human Learning and Memory (Lyle E. Bourne, Jr., Editor) will publish experimental studies on fundamental acquisition, retention, and transfer [illegible] in human behavior.

The Journal of Experimental Psychology: Human Perception and Performance (Michael I. Posner, Editor) will publish experimental studies designed to foster understanding of [illegible] operations and their relation to experience and performance.

The Journal of Experimental Psychology: Animal Behavior Processes (Allan R. Wagner, Editor) will publish experimental studies concerning the basic [illegible] perception, learning, [illegible], and performance, especially as revealed in the behavior of [illegible] animals. The studies should make significant contributions to general behavior theory.

The Journal of Experimental Psychology: General (Gregory A. Kimble, Editor) will publish experimental articles in any of the [illegible] represented by the above [illegible] when the articles involve a longer, more integrative report leading to an advance in knowledge that is [illegible] of [illegible] community of experimental psychologists. The section will include but not be limited to articles such as those that have appeared as *Journal of Experimental Psychology* monographs and as chapters [illegible] books of "advances." Republication of a limited number of data may be permitted if necessary to [illegible] the article complete and definitive.

In some instances it may be difficult for the author to decide whether one of the above [illegible] sections or the *Journal of Comparative and Physiological Psychology* is most appropriate for a given [illegible]. The author should weigh the essential implications of the research rather than the specific [illegible] subject population employed. Is the central message concerned with the issues and concepts of [illegible] theory (*JExP*) or with the biological substrates of behavior (*Journal of Comparative and Physiological Psychology*)? Is the study primarily addressed to theory of human behavior (*JExP: Human Learning and Memory* or *JExP: Human Perception and Performance*) or to theories equally or more relevant to infrahuman subjects (*JExP: Animal Behavior Processes*)? Is the major emphasis on the acquisition, retention, or transfer of new information, concepts, or problem-solving strategy (*JExP: Human Learning and Memory*) or on the organization or control of structures or mental operations, where the acquisition of new skills is only incidental (*JExP: Human Perception and Performance*)?

Manuscripts should be sent directly to the Editor of the relevant section at the address listed below. In cases where an Editor believes a manuscript is clearly more appropriate for an alternative journal of the American Psychological Association, he may redirect the manuscript with the approval of the author. A final action taken by one of the Editors will be final for all sections of *JExP*.

Manuscripts should be submitted in triplicate and according to the instructions contained in the *Publication Manual* of the American Psychological Association.

Authors should note that limitations on total pages make it necessary to restrict publication to those papers that in the opinion of the Editors make a notable contribution to the literature. Preference can be expected for sets of interrelated experiments that are definitive or provocative.

Addresses for the 1975 Editors-Elect are as follows. *JExP: Human Learning and Memory*, Lyle E. Bourne, Jr., Department of Psychology, University of Colorado, Boulder, Colorado 80302; *JExP: Human Perception and Performance*, Michael I. Posner, before June 1, 1974, same as Allan R. Wagner, after June 1, Department of Psychology, University of Oregon, Eugene, Oregon 97403; *JExP: Animal Behavior Processes*, Allan R. Wagner, Department of Psychology, Yale University, 333 Cedar Street, New Haven, Connecticut 06510; *JExP: General*, Gregory A. Kimble, Department of Psychology, University of Colorado, Boulder, Colorado 80302.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive galley proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P. O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

SIMULTANEOUS DISCRIMINATIONS: TWO SEPARATE TYPES OF CONTROL [1]

MICHAEL D. ZEILER [2]

Emory University

Children and retarded adults were given four different learning conditions and a series of transfer tests to determine which stimulus aspect controlled performance in a simultaneous discrimination. An adequate description of the discrimination performance entailed the recognition that different individuals displayed equal accuracy but were not controlled by the same stimulus aspect. Eight of the *S*s responded on the basis of stimulus relationships, but the other 14 *S*s were not sensitive to those aspects of the stimuli. One *S* was controlled by irrelevant stimulus properties; the others demonstrated that choices depended on the size differences among the stimuli of each three-member set and the differences between the learning and the transfer sets. A model proposed to explain these performances could describe the probability of responding in each individual. Thus, individuals showed two types of control, one characterized by sensitivity to stimulus relations and the other described by the model.

Two problems confronted by theoretical accounts of discrimination learning are specifying the controlling aspect of stimuli and describing the way the discriminations are learned. Stimuli can differ along a number of dimensions, e.g., two visual stimuli can have different colors, forms, sizes, spatial locations, etc. An individual whose responding varied depending on which of the two stimuli was presented might be under the control of any or all of these aspects, but which one was relevant could not be determined from the sheer occurrence of differential responding. The achievement of differential responding also does not indicate the way the problem was learned (e.g., incrementally, all-or-none learning, etc.). In fact, it has been demonstrated that similar criterion performances can be attained in a variety of ways in the same task (Gholson, Levine, & Phillips, 1972), thereby indicating that no single-process model can provide a comprehensive account. The same conclusion can be reached about models attempting to explain which aspect of the stimuli controls performance in even a simple situation involving stimuli differing on only a single dimension.

One reason that research on controlling stimulus aspects has been insensitive to the possibility of multiple sources of control has been that data were averaged over groups of *S*s (cf. Reese, 1968). Theories were devised to explain these averaged

[1] This research was supported by Research Grant HD-05752 from the U.S. Public Health Service. The author would like to thank Howard Rollins for his many helpful comments and criticisms.

data on the implicit assumption that the means estimated the performance of individual *Ss* (e.g., Zeiler, 1963). However, the detailed evaluation of individuals revealed that the means were not an adequate approximation and consequently the theories were not explaining individual performance corrected for sources of uncontrolled error by averaging across *Ss*. For example, some *Ss* were always controlled by the relational characteristics of two simultaneously presented stimuli, whereas others were sensitive to absolute stimulus sizes rather than to relationships (Kuenne, 1946; Porter, 1969). With situations involving three stimuli with the middle-size member of an original training condition as the correct set member, some *Ss* were always controlled by the middle-size relation, but others responded to the middle-size stimulus in transfer tests only if the new stimuli were very similar to the originals (Zeiler & Friedrichs, 1969; Zeiler & Salten, 1967). In fact, the same individuals have even revealed both types of control simultaneously (Zeiler, 1964).

The existence of two controlling stimulus aspects means that the averaging of the performances of different individuals must yield misleading data. A more profitable approach might be to recognize the heterogeneity and attempt to formulate a theoretical description of each type. Subsequent steps would be to try to understand what variables are responsible for determining which aspect will predominate, as well as to analyze how both are combined in the behavior of adult humans. The present experiment was intended to provide the first step, i.e., the description of the two types of control emerging with three stimuli varying in size.

One type of control seems straightforward. Some *Ss* are controlled by the relationships of one stimulus to another. However, the second form of control cannot be analyzed so simply. In this case, individuals sometimes choose the stimulus having a certain relationship, but at other times do not. This sort of profile is predicted by the ratio theory (Zeiler, 1963). According to the ratio theory model, each stimulus is defined by the ratio of [illegible] the prevailing stimulus contex[illegible]daptation level). The training adaptation level is determined by the training stimuli alone (the geometric mean of their areas), and the test adaptation level is the weighted sum of the geometric mean of the test stimuli and the geometric mean of the training stimuli. In the t[illegible] will prefer the set member having the [illegible] closest to that of the positive stimulus (S+) in training.

With three stimuli differing in size by equal units and the middle-sized stimulus as S+ during the training phase, which test stimulus will be preferred depends on the similarity of the stimuli within each set and the similarity of the training stimuli to the test stimuli. As the difference *between* the training and the testing conditions increases from zero, the test adaptation level changes in such a way that the model predicts that the preferred stimulus should shift from the middle-sized test set member to a different stimulus. The stimulus differences *within* the test sets are also critical. If a particular stimulus is the middle-sized member of a test set and is preferred, increases in the differences between it and the accompanying larger and smaller set members will not affect the preferences. However, if either the large or the small stimulus is preferred, increasing within-set differences will eventuate in a shift to preference of the middle-sized member. Thus, the model predicts that between- and within-set differences operate in conjunction to determine choices in the tests.

None of the research up to this point that has studied the performances of individual *Ss* can evaluate the accuracy of this prediction, because no experiment has manipulated within- and between-set stimulus differences within the same individuals. The purpose of the present experiment was to do this. Because normal adults have been shown to switch the basis of their choices as a function of between-set similarity (Zeiler, 1964), young normal children and retarded adults were used as *Ss* in order to assure the observation of independent patterns of transfer performance.

These Ss were expected to reveal one or the other of the two components that interact to determine the adult behavior.

Method

Subjects. The Ss were 16 5- and 6-yr. old children (8 boys and 8 girls) attending a summer day camp for normal children and 6 institutionalized retarded adult women ranging in age from 16–30 yr. There were no current intelligence test scores available for any of the Ss, but a variety of tests conducted on admission reported that the IQs for the retarded women ranged 40–68.

Apparatus. The stimuli were two identical sets of 3-mm.-wide black lines, one set used for training and the other for the transfer tests. The lines are designated in order of length; the smallest (1) was 18-mm. long, and each successive line increased in length by a factor of 1.2:1. Each line was cut from glossy drafting tape and was mounted on a 5 × 25 cm. block of 6-mm.-thick white Masonite. A piece of 6-mm.-thick clear plastic (Plexiglas) was cut to the same size as the Masonite block and glued over it. The lower edge of each line was 1 cm. from the bottom of the block.

Stimuli were displayed on a turntable that could be rotated to interpose a screen between S and the blocks. The three blocks used on each trial were arranged so that the lines were vertical with respect to S and bottoms of the lines were aligned. The long edges of the blocks touched, and the bottoms faced S.

The stimuli comprising the training and test sets are shown in Table 1. The combinations of sets differed from each other in the similarity of set members to each other (within-set difference), and the four test sets varied in their similarity to the training set (between-set difference). The same stimulus (Line 5, length = 36 mm.) was the middle-sized and positive member of the four different training sets.

Procedure. A noncorrection procedure was used throughout. On each trial three blocks were exposed until S made a choice. Then the screen was interposed between S and the blocks, and E made any necessary changes in position and/or blocks. Stimulus positions varied according to a predetermined irregular sequence.

In Phase 1 the child found a plastic chip under the middle-sized stimulus of the training set. The three blocks were in view when S came into the experimental room. Instructions were as follows.

> See this chip? See these blocks? I am going to hide this chip under a block. You find it. Try to find as many as you can. Choose only one block on each turn.

Phase 1 ended when S made five successive choices of the middle-sized block.

In Phase 2, the chips were discontinued for the normal children (they were continued for the retarded Ss), but a penny was given following every fifth correct response. The S was told that a penny would be hidden instead of the chip and could be earned by choosing the correct block a few times in a row. The S was also told:

> Only one block is right. The same block is always right. I always hide the penny under the same block.

Phase 2 concluded with 20 successive correct choices of the middle-sized stimulus.

Phase 3 was the testing phase. Each of the four test sets associated with each training set was presented for four trials. The order of test set presentation was random with the limitation that each set appear in each block of four test trials. A test trial appeared after six or seven successive correct responses with the training set. Pennies continued to be given for every fifth correct response with the training set, but choices had no consequences on test trials.

After the three phases were completed with the first training set and its associated test sets, a different training set was introduced and the procedure was repeated. This sequence of conditions was continued until each S had been given the four different training sets and the four appropriate test sets. Thus, after the first four conditions, S had been trained with the four training sets and had been given four trials with each of the test sets. There were then four more conditions which repeated the first four, thereby yielding a total of eight trials with each test set. The order of conditions was randomized with the limitation that each of the four training sets be used once before any was used twice—each S had a different order. Within each condition, the order of the test sets was also randomized with the same limitation.

In the first condition Phases 1 and 2 were conducted in a single session, and all of Phase 3 was conducted in a single session. For the retarded Ss Phases 1 and 2 sometimes required as many as 3 sessions to attain criterion performance in each. In the seven subsequent conditions, Phase 1 was omitted, and Phases 2 and 3 were conducted in a single session. The experiment, therefore, involved 9 sessions for the normal children and between 9 and 11 sessions for the retarded adults.

A display of toys and candy was located on shelves in the experimental room. Also, there was a box

TABLE 1

Stimulus Sets

Within-set difference	Training set	Training–test difference			
		1.2 :1	1.4 :1	1.7 :1	2.1 :1
1.2:1	4-5-6	5-6-7	6-7-8	7-8-9	8-9-10
1.4:1	3-5-7	4-6-8	5-7-9	6-8-10	7-9-11
1.7:1	2-5-8	3-6-9	4-7-10	5-8-11	6-9-12
2.1:1	1-5-9	2-6-10	2-7-11	4-8-12	5-9-13

containing trinkets located on the table holding the turntable. The trinkets were valued at 1 cent (normal *Ss*) or 1 chip (retarded *Ss*) each, whereas the toys and candy ranged from 5 to 20 cents or chips. On any given day, *S* could buy toys and/or candy if he or she had sufficient money or chips, buy trinkets, keep the pennies or chips, and/or save as many as desired to purchase more expensive toys.

Results and Discussion

Performance with training sets. The mean number of errors made in attaining criterion in Phase 1 with the first training condition was 15.6 for the normal children and 38.3 for the retarded adults. This difference was significant ($p < .01$, Mann–Whitney U test). No errors were made in Phase 2 or in the training trials of Phase 3. Errors in Phase 1 did not differ significantly ($p > .10$, Kruskal–Wallis test) depending on the particular training set either for all of the *Ss* combined or for the normal children aad retarded adults separately. The means and ranges of errors were as follows: Set 4-5-6, $M = 25.3$, range = 3–65; Set 3-5-7, $M = 17.0$, range = 2–36; Set 2-5-8, $M = 20.0$, range = 2–45; Set 1-5-9, $M = 26.3$, range = 6–50.

In training subsequent to the first condition, errors occurred only with Set 4-5-6, with a mean of 2.3 (range 0–12) for the normal children and a mean of 13.3 (range 3–27) for the retarded adults. This difference did not attain statistical significance ($p > .05$, Mann Whitney U test). No errors occurred with any other training set. As in the first condition, there were never any errors with the training trials of Phase 3. Interpolated test trials in which responses were not reinforced had no apparent effect on the accuracy of the training performance.

Performance with test sets. The *Ss* had 8 trials with each test set under each of the four training conditions. Eight normal children (five girls and three boys) chose the middle-sized test set member in all 32 test trials. Consequently, their behavior fits the hypothesis that they were controlled by the middle-size relation. None of the remaining *Ss* demonstrated equivalent performance.

One normal child [illegible] different choice on each exposure to [illegible] iven test set and was able to choose S+ [illegible] n when the lines were covered. Verbal [illegible] rt and selective covering of various pa[illegible] he training blocks revealed that she [illegible] ponding to a discoloration on the block [illegible] er than to the line. Since this disc[illegible] n was not present on any test stim[illegible] lock, the responses during the tests [illegible] istributed at random.

The remaining seven norm[illegible] ldren and all retarded adults were sen[illegible] o changes in the sizes of the lines. [illegible] e was no relation between the perfor[illegible] e in original learning and the type of [illegible] patterns revealed by the normal c[illegible] Those children who did not reveal [illegible] choice of the middle-sized test stimu[illegible] d not be differentiated from those w[illegible] on the basis of the number of errors [illegible] riginal learning phases; they range[illegible] om the fastest to the slowest learner[illegible]

Figure 1 indicates the fr[illegible] cy of choices of the middle-sized t[illegible] imulus for each of these 13 *Ss*. All of [illegible] ponses not occurring to the middle-siz[illegible] timulus were to the smallest stimulus [illegible] he test set, i.e., there were no choices of [illegible] largest test set member. In every case, the frequency of choices of the middle-sized test set member declined and the frequency of choices of the smallest stimulus increased as the differences between the training and the test sets increased. The gradients of choice of the middle-sized stimuli typically were higher with each progressive increase in within-set stimulus difference, although there were occasional reversals.

Although there was only one instance of 2 *Ss* revealing the same choice gradients in all of the conditions (C_{16} and C_{20}), there were several in which 2 or more *Ss* revealed the same gradient in a given condition of within-set difference. In fact, 8 *Ss* revealed the identical gradient with the within-set difference of 1.2:1. The heterogeneity among the 13 *Ss* was larger with increased within-set stimulus differences.

Quantitative analysis. The dependence of choices on the combined effects of within- and between-set stimulus differences

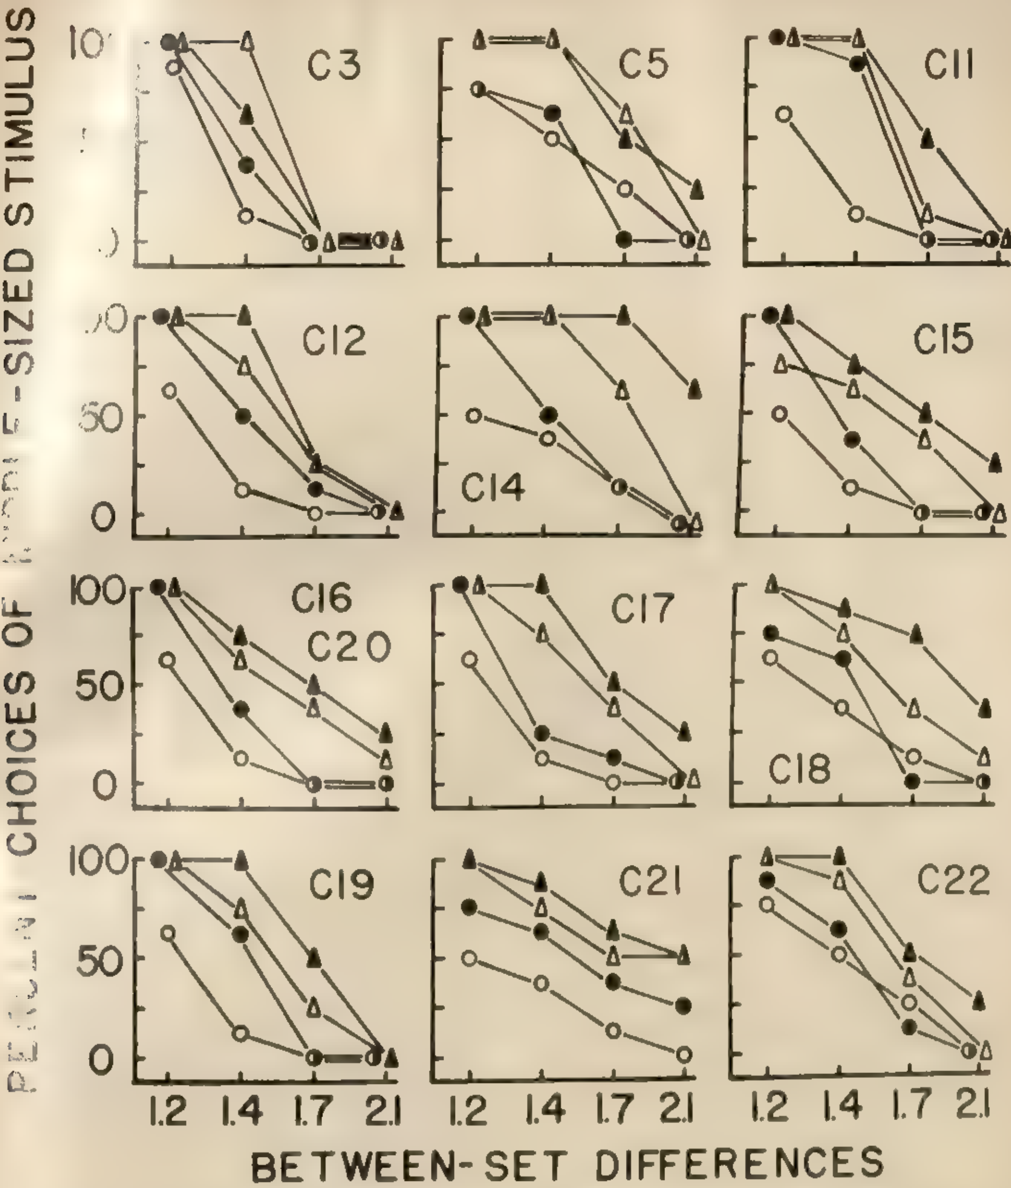

FIGURE 1. Percentage of choices of the middle-sized stimulus in each test set (The data are shown separately for each S. Open circles, within-set difference = 1.2:1, filled circles, within-set difference = 1.4:1; open triangles: within-set difference = 1.7:1; filled triangles: within-set difference = 2.1:1.)

was predicted by the ratio theory model (Zeiler, 1963). The two general predictions were confirmed: (*a*) at any one level of between-set difference, choices of the middle-sized stimulus increased and choices of the smallest set member decreased with increases in within-set difference; and (*b*) at any one level of within-set difference, choices of the middle-sized set member increased and choices of the smallest stimulus decreased with increases in between-set differences. It also appeared that a modified

form of the model could describe the probabilities of response in the 13 *Ss* sensitive to within- and between-set differences. The revised model consists of seven assumptions. Let Z_{oi} = area of training stimulus i ($i = 1, \ldots, m$); Z_{oc} = area of positive stimulus in training; Z_{ti} = area of test stimulus i ($i = 1, \ldots, n$); P_{ti} = probability of response to Z_{ti}; and y and b = constants. The seven assumptions are as follows:

Training adaptation level (A_o):

$$\log A_o = \frac{1}{m} \left(\sum_{i=1}^{m} \log Z_{oi}\right). \quad [1]$$

Test adaptation level (A_t):

$$\log A_t = y\left(\frac{1}{n}\left(\sum_{i=1}^{n} \log Z_{ti}\right)\right) + (1 - y) \log A_o. \quad [2]$$

Positive stimulus ratio (X_{oc}):

$$X_{oc} = \frac{Z_{oc}}{A_o}. \quad [3]$$

Test stimulus ratios (X_{ti}):

$$X_{ti} = \frac{Z_{ti}}{A_t}. \quad [4]$$

Probability of response:

$$D_{ti} = |X_{ti} - X_{oc}|, \quad [5]$$

$$V_{ti} = e^{-bd_{ti}}, \quad [6]$$

$$P_{ti} = \frac{V_{ti}}{\sum_{i=1}^{n} V_{ti}}. \quad [7]$$

Equations 6 and 7 were not contained in the original ratio theory: they represent two new assumptions and the addition of Luce's (1959) choice axiom to the model. The adoption of this axiom is not intended to imply that it is uniquely applicable to the present data (cf. Friedman, [illegible], & Padilla, 1968); it was chosen simply as a convenient technique for demonstrating the possibility of describing response probabilities within the context of the ratio theory.

For each *S* values of y and b were found that could describe the obtained probabilities of responding for the four test sets used under each level of within-set stimulus difference. Since $p = 0.0$ for the four largest stimuli of the test sets, these probabilities were excluded. The probabilities predicted by each pair of y and b values were compared with those obtained to determined which pair produced the smallest deviation. The search for the best was conducted by incrementing y in steps of .10 and b in steps of 2.0 until the average of the squared deviations for the four test sets was less than .01. The smallest values of the constants that produced deviations of this magnitude are shown in Table 2. (Note: once the b value that produced this small a deviation was found, y was set at the value that produced the least deviation.) Because there were 13 *Ss* × 16 Test Sets × 2 Stimuli in each, it is most awkward to try to present all of the expected probabilities. It is perhaps sufficient to indicate that no expected and obtained response frequency to a given stimulus deviated by as much as one response.

The constants varied among and within *Ss*. Since both tended to decrease as within-set differences increased, the constants seemed not to be arbitrary but rather to be a function of the particular stimuli

used. constants may also be a function dividual differences; however, their ricted range implies that such diff es may be less important than the stim us variables in determining the val s.

conclusion, these data indicate that the behavior of individuals in a three-mulus simultaneous discrimination can be classified into two general types. One involves control by stimulus relationships (although it may be worth noting that uni-rm choice of the middle-sized stimulus is predicted if y is 1.00); the other is described by the ratio theory model. Furthermore, it appears possible to provide a quantitative count of performance over a range of ining and testing conditions. Less clear this time is what variables are respon-ible for establishing one or the other type of control.

AN ANALYSIS OF INTERSENSORY TRANSFER O[illegible][1]

RONALD W. SHAFFER[2] AND HENRY C. ELLIS

University of New Mexico

The relative contributions of four sources of transfer in intersensory [illegible] between vision and touch were examined. Following a training task i[illegible] tifying visually presented polygons or histoforms, six groups learned t[illegible] a motor switching response to tactually presented polygons in a tr[illegible] task. Transfer performance showed reliable evidence for the transf[illegible] forward associations, minimal evidence for the transfer of stimulus [illegible] and no evidence for two types of nonspecific transfer.

Learning to make specific identifying responses to different stimuli in a training task is known to affect performance in a subsequent transfer task where the "same" stimuli are presented via different sensory modalities (e.g., Bjorkman, Garvill, & Molander, 1965; Gaydos, 1965; Holmgren, Armoult, & Manning, 1966; Sinha & Sinha, 1960). Such transfer has been termed intersensory transfer and several hypotheses have been advanced to account for its occurrence (e.g., Gibson, 1969, chap. 11; Wright, 1970). While intersensory transfer has been repeatedly demonstrated, very few studies have provided the kinds of operations that allow the partitioning of contributing sources of transfer. The present experiment provides controls not previously contained in intersensory transfer studies (e.g., Gaydos, 1956; Holmgren et al., 1966; Sinha & Sinha, 1960), thereby allowing isolation of sources of transfer specifically related to stimulus modality.

Two potential sources of specific transfer are of immediate interest in the intersensory transfer paradigm: the transfer of forward associations and of stimulus learning, i.e., learning how to discriminate among the stimuli. Transfer of forward associations with unfamiliar form stimuli can imply the operation of a stimulus encoding system superordinate to the separate sensory systems, since it would suggest that *S*s could "recognize" the same stimul[illegible]ed via a second sensory system. B[illegible] stimuli for which *S*s could have ha[illegible]revious opportunities to learn medi[illegible]ponses to their intersensory equiva[illegible]an be determined whether this kind [illegible]coding system need be advanced.

If, after learning to associat[illegible]tifying responses with stimuli, *S*s sh[illegible] performance decrement when tran[illegible] to a new modality, then the functio[illegible]ivalence of the intersensory stimu[illegible]d be evident. However, less than pe[illegible]ransfer performance requires controls [illegible]rtial out sources of transfer other tha[illegible]at of forward associations. The si[illegible]ntrol groups included in the present stud[illegible]ermit the separation of forward associations and the second source of specific transfer, stimulus learning, while additional controls allow the separation of two nonspecific sources of transfer.

The transfer of stimulus learning would suggest that the *changes* in the way stimuli are encoded are not specific to the particular sensory system under which they were learned. This finding would follow from the assumption that there are amodal sources of information (Gibson, 1969, chap. 11), and that learning to respond to these amodal stimulus attributes should modify how the same stimuli are encoded when presented to another sensory system.

In addition to converging on two specific sources of transfer, the present study provides the conditions for assessing nonspecific transfer in an intersensory transfer paradigm. It is common practice in studies of verbal transfer to use items for the nonspecific control that are independent of

[1] This research was supported by National Science Foundation Grants GB-7296 and GB-27413X to the second author.

specific list content, but are nevertheless sampled from the same class of stimuli as the other training conditions. For example, if adjectives are used as first-list items, then the baseline nonspecific control would also employ adjectives. While the dependency of the class of stimulus items on the amount of nonspecific transfer with verbal items has been demonstrated by Postman and Schwartz (1964), this variable has not been directly investigated with "nonverbal" form stimuli. It is not apparent, therefore, whether the degree of nonspecific transfer will remain invariant across different classes of nonverbal first-list stimuli. Moreover, the potential role of the *nature* of the form stimuli to be used for nonspecific controls becomes magnified when concern is focused on stimulus encoding changes relevant to the specific form stimuli used in the training–transfer task (i.e., stimulus learning), as opposed to *general* encoding changes particular to the class of form stimuli used but not to specific members within that class. Accordingly, several nonspecific controls are contrasted to the conditions given exactly the same forms in the visual training and tactual transfer task: Two groups receiving visual training forms from the same class (WC), and two groups receiving visual training forms from a completely different class (BC), which are of comparable ease with regard to associative learning.

Method

Stimuli and apparatus. Three sets of six forms were cut from 3.2-mm.-thick black rubber tile and mounted on white translucent plastic squares. Twelve of the stimuli were 12-point constrained metric polygons (CMPs) sampled from the population of shapes described by Thurmond and Alluisi (1967). The CMPs were constructed from a radiating matrix of 12 "lines" of points with a 30° angle between each successive radii of lines and with 12 points along each line. Sampling by constrained rules simply means that a particular point on any one line of points can appear once and only once in each form. The difference between successive points was arbitrarily set at 3.175 mm.

Another set of six stimuli (used for the BC nonspecific control) were six-column constrained metric histoforms (CMHs), also described by Thurmond and Alluisi (1967). The sides of the matrix from which the CMHs were generated were set at 7.62 cm. so that the CMH would approximate the overall size of the CMP. This particular subset of CMHs was chosen because pilot data had indicated that visual learning rates (training) would be comparable to learning rates with CMP stimuli.

The apparatus was constructed so that any particular form could be either viewed or tactually manipulated. The *S*s were seated in front of a 55.8 × 55.8 cm. plywood display panel painted flat black. Tactual manipulation was achieved by *S* reaching under a hood located at the bottom of the panel and tracing the perimeter of a particular form with his forefinger. The plastic square mounts were inserted individually by *E* into a holder located horizontally under the hood. The raised forms were used for visual presentation by inserting them behind a piece of 10.1 × 12.7 cm. one-way glass located directly above the hood. A rectangular tunnel was constructed directly behind the one-way glass. The pieces of plastic with the mounted forms were inserted into a tray slid through an opening in the tunnel by *E*. Hunter decade timers were used to control the duration of a 100-w. bulb located behind the slide opening. When the bulb was activated *S* was able to view the form through the one-way glass. Directly above the one-way glass was a window with a white paper insert which served as a rear-projection screen for the letter responses used in the training task.

The six letters (A, E, H, N, O, and R) used as the verbal response terms in the training task for three of the groups were projected on the rear of the paper via a Kodak Carousel 700 projector. Located directly above the verbal response "window" were six horizontally arranged spring-loaded toggle switches to which *S* responded in the training task for three groups and in the transfer task for all groups. Over each switch was a circular green confirmation light which, at the end of the anticipation interval, informed *S* as to the correct response. The *E*'s control panel contained switches to program the confirmation lights, a display panel to indicate which switch was chosen by *S*, and a master switch to initiate the presentation of each paired associate.

Experimental design. Ninety-eight undergraduate *S*s were assigned to each of seven treatment conditions. The *S*s were randomly assigned to conditions in blocks of 7, with 1 *S* from each condition per block.

All groups except one with no training received two paired-associate learning tasks. The stimuli in the training tasks were presented visually, while in the transfer task either the same or different stimuli, depending on the treatment condition, were presented via the tactual modality. This sequence was used exclusively, since there was no interest in the well-known asymmetry in visual–tactual vs. tactual–visual transfer (e.g., Gaydos, 1956). In addition, Lobb's (1970) finding of no transfer from touch to vision but reliable transfer from vision to touch in a discrimination–recognition task suggests that a visual-to-touch training–transfer sequence would optimize the transfer of stimulus learning. The treatment conditions were differentiated only by the conditions of training. The seven training

conditions are described below, after which the rationale is given for the inclusion of the various conditions.

Group 1: Six CMPs were paired with six motor switching responses in the first training task. The transfer task was essentially a continuation of training with the exception of the change in modality of the stimulus presentation. Thus, *S* first learned to associate a particular motor switching response to a particular visual CMP, and then learned to associate the analogue tactual form to the same motor response.

Group 2: Same as Group 1, except that the response terms in the training task consisted of six letters of the alphabet (A, E, H, N, O, and R). The six letters ranked within the top nine of the alphabet in absolute frequency of occurrence (Underwood & Schulz, 1960).

Group 3: Same as Group 1, except that a different set of six CMPs were used in training.

Group 4: Same as Group 3, except that the response terms in training were the same letters used for Group 2. This is the WC nonspecific control.

Group 5: Same as Group 1, except that the stimuli used in the training task were six CMHs, thus making the stimuli different from those in the transfer task.

Group 6: Same as Group 5, except that the response terms in training were the same letters used for Group 2. This is the BC nonspecific control.

Group 7: Same as Group 1, except that the training task was not administered.

The transfer of forward associations is given by contrasting the transfer performance of Groups 1 and 2 under the assumption that superior transfer for Group 1 is not due to the transfer of response learning or, alternatively, is not spuriously given by the depressed transfer performance of Group 2 due to the transfer of inappropriate response terms. Violation of either assumption would give an inappropriate estimate of the transfer of forward association. The first assumption is readily met by trivializing response learning in the training task by using single-letter response terms and making them available for continual inspection. The second assumption is not as easily met; however, this source of forward transfer can be minimized by using training- and transfer-task response terms from grossly different categories (Ellis, 1969, p. 408).

The transfer of stimulus learning is provided by a direct comparison between Groups 2 and 4. Both groups contain the operations for potential sources of WC nonspecific transfer; however, since Group 2 has the same nominal stimuli in both tasks, the conditions are provided for the transfer of stimulus learning. Accordingly, if Group 2 learns some *specific* stimulus encoding skills associated with the visual training stimuli and if these skills transfer to the tactual transfer task when the same nominal stimuli are presented, then Group 2 will evidence superior transfer performance relative to the nonspecific control (Group 4).

Reliably more transfer for G[illegible]ompared to Group 6 would indicate that n[illegible] transfer in an intersensory transfer paradi[illegible]pendent on the class of form stimuli that are employed. A comparison of Groups 6 and 7 would yield evidence as to whether any nonspecific effects are [illegible]lent.

The inclusion of Groups 3 an[illegible]plements of Groups 4 and 6, respectively, w[illegible]rovide evidence as to whether any reliable t[illegible] response learning was present, since t[illegible]er groups' response terms were used in both tasks; hence, equivalent transfer performance for both "pairs" would further substantiate the above assumption that sources of transfer due to response learning were effectively eliminated.

Visual training. A standard paired-associate anticipation learning situation was presented to all *S*s except the no-training control condition. The 6-sec. intrastimulus interval included [illegible] stimulus exposure and a 3-sec. [illegible] response exposure.

Each of the six forms was presented for 10 anticipation trials for all training conditions. Evidence obtained from pilot data indicated that asymptotic performance would be achieved with this number of trials. An 8-sec. interstimulus (ISI) and intertrial interval (ITI) were employed. The ISI and ITI were kept the same so as to minimize the possibility that *S* could exclude certain response alternatives (switches or letters) as having already occurred within any one trial block. The stimulus–response pairs were randomized within each trial with two restrictions: (*a*) no more than two consecutive switching responses in either ascending or descending series were allowed, e.g., Switches 1, 2, and 3 could not occur as response terms for the first three forms; and (*b*) the same stimulus–response pair could not occur as the last pair of one trial and the first pair of a following trial.

Standard paired-associate instructions were read to all *S*s receiving training. The six letters were printed on a card and given to *S*s using the letters as response terms. The instructions were that *S*s could refer to the card as often as needed, but that they were to rely on the card as little as possible.

Tactual transfer. All *S*s received the same instructions and the same tactual paired-associate learning task. For each stimulus–response presentation, *S*s were instructed, following a ready signal from *E*, to locate with their index finger a small notch centered on the front edge of the plastic mount. When this was done, *S*s then located the attached form by pushing the index finger forward. The forms retained the same orientation trial-to-trial within the holders. Moreover, for Groups 1 and 2, the placement of the forms for tactual manipulation was such that the top of the forms when presented visually coincided with the most distant aspects of the forms when presented tactually. The 14-sec. ISI, including a 7-sec. anticipation interval and a 7-sec. stimulus and response interval, was started when *S*s began tracing the perimeter of the forms with the index finger. All tracing was done in a

clockwi... ...ction, and *Ss* were instructed to pace themse... ...o that at least one complete tracing of the fo... ...ould be achieved before the correct response ... s displayed. Upon presentation of the corr... response, as indicated by a light located abov... the correct switch, *Ss* were instructed to continu... tracing the form until the "correct green light goes out." Again, as was the case with the visual tr...ing, the ISI and ITI were kept constant at ...roximately 8 sec.

The six forms were presented for 10 anticipation trials following 1 study trial. The same "randomiza... ...rocedure used in the visual training task was also used... The *Ss* were not informed as to ...hether the same or different forms would be pre... ...d in the transfer task. If *S* specifically asked ... information, he was told that a study trial ... be given first, and he could determine this ...imself.

Results

Training. An analysis of the number of correct responses for Groups 1 through 6 across five blocks of two trials each did not yield a reliable difference, F (5, 78) = .40, nor was the Groups × Trials effect reliable, F (20, 312) = .73. Both findings are commensurate with the assumption that the six experimental groups were equivalent with respect to their learning rates during acquisition, hence differences in transfer performance must reflect paradigmatic operations and not differences in degree of original learning.

Transfer. Table 1 presents the transfer results in the form of mean correct responses averaged across all 10 transfer trials for each of the seven groups.

The comparison of initial interest, although itself nonanalytical in character, was that of Groups 1 and 7. A difference in favor of Group 1 has typically been taken as evidence for the transfer of specific associative habits. It was necessary that this difference be shown to be reliable, since all of the separate component sources of transfer were embodied in Group 1. An application of Dunnett's test to this comparison revealed a reliable difference, t (91) = 3.15, $p < .01$.

Evidence for the transfer of forward associations is given by comparing the performance of Groups 1 and 2. An analysis of the transfer performance for these two groups yielded a significant difference, t (26) = 2.22, $p < .05$. That the superior transfer performance obtained by Group 1 is not in any way attributable to the transfer of response learning is indicated by identical performances of Groups 5 and 6, and nearly equal performances of Groups 3 and 4, $t(26) < 1$.

TABLE 1

Mean Correct Responses Averaged Across All 10 Transfer Trials for Each Paradigm

Group	Mean correct responses	*SD*
1	33.64	8.58
2	26.21	9.14
3	23.64	9.77
4	23.14	5.54
5	25.78	9.38
6	25.78	7.05
7	23.28	10.37

Note. See text for description of groups.

Although Group 2 did evidence more correct transfer responses than any other control group (3 through 7), as indicated in Table 1, the Dunnett test contrasting Group 2 with 7 did not yield a reliable difference, t (91) < 1. Accordingly, none of the other control groups (3 through 6) were reliably superior to the no-training control; and the combined Groups 3 and 4 when compared to the combined Groups 5 and 6 did not yield a significant difference, t (54) = 1.12. No reliable evidence was therefore obtained in the present study for the transfer of any nonspecific sources.

Discussion

The principal finding of the present study was the positive transfer of forward associations evidenced by Group 1, which received the same stimuli and responses in both the training and transfer task. This finding is taken as an unequivocal demonstration of the transfer of forward associations under conditions where the mode of stimulus input is changed.

Two contrasting interpretations of this finding are possible. First, it could be assumed that *Ss* had, in advance of the present study, established common mediating responses to the intersensory equivalents of the six stimuli, or fractions thereof, and that the transfer of newly learned associations was therefore made possible via these mediators. A four-stage stimulus

equivalence paradigm, A–B, C–B, A–D, C–D, would provide an account consistent with the observed transfer of forward associations. It should be noted that this interpretation makes no necessary assumptions about whether the A and C terms possess any common attributes. The A and C terms could become functionally equivalent due simply to the addition of common mediating responses.

An alternative interpretation (Gibson, 1966, p. 55) is that although the stimulus objects are presented to different sensory systems, *S*s can learn to encode on features of the input that are invariant with the sensory system to which they are presented. The degree of intersensory transfer would be directly related to *S*'s ability to respond to features of information that are common to the various input systems.

The procedure for generating form stimuli in the present study was chosen because the forms were not highly representative of stimuli with which *S*s would have had previous experience. Accordingly, the likelihood of the transfer of forward associations being attributable to previously learned mediators would be minimal. On the other hand, acceptance of the second explanation given above as a basis for the transfer of forward associations minimally requires that it be shown that *S*s can in fact encode stimulus attributes that are invariant to the mode of input. Group 2 provides the *conditions* for satisfying this assumption. Recall that the only source of positive transfer other than nonspecific sources for Group 2 was the transfer of stimulus learning. In short, if *S*s in the training task learned specific stimulus encoding skills for the training stimuli, and if these skills transferred to the situation where the same stimuli were presented via another sensory system, then it must perforce follow that *S*s were responding to some common stimulus attributes in both tasks. Although Group 2 showed more transfer than the nonspecific controls, this effect was not reliable. Therefore, the results of the present study, although suggesting support for a "higher level" encoding system insensitive to mode of sensory input, do not converge on either alternative explanation. Ellis (1973) has, however, shown the transfer of stimulus learning in an intramodal transfer paradigm with 24-point shapes as stimuli, and has proposed that the transfer of stimulus learning depends on complex stimuli containing multiple redundant cues. Perhaps support for the invariant-features hypothesis could be obtained by employing more complex stimuli in [illegible]tersensory transfer paradigm, thereby p[illegible]g the basis for possible stimulus learning [illegible]r.

The reasons for the failu[illegible]tain any transfer attributable to non[illegible]sources of facilitation, as evidenced by [illegible]t that the transfer performance of Grou[illegible]hrough 6 was comparable to Group 7, a[illegible]ot immediately apparent. This finding, [illegible]ver, is not unique, as Clark, Warm and, Se[illegible]sky (1972) also recently reported no evi[illegible]e for nonspecific transfer in an inters[illegible] transfer paradigm.

Several possiblities exist that [illegible], in part, explain the lack of nonspecific t[illegible]fer in the present study. First, the tra[illegible], criterion was fixed at 10 trials for all gro[illegible]since preliminary evidence from pilot inves[illegible]tions indicated that near asymptotic perfo[illegible]ce would be obtained. Schwenn and Po[illegible] (1967) have found a direct relationship [illegible]ween the level of training and the amount [illegible]nspecific transfer. The possibility exists[illegible]herefore, that nonspecific sources of transfe[illegible]ld have been operative in the present st[illegible] had the level of training been extended [illegible]nd the criterion of 10 trials. Second, re[illegible]vidence (Rogers, 1968) suggests that a pa[illegible] what is learned as a nonspecific component i[illegible] rhythm of observing stimuli and a latency [illegible] giving overt responses. Rogers found t[illegible] decrements were observed when the a[illegible]ipation intervals were shortened or lengthened. He argued that a reduction in performance correlated with a change in the intervals in the direction of making them longer might be due, in part, to a disruption of stable pacing behavior which in turn would affect specific techniques in learning to make associations. Therefore, the change in intervals from the training to the transfer task in the present study might have contributed to the failure to obtain any nonspecific transfer. The fact that Holmgren et al. (1966) found evidence for BC nonspecific transfer in an intersensory transfer paradigm with the use of consistent training-transfer anticipation intervals would support this interpretation.

Both of these interpretations of the lack of nonspecific transfer address themselves to training-transfer parameters, variables unrelated to changes in stimulus modality. Alternatively, it could be argued that part of the nonspecific skills that are learned is how to encode the information for particular modes on input, implying, therefore, no transfer of those skills when the stimulus modality is changed.

PARTIAL REWARD EITHER FOLLOWING OR PRECEDING CONSISTENT REWARD: A CASE OF REINFORCEMENT LEVEL[1]

E. J. CAPALDI[2]

Purdue University

Previous investigations in which partial reward either preceded consistent reward (P-C) or followed it (C-P) employed the same reward magnitude in connection with both schedules. Findings similar to those previously obtained were obtained here when the reward magnitude associated with the C schedule was larger than that associated with the P schedule. However, associating smaller reward with the C than with the P schedule reduced resistance to extinction under P-C conditions and increased resistance to extinction under C-P conditions. These and earlier separate-phase extinction findings were found to be compatible with the principle of reinforcement level, which also has implications for positive and negative contrast effects, as well as a variety of other phenomena such as the frustration suppression effect.

In separate-phase investigations, a particular level of some variable occurs for a block of trials, e.g., large reward, partial reward, etc., followed in a second block of trials by a different level of the variable, e.g., small reward, consistent reward, etc. Separate-phase investigations have been concerned primarily either with early postshift behaviors, i.e., positive and negative contrast effects, or with extinction behavior, or with both. Of these findings, only negative contrast is explained reasonably well by available hypotheses (see Capaldi, 1972). Most hypotheses do not attempt to explain positive contrast (see Weinstock, 1971), and a variety of separate-phase extinction findings either contradict or are not explained by available hypotheses (e.g., Robbins, Chait, & Weinstock, 1968; Spear, Hill, & O'Sullivan, 1965; Sutherland & Mackintosh, 1971). The purpose of the present investigation was to test a hypothesis, to be considered later, which is consistent with findings reported in available varieties of separate-phase investigations. The basic idea contained in this hypothesis is that any change in reward schedule affects reinforcement level, which determines stimulus control over behavior and thus performance.

In previous investigations partial reward has both preceded consistent reward (P-C) and followed it (C-P). C-P training consisting of 100 C and 60 P trials reduced resistance to extinction very substantially relative to 60 P trials (Sutherland, Mackintosh, & Wolf, 1965; see Sutherland & Mackintosh, 1971, for other similar findings). Under P-C conditions a slight decrease in resistance to extinction was associated with a substantial number of interpolated C trials (70 P and 70 C trials) but not with a moderate number (70 P and 25 C trials) in an investigation by Theios (1962; see also Sutherland et al., 1965). Sutherland and Mackintosh have reviewed this literature and have characterized its findings as follows: The first of the two schedules given has had a major or disproportionate effect on resistance to extinction. This means that if enough first-schedule training is provided, extinction will be rapid if the first schedule is C and slow if the first schedule is P. Sutherland and Mackintosh have suggested that this disproportionate first-schedule effect, especially for C-P, while consistent with their attention model, is not consistent with hypotheses more commonly applied

to re schedule effects such as the frust (Amsel, 1958) and sequential (Cap , 1966) hypotheses.

Th sequential hypothesis explains reward schedule and other effects by emphasizing the control over behavior exercised by both external cues, e.g., alley cues, and internal cues, e.g., those produced by nonreward, smaller reward, and so on. This sort of analysis might be successfully applied to P-C and C-P training, it was hypothesized, by assuming that changes in reward percentage involve the same sorts of principles as changes in reward magnitude. Within the sequential hypothesis, it has been assumed that the capacity of available stimuli to evoke the reaction is an increasing function of reward magnitude (e.g., Capaldi & Capaldi, 1970; Leonard, 1969).

In available P-C and C-P investigations, the same reward magnitude has been associated with the P and the C schedules. In the present investigation, the reward magnitude associated with the C schedule (either 1 or 12 .045-gm. pellets) was either less than or greater than that associated with the P schedule (always 6 pellets). The five groups employed were designated C1-P6, C12-P6, P6-C1, P6-C12, and P6.

Method

Subjects. The *S*s, about 120 days old at the start of the experiment, were 50 naive male rats purchased from the Holtzman Co., Madison, Wisconsin.

Apparatus. The apparatus was a straight alley, 208.3-cm. long, 10.2-cm. wide, and enclosed by 22.9-cm.-high sides, covered with hinged 1.3-cm. hardware cloth. It was constructed of wood and painted a medium gray. It had three basic sections: a 35.6-cm. start section, a 117.1-cm. run section, and a 40.6-cm. goal section. On all trials, *S* was placed at the rear of a 25.4-cm. start treadle suspended over a microswitch, starting a .01-sec. clock. This clock stopped and a second started when *S* broke a photobeam 10.2 cm. from the treadle's tip (start time). The interruption of a second beam 117.1 cm. from the first stopped the second clock (run time) and started a third clock. The third photobeam was 30.5 cm. from the second beam and 5.1 cm. from the front edge of a brass 5.1 × 10.2 × 3.8 cm. food cup. Interrupting it stopped the third clock (goal time). When *S* broke the third beam a brass guillotine door, 30.5 cm. from the alley's distal end, was lowered manually, thereby confining *S* to the goal area. Individual times for all three sections were recorded, as well as "total" time, which was the sum of the elapsed times on the clocks.

Procedure. The *S*s were individually caged, fed 12 gm. of Lab Blox each day, water always being available, and on Days 7–10 handled in groups of three for about 3 min. On Days 8–10 each *S* received six .045-gm. Noyes pellets in the home cage.

On Day 11, which began experimental training, *S*s were randomly divided into five groups of 10 *S*s each. In each of the three phases of experimental training there were five trials each day. Phases 1 and 2 lasted for nine days each and Phase 3 (extinction) for eight days. Reward consisted of .045-gm. pellets, nonreward in all phases of 20-sec. confinement in the unbaited goalbox. Group C1-P6 received one pellet consistent reward in Phase 1 and six pellets partial reward in Phase 2. The remaining groups were designated in identical fashion. Group C1-P6 along with Groups P6-C1, C12-P6, and P6-C12 comprised the factorial portion of the experimental design. Group P6 began training in Phase 2. Three schedules of partial reward were used in rotation over the nine days of each acquisition phase, RNRNR, RNNRR, and RNNNR, where R denotes six-pellet reward and N, nonreward.

The *S*s were brought into the room in squads of five in holding cages, a squad consisting of one *S* from each group. The *S*s were run in rotation, running order within a squad being varied randomly each day. In Phase 1 Group P6 *S*s were handled briefly during their order in the rotation. The intertrial interval was about 5–8 min. in each phase. Following the last daily trial, *S*s were returned to the home cage, where the 12-gm. daily ration was provided about 15 min. later.

Results

Time scores in each alley section were converted to speeds. The measure employed was the daily median speed for each *S* in each alley section.

The performance of each of the groups in each of the alley sections on the last two days of Phase 1 training (P1) and on each of the training days in Phase 2 is shown in Figure 1. An analysis on the last two days of Phase 1 training indicated that differences were significant in each of the alley sections, start; $F(4, 45) = 4.31$, $p < .01$; run, $F(4, 45) = 4.06$, $p < .01$; and goal, $F(4, 45) = 3.98$, $p < .01$. Newman–Keuls tests indicated that in start and run Group C1-P6 ran more slowly than each of the remaining groups ($p <$

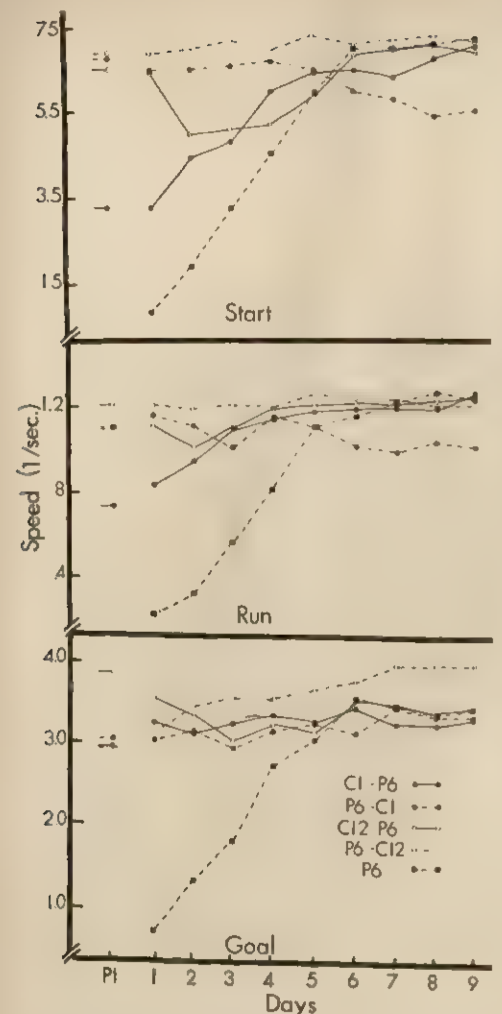

FIGURE 1. Median daily speeds for each of the groups in each of the alley sections of the last two days of Phase 1 training and on each of the training days in Phase 2.

.01), and in goal Group C12-P6 ran more rapidly than each of the remaining groups ($p < .01$), no other differences being significant. It is sometimes reported (e.g., Goodrich, 1958) that when partial and consistent groups receive the same reward magnitude, the partial group is faster than the consistent group in the start and run sections of the alley but slower than the consistent group in the goal section of the alley. Thus, it is unclear whether the superiority of Groups P6-C1 and P6-C12 relative to Group C1-P6 in start and run was a reward magnitude eff… reward percentage effect, or a combin… of both.

On the last two days of Ph… training differences were significant in …h of the alley sections; start, F (4… 3.09, $p < .05$; run, F (4, 45) = 2… $< .05$; and goal, F (4, 45) = 2.81, p … New-man–Keuls tests indicated … start and run Group P6-C1 ran … slowly than each of the remaining … ($p <$ .05), and in goal Group P6-… n more rapidly than the remaining … ($p <$ .05), no other differences bein… nificant. Thus, terminal Phase 2 differ…s as a function of reward condition w… much like terminal Phase 1 difference… func-tion of reward condition, e… that terminal differences were smaller… Phase 2 than in Phase 1.

Extinction. In view of the …rminal acquisition differences obtaine… ere, in some cases it is best to em… ize in extinction the interaction of … icular variables with extinction days. …he ex-tinction data were analyzed in … ways. Following a one-way analysis of …riance, a 2 × 2 factorial analysis was p…formed (Group P6 omitted) employing t… error term from the one-way analy…. The factorial analysis evaluates the effects of reward magnitude (C12 vs. C1) and order of presentation of P and C (P-C vs. C-P).

The performance of the five groups in each of the alley sections of each of the extinction days is shown in Figure 2. Figure 2 shows that Group P6-C1 tended to extinguish rapidly in early alley sections and that Groups C1-P6 and P6 tended to extinguish slowly in later alley sections. The one-way analysis indicated that the groups differed significantly in each of the alley sections; start, F (4, 45) = 6.71, $p < .001$; run, F (4, 45) = 9.48, $p < .001$; and goal, F (4, 45) = 6.81, $p < .001$, and that the Groups × Days interaction was significant in each of the alley sections; start, F (28, 315) = 1.75, $p < .01$; run, F (28, 315) = 2.08, $p < .01$; goal, F (28, 315) = 1.71, $p < .01$. Newman–Keuls tests indicated that Group P6-C1 ran slower than all other groups in start and in run (all ps $< .01$), that Group C1-P6

differ from all other groups in run (ps < .05 or better) and in goal ($p < .01$), and Group P6 differed from all other groups in goal ($ps < .01$), no other differences being significant. Except for Group P6-C1, these significant differences meaningful, for in no other case could they be due to inferior terminal acquisition performance.

In start, the effects of reward magnitude, F (1, 45) = 4.13, $p < .05$; of presentation order, F (1, 45) = 7.09, $p < .05$; and the Reward Magnitude × Presentation Order interaction, F (1, 45) = 10.91, $p < .01$, significant. In addition, each of these interacted significantly with days, Reward Magnitude × Days, F (7, 315) = 2.11, p < .05; Presentation Order × Days, F (7, 315) = 2.16, $p < .05$; and Reward Magnitude × Presentation Order × Days, F (7, 315) = 2.31, $p < .05$. The major basis of these significant effects in start was the rapid extinction over days of Group P6-C1. In start, then, C1 produced less resistance to extinction than C12 when combined with P6, and P-C produced less resistance to extinction than C-P. In goal, all these effects were, again, significant, reward magnitude, F (1,45) = 4.27, p < .05; presentation order, F (1, 45) = 4.13, $p < .05$; Reward Magnitude × Presentation Order, F (1, 45) = 5.27, $p < .05$; Reward Magnitude × Days, F (7, 315) = 2.26, $p < .05$; Presentation Order × Days, F (7, 315) = 2.09, $p < .05$; and Reward Magnitude × Presentation Order × Days, F (7, 315) = 2.45, $p < .05$. Unlike in start, the major basis of the goal effects was the great resistance to extinction of Group C1-P6. In goal, then, C1 produced greater resistance to extinction than C12 when combined with P6, and C-P produced greater resistance to extinction than P-C. In run, the only significant effects were those associated with Reward Magnitude × Presentation Order, F (1, 45) = 14.82, $p < .01$, and with Reward Magnitude × Presentation Order × Days, F (7, 315) = 2.82, $p < .01$. The trend in run, then, was intermediate to the extremes shown for start and goal, thus producing significant differences only

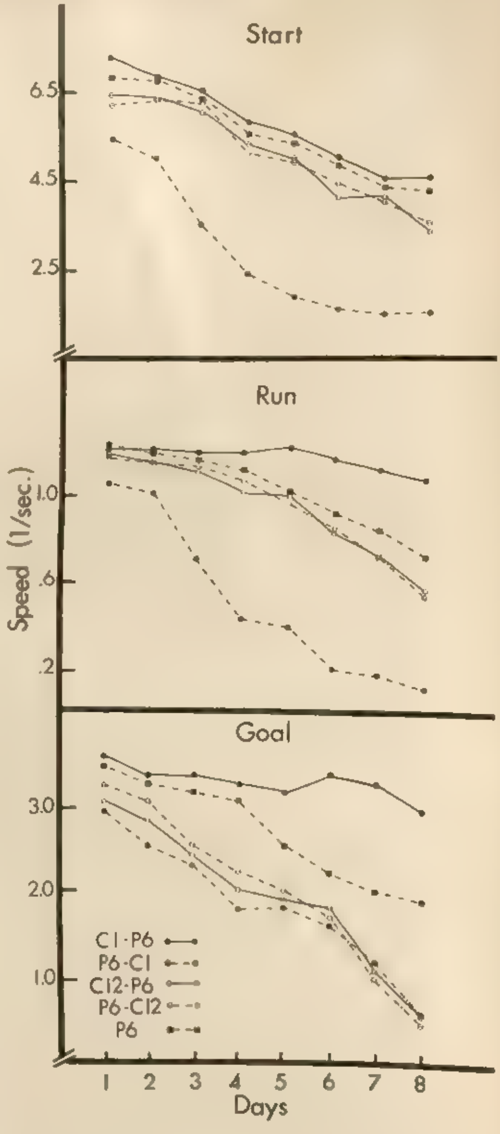

FIGURE 2. Median daily speeds for each of the five groups in each of the alley sections on each of the extinction days.

when reward magnitude and presentation order interacted. The major findings that emerged in extinction were as follows. Group C1-P6 showed very great resistance to extinction relative to all other groups in the goal section, a tendency which, while somewhat evident in the run section, was evident only in relation to Group P6-C1 in the start section. In each alley section, Group P6 performed much as did

Group C1-P6 except, of course, that Group P6 ran more slowly than Group C1-P6 in the run and goal sections. Group P6-C1 extinguished rapidly relative to all other groups in the start section, a tendency which, while somewhat evident in the run section, was evident only in relation to Groups C1-P6 and P6 in the goal section. Finally, Groups P6-C12 and C12-P6 failed to differ from each other in any alley section.

Discussion

In the runway, small consistent reward has produced greater resistance to extinction than large consistent reward and less resistance to extinction than a larger magnitude of partial reward (e.g., Hulse, 1958). However, whatever might have been the effects on extinction of C1 in isolation, these cannot have been its effects when employed in combination with P6, for Group C1-P6 was very resistant to extinction, while Group P6-C1 extinguished very rapidly. Such interactive effects between schedules, while new to C-P and P-C investigations, are not new to separate-phase investigations. The major examples of such interactive effects, of course, are the positive contract effect, or better performance on the part of a group shifted from small to large reward (Group C1-P6 was shifted from small to large reward) than on the part of a large-reward control, and the negative contrast effect, or poorer performance on the part of a group shifted from large to small reward (Group P6-C1 was shifted from large to small reward) than on the part of a small-reward control group. The problem for theory is to identify the processes responsible for these interactive effects. The attention theory of Sutherland and Mackintosh (1971) is so stated that it expects that C-P training will either reduce resistance to extinction or at least produce no greater resistance to extinction than P training (the precise form of the deduction depends upon number of P training trials). Also, given that Group C1-P6 showed very great resistance to extinction, the Sutherland and Mackintosh model would not expect Group P6-C1 to extinguish rapidly (see Sutherland & Mackintosh, 1971). However, inability to deal with the Reward Magnitude × Presentation Order interaction obtained here is not confined to attention theory. It is suggested that the present Reward Magnitude × Presentation Order interaction is simply an example of interactive effects between reward schedules, which at present are not well understood. A model is considered below that appears to adequately explain known interactive schedule effects, whether manifested in extinction, negative contrast, or positive contrast.

Traditionally, the conditioning of stimuli to responses has been considered to be accomplished through either contiguity or reinforcement. The sequential view (e.g., Capaldi, 1966), for example, emphasizes reinforcement. The reinforcement assumption of the sequential model is replaced by that of reinforcement level, all other assumptions of that view being retained. It is suggested that strength of conditioning is always determined by the relationship between the reward that is expected and the reward that is obtained. This relationship determines reinforcement level. More specifically, the view that strength of conditioning is determined by reward magnitude defined physically in terms of weight of incentive, etc. (e.g., Capaldi, 1966), is replaced by the view that strength of conditioning is determined by reinforcement level (obtained reward is, of course, defined physically). Accordingly, if obtained reward is greater than expected reward, then available stimuli will acquire a greater capacity than otherwise to elicit the reaction. However, if obtained reward is smaller than expected reward, then available stimuli will suffer a decrease in their capacity to elicit the reaction (unconditioning). Stimuli that are unconditioned acquire an increased capacity to elicit competing reactions. Variables that are assumed to determine expected reward are considered below, along with selected assumptions of the sequential view that are relevant to understanding reward schedule effects.

Expected reward is assumed to increase as reward magnitude increases and to increase as reward percentage increases. Accordingly, with reward magnitude held constant, expected reward will be higher the greater the reward percentage. Expected reward is assumed to increase along with number of training trials. Under consistent reward, conditioning will eventually be weak, because under consistent reward the value of expected reward eventually becomes identical to that of obtained reward. Under partial reward, the value of expected reward eventually stabilizes between two values of obtained

reward, that available on rewarded trials and that available on nonrewarded trials. Under partial reward, then, there is both strong conditioning (rewarded trials) and unconditioning (nonrewarded trials). Adjustment of expected reward to prevailing reward condition will be fastest where no specific former expected reward level has been established (as in Group P6), and it will be slower the stronger is the former expected reward (as in Group C1-P6). In considering groups such as P6 vs. C1-P6, or groups that may be currently receiving the same reward magnitude but that have different expected reward values, it should be borne in mind that not only are rewarded-trial conditioning effects stronger where expected reward is lower, but nonrewarded-trial unconditioning effects are weaker. Accordingly, in comparing groups of this sort below, only rewarded-trial conditioning effects will be considered in the interest of simplicity. It has been suggested (e.g., Capaldi, 1972) that nonreward or smaller reward produces an internal stimulus (a memory) which has two components, an emotional or aversive component, and a component that corresponds to such characteristics of the reward as its size and so on (perceptual or cognitive component). Call this stimulus S^N. The frustrative or aversive components of S^N occur only when obtained reward is below expected reward, the perceptual components of S^N being independent of expected reward. Since S^N is a memory, the frustrative components of S^N are available to be conditioned or unconditioned to the reaction only on trials which follow trials on which obtained reward was below expected reward. These assumptions are now applied to present and previous separate-phase findings.

When the same reward magnitude is associated with the P and C schedules and P training follows C training, the higher expected reward level appropriate to the C schedule persists for some number of P trials, and thus, on those P trials S^N is less strongly conditioned to the instrumental reaction than where P-alone training is provided, and thus, C-P is less resistant to extinction than P (see Sutherland & Mackintosh, 1971). Under same-magnitude P-C conditions, expected reward level rises over the C trials, which would tend to produce less resistance to extinction in P-C than in P, but at the same time, a variety of stimuli gain in their capacity to evoke the reaction over the C trials (expected reward is below obtained reward on initial C trials). This would tend to oppose the greater eventual unconditioning in P-C relative to P, and perhaps accounts for the fact that, even following extensive interpolated C training, P-C is not much less resistant to extinction than P (Theios, 1962). Employing the reasoning used above, it can be understood why in the present investigation Groups C12-P6 and P6-C12 were less resistant to extinction than Group P6.[3]

In dealing with the case in which the C schedule reward magnitude is smaller than the P schedule reward magnitude, the specific assumption is entertained that the expected reward level associated with P6 was higher than that associated with C1. For Group P6-C1, then, on some number of C1 trials expected reward was above obtained reward (unconditioning), and therefore S^N lost some of the capacity to evoke the reaction that it had acquired under P6 training. For Group P6-C1, then, at least some C1 trials functioned as nonrewarded extinction trials (although less so), and thus, Group P6-C1 was less resistant to extinction than Group P6 and Group P6-C12. For Group C1-P6, on the other hand, expected reward level was below obtained reward for some number of P6 trials (strong conditioning of S^N), and thus, Group C1-P6 was very resistant to extinction. Of course, expected reward was below obtained reward in Group P6 as well, but in Group P6 expected reward was not below obtained reward for as many trials as in Group C1-P6 (previously established expected reward levels are resistant to change).

The considerable similarity between the frustration suppression effect, or FSE (e.g., Dunham & Marx, 1967), and particularly Groups C12-P6 and P6-C1 here is worth noting. A group that receives a larger reward each day in magazine training than in lever

[3] After this report was prepared, an investigation by Mellgren, Lombardo, Wrather, and Weiss (1973) appeared which showed that C-P (20 trials in each phase) produced greater resistance to extinction than P (20 trials) when the same reward magnitude was associated with each schedule. Following only 20 C trials, expected reward would not be firmly established, and thus, S^N was conditioned to the reaction in the P phase about as strongly in Group C-P as in Group P. Too, where only 20 P trials are employed, alley and other stimuli would not be strongly conditioned to the reaction in Group P. Such stimuli would be more strongly conditioned to the reaction in Group C-P due to the additional 20 C trials, and thus, Group C-P was more resistant to extinction than Group P.

training (downshifted group) is less resistant to extinction than a control that receives the same smaller reward magnitude under both magazine and lever conditions. It is reasonable to assume that the downshifted group is frustrated during lever training. As Dunham and Marx point out, a contiguity emphasis (e.g., Amsel, 1958) would suggest that the frustrative stimuli would acquire control over the instrumental reaction in the downshifted group and, therefore, elevate resistance to extinction in that group. The same, of course, would be expected on the basis of a traditional reinforcement view (e.g., Capaldi, 1966). On the other hand, the FSE is clearly consistent with the reinforcement level view. That is, the larger reward associated with magazine training would elevate expected reward in lever training, thereby allowing frustrative and other stimuli to acquire but little control over the instrumental reaction, and thus, the downshifted group would extinguish rapidly.

Other varieties of separate-phase extinction findings are consistent with the reinforcement level view, although these findings, like the FSE and C-P and P-C extinction findings, create considerable difficulty for available theories. It has been reported (e.g., Robbins et al., 1968; Spear et al., 1965) that groups given initial nonrewarded trials (no prior reward trials) prior to rewarded trials showed greater resistance to extinction than controls given rewarded trials only. These findings create difficulty for the sequential view, because only one transition from nonrewarded to rewarded trials occurs (see Capaldi, 1966), and they create difficulty for Amsel's (1958) frustration hypothesis, because initial nonrewarded trials are presumably not frustrative (see Robbins et al., 1964; Spear et al., 1965). According to the reinforcement level view, however, stimuli occurring in the rewarded phase would be more strongly conditioned to the instrumental reaction in the initially nonrewarded group (expected reward is below obtained reward) than in the rewarded-trial control (expected reward and obtained reward more quickly become the same). The similar finding reported by Capaldi (1970), that a small magnitude of consistent reward followed by a large magnitude of consistent reward produced greater resistance to extinction than large consistent reward alone, is also consistent with the reinforcement level view. The similarity of the above finding to those obtained here for Group C1-P6 is perhaps obvious; in all cases, postshift expected reward was below obtained reward. [illegible]ll cases, resistance to extinction was in[illegible] by postshift training. A difference be[illegible] the case being considered and the sa[illegible]agnitudes P-C vs. P case is worth no[illegible] to avoid possible confusion. Expected [illegible]ard level and thus unconditioning is gr[illegible] for P-C than for P in extinction. But [illegible] expected reward level of, e.g., an initially [illegible]rewarded group, is either below that or [illegible] to that of its rewarded control at th[illegible]e of extinction, depending on rewarde[illegible] training level.

When expected reward is ab[illegible]btained reward, both unconditioning an[illegible]^N occur. In most available negative contra[illegible]vestigations, S^N has not been conditi[illegible] to the instrumental reaction in preshift [illegible], most negative contrast findings can be sa[illegible]actorily explained in terms of the genera[illegible]ion decrement and other effects of S^N, w[illegible] appeal to unconditioning being unnece[illegible]y (see Capaldi, 1972). There appears to [illegible]t least one case of negative contrast, h[illegible]er, in which appeal to unconditioning as [illegible] as S^N is required. Ison, Glass, and L[illegible] (1969) reported that a shift from a large [illegible] small magnitude of partial reward produc[illegible] negative contrast effect, however, not [illegible]arly in postshift, as is usual, but only follo[illegible]ng considerable training. Early in pos[illegible]hift S^N would elicit responding strongly, [illegible]ause it was previously conditioned to the reaction by means of a large magnitude of partial reward. However, because in postshift expected reward was above obtained reward on both rewarded and nonrewarded trials, unconditioning would eventually be considerable, and presumably it was this rather substantial unconditioning effect that was responsible for the late-trial negative contrast effect reported by Ison et al. If the postshift condition following large partial reward is small consistent reward rather than small partial reward, the unconditioning effect would be less severe (no nonrewarded trials) and unconditioning would not occur over so many trials (the preshift and postshift expected reward level discrepancy is smaller). These are, perhaps, among the reasons why a shift from large partial reward to small consistent reward did not produce a negative contrast effect in an investigation reported by Capaldi and Ziff (1969).

Whether positive contrast has been obtained seldom or frequently seems, in part, definitional. If the meaning of positive contrast

is res[illegible] to cases in which reward magnitud[illegible]gher in postshift than in preshift, then [illegible]ve contrast has been obtained less frequ[illegible] than otherwise. According to the reinf[illegible]ment level view, however, the necessary [illegible] not sufficient conditions for positive con[illegible]st exist whenever expected reward lies be[illegible] obtained reward, which widens consi[illegible]rably the permissible instances of positive [illegible]trast. Thus, according to reinforcement level, positive contrast can occur on a shift from partial to consistent reward as well as on a shift from smaller to larger reward. [illegible]eung and Jensen (1969) reported positive [illegible]ntrast following shifts from various per[illegible]tages of partial to consistent reward. In [illegible] and run sections of the runway, [illegible]ial reward sometimes produces faster [illegible]ning than consistent reward (e.g., Good[illegible], 1959), which is, according to reinforce[illegible]nt level, a positive contrast effect. In the [illegible]al section, partial reward produces slower running than consistent reward, which is consistent rather than inconsistent with the present view. In the goal section, nonrewarded-trial unconditioning effects under partial reward are potent, and as Miller (1959) suggests (see also Capaldi & Levy, 1972), approach tendencies generalize more widely than inhibitory tendencies, which means that in earlier alley sections rewarded-trial conditioning effects under partial reward will be potent relative to nonrewarded-trial [illegible]conditioning effects. Positive contrast was [illegible]served by Robbins et al. (1968) on a shift [illegible]m initial nonrewarded trials to rewarded [illegible], although not classified as such by those authors. More orthodox instances of positive contrast were reported recently by Weinstock (1971) on a shift from small to large consistent reward, and by Mellgren (1971, 1972) on shifts from a small to a large magnitude of delayed reward.

Mellgren (1971) observed a positive relation between number of preshift trials and absolute speed on postshift trials, and this effect extended over 32 trials, at which point training was discontinued. According to the reinforcement level view, as the number of preshift trials increases, the number of postshift trials over which obtained reward will remain above expected reward increases. Thus, as number of preshift trials increases, the stronger should be postshift conditioning, producing, accordingly, a positive relation between number of preshift trials and absolute speed in postshift.

[illegible]D RECOGNITION AND MORPHEMIC STRUCTURE[1]

GRAHAM A. MURRELL[2] AND JOHN MORTON

Medical Research Council, Applied Psychology Unit, Cambridge, England

Six[illegible] *Ss* learned a w[illegible]d list and were then tested on recognition of words presented tachistoscopi[illegible]. When a test word was identical to one of the learned words, recognition was facilitated in the usual way. Pretraining with word[illegible]t was a different derivative of the same root morpheme as a test word [illegible] facilitation of recognition of that test word. However, learning [illegible] comparable visual-acoustic similarity but no morphemic relation [illegible] word gave only slight, nonsignificant facilitation of recognition. It [illegible]cluded that the process of recognizing a word involves assigning it to a [illegible]istic unit with specific semantic associations, i.e., a morpheme. Analysis [illegible]or responses suggested that, to some extent, root and suffix morphemes [illegible]re recognized independently, and that suffixes themselves may be subject to frequency effects. The principles underlying the phenomena studied may be most appropriately characterized as "the morpheme-frequency effect."

Words of higher frequency of occurrence in the language are more easily recognized than low-frequency words. The nature of the mechanism leading to this phenomenon is a subject of current debate (Broadbent, 1967, 1971; Catlin, 1969; Morton, 1968; Nakatani, 1970; Treisman, 1971). All current theories, however, are agreed that the recognition system is biased toward high-frequency words, although that bias is seen as operating in different ways. In the past, it was debated whether this bias was a function of the differential frequency of the perceptual experience of words (Howes, 1954; Neisser, 1954) or [illegible] frequency of production of words (D[illegible]ston, 1957), with corresponding definition of the unit of recognition as perception or response based.

[illegible] way of reconciling these positions was put forward by Morton (1964, 1969), who proposed the logogen model, in which the central units, logogens, were affected not only by visual and acoustic information, but also by semantic information. The latter is implicated in speech production and also in the recognition of connected material. Any logogen receiving more than a threshold amount of information "fires," making the corresponding word available as a response. As a result of firing, the threshold of the logogen is lowered and very gradually rises to a level slightly below its previous value. In this way, experience with words, both recognition and production, leads to permanent changes in threshold, biasing future responses.

The short-term change in threshold was included in the model to account for the finding that when a word is recognized, the same word will be recognized more easily if presented again within a short time.

The latter effect was utilized in the present experiment to create a short-term, experimentally controlled word-frequency effect. The technique has been used previously by Solomon and Postman (1952), who used nonsense words so there would be no "a priori" word-frequency effect. As will become clear, it was necessary to use familiar real words in the present experiment, but the uncontrolled a priori frequency effect could only mask the results and will not affect the conclusions.

Neisser (1954) found that pretraining with a word facilitated recognition of the same word but not of a homonym, e.g., after priming with "phrase," recognition of this word was easier than normal, but recognition of "frays" was not affected.

[1] This work was carried out at the Psychological Laboratory, University of Cambridge, while the first author was a final year undergraduate. The assistance of those who acted as *Ss* is gratefully acknowledged.

TABLE 1

Experimental Words

(1)	(2)	(3)
Car	Cars	Card
Bored	Boring	Born
Sings	Singer	Singe
Pains	Pained	Paint
Lives	Lively	Livery
Sees	Seen	Seed
Man	Manned	Manner
Hanging	Hang	Hangar
Reader	Reading	Ready
Placed	Places	Placate
Walled	Wall	Wallet
Topped	Topping	Topple
Basis	Basic	Basin
New	Newer	Newt
Mile	Miles	Mild
Numbing	Numb	Numbers

His interpretation was that pretraining "does not merely raise the probabilities of certain verbal responses, but rather facilitates the perception of specific visual patterns [Neisser, 1954, p. 402]." Following this, Ross, Yarczower, and Williams (1956) attempted to demonstrate a monotonic relation between degree of facilitation and level of visual similarity between pretraining word and test word. They found no such relation, although they confirmed Neisser's main result. This, and other considerations, casts doubt upon Neisser's interpretation, and particularly his assumption that "phrase" and "frays" may be regarded as the same response (even assuming they are phonetically identical).

The interaction of semantic and sensory information necessary to account for the facilitative effects of a context on word perception (Morton, 1969; Rubenstein & Pollack, 1963; Tulving, Mandler, & Baumal, 1964) also necessitates a refinement of the definition of the unit of recognition. Thus, since the contexts appropriate to the two homographs "chop" are totally different, they might be expected to have functionally separate representations in the recognition system.

The question of interest in the present study is whether the unit concerned in recognition facilitation effects is a word as a visual–phonetic pattern, or a form bound to a specific semantic unit, i.e., a morpheme. The conclusions will bear on the nature of the response units made available by logogens.

The experiment investigated the effect on word recognition of pretraining with a word containing the same root morpheme, compared with pretraining with a word containing the same visual–phonetic pattern as its "root" when this is not actually the same morpheme. The effects of pretraining with the identical word and zero pretraining, as control conditions, were also tested.

Method

Subjects. Sixteen male undergraduates volunteered as *S*s, and were divided into two groups of 8. None were psychology students. Each completed the procedure once only, with no prior information about the experiment apart from the specific instructions (see below).

Materials. The apparatus was a Cambridge tachistoscope with an auxiliary timing device to permit control of flash duration in 5-msec. steps between 10 msec. and 140 msec. A neutral density filter (×16) was fitted over the viewing aperture to reduce stimulus contrast. The stimulus words were typed in lowercase on plain white cards, aligned so as to appear in the space between two short horizontal lines drawn on the "background" card upon which a word was superimposed in the stimulus flash. The *S* was provided with the tachistoscope trigger button on a cable, to initiate the flashes.

The experimental words are shown in Table 1. The three words in each row of the table have an initial sequence of letters in common. Group 1 and 2 words differ only in the inflection of their common root morpheme, but the same letter sequence in the Group 3 word is not the same morpheme, and the word bears no semantic relation to the other two. However, viewed purely as visual–acoustic patterns, the degrees of similarity between the words in different columns are comparable (e.g., the mean suffix length of Group 3 is intermediate between Groups 1 and 2, the difference between the means of Groups 1 and 2 being less than half of one letter).

Twenty other words were used in initial practice on tachistoscopic recognition. These were selected for low similarity with experimental words.

There were four sets of 12 words for pretraining. Each set comprised 4 words from each of Groups 1, 2, and 3, typed on a card in random order. Each *S* received a recognition test on the words of either Group 1 or Group 2 of Table 1. Thus, of the 16 words each *S* was tested on, 4 were subject to each of the four pretraining conditions, which were as follows: (*a*) pretraining with the same word (Condition S), (*b*) pretraining with a different inflection

of the same root morpheme (M), (*c*) pretraining with an unrelated word containing the same visual–acoustic form but different terminal letters (V), and (*d*) zero pretraining, no similar word having been presented (O).

Over the eight combinations of pretraining and testing word sets, every test word was subjected to every pretraining condition. Thus from each group of eight *Ss*, recognition scores for each word under each condition were obtained.

Procedure. The outline of the procedure is best conveyed by quoting the instructions read to *Ss*.

> The experiment is in three phases. First, I am going to [illegible] ability to recognize words that are presented to you in a very brief flash. Secondly I will give you a short list of words to [illegible]. I will test your recognition of [illegible] of words on brief exposure, some of the words being among those you have learned. Please place your face against the rubber visor on this apparatus, and view the white card. When I say 'now,' focus between the lines and when you're ready press the button once to flash up the word. Then, immediately say aloud and distinctly what you think the word was. Guess if you're not sure, and if you have no idea what it was, say 'no.' [practice phase]
>
> For the next phase, there are 12 words printed on this card in a random order. You have three minutes to learn them and go over them in your head. You will need to keep them in your mind through the third phase. Begin now. [pretraining]
>
> Time is up, and it is time for the third phase, but try to remember those words. Some of the following series of words will be among the words you have learned, some will be similar to those you have learned, and others will be quite different words. The procedure is the same as before. When I say 'now,' focus between the lines . . . . [testing]

In the practice period, about 100 word exposures were given, of varying durations, to familiarize *S* with the task. The shortest duration at which words were correctly recognized at the end of the practice was taken as the individual *S*'s baseline for testing.

The set of words for testing was presented in a random order at baseline flash duration, then in the same order again at 5 msec. longer duration, and so on for nine serial presentations. Baselines varied from 20 msec. to 60 msec., and each *S* received exposures increasing in duration to 40 msec. above his baseline.

All responses in the test were recorded, but no knowledge of results of any kind was given.

Results and Discussion

There were 39.8% correct responses, 48.1% error responses and 12.1% "no" responses. Only 7.0% of the error responses were not real words. Of these, nearly three-quarters were from four of the *Ss*, and five *Ss* gave no such responses. In general, error responses were similar in word length and gross shape to their eliciting test words.

TABLE 2

Recognition Performance

Scoring measure	Pretraining condition			
	S	M	V	O
Mean recognition score for words	86.8	63.3	51.1	46.8
Mean recognitions per 9 presentations	4.35	3.72	3.25	3.02
Percent recognition of root morphemes	49.9	46.4	36.8	36.6
Percent recognition of suffix morphemes	62.2	54.2	51.6	51.0

Note. See text for explanation of pretraining conditions.

It was decided not to use a "threshold" measure for comparison of scores, since it would depend heavily upon the arbitrary criterion set by *E* and would neglect much of the available data. Instead, a measure of performance was devised which gave a value to every correct response according to exposure difficulty, normalized across *Ss*.

First, each correct response was given a value equal to the reciprocal of the proportion of correct responses at that exposure over all *Ss*. This weighting gives higher values to more difficult discriminations. Thus weighted, correct responses were summed over the nine exposures to give a score for each word by each *S*. The scores of each *S* were further weighted by the multiplier necessary to correct his total score to 100. This procedure compensated for individual differences.

The mean recognition scores under the four conditions are shown in the first row of Table 2. The untreated data are summarized in the second row of Table 2 as the mean number of wholly correct recognitions per nine presentations under each condition. No further reference will be made to the latter figures.

A three-factor analysis of variance was carried out on the recognition scores

(model from Winer, 1971, p. 380). The factors were conditions, words, and replications (i.e., the two sets of eight *S*s duplicating each result). The pretraining conditions differentially affected word recognition, $F\ (3, 93) = 12.65$, $p < .001$.[3] The result of principal interest is that although the difference between scores under Conditions V and O fell well short of reliability ($F < 1$), Condition M did facilitate word recognition compared with O, $F\ (1, 93) = 5.38$, $p < .025$. However, the effect of Condition M was rather less than that of S, $F\ (1, 93) = 10.79$, $p < .01$. The Replications × Conditions interaction was not significant ($F < 1$), indicating that the differences between conditions were consistent between the two groups of *S*s. Similarly, the Words × Conditions interaction was not significant, $F\ (93, 93) = 1.32$, indicating that the conditions had the same effects over all the test words used.

There is some indication of effects of phonological similarity, which may be worthy of study in their own right. In six of the rows of words in Table 1, the "root" of Word 3 differed phonologically from those of Words 1 and 2, e.g., reader, reading, ready. A separate analysis of the recognition of the 12 test words from these rows indicated that under Condition V the phonological dissimilarity tended to counterfacilitate recognition. However, the analysis of variance of recognition scores was repeated with these 12 words excluded, and even when the pretraining and test word roots had the same phonology under Condition V, there was no significant facilitation compared with O, $F\ (1, 57) = 1.20$.

The results confirm the effectiveness of the pretraining technique for creating a short-term, experimentally controlled word-frequency effect. This effect does not occur when the pretraining word resembles the test word in visual–acoustic features only. There is reliable facilitation only when there is morphemic identity in addition to visual–acoustic similarity.

Considered in terms of the logogen model, this means that the logogen whose threshold is lowered by pretraining with a word corresponds not to that word, nor even to the visual–acoustic pattern it contains as root, but strictly to the morpheme from which the word is derived. Thus, the word recognition process, even in the absence of contextual or semantic stimulus information, involves assignment of the stimulus to a particular morpheme with its specific semantic associations. The morpheme, and only that one morpheme, to which the decision process assigns the word, has its logogen threshold lowered. Thus, when a pretraining word belongs to a different morpheme from a similar test word (as in Condition V), no facilitations would be expected. This interpretation would also account for the negative results of Ross et al. (1956).

The conclusion that the unit involved in facilitation effects is the morpheme was further illustrated by the percentage of responses containing the same root morpheme as the eliciting test word. These results are shown in the third row of Table 2. Bearing in mind that the recognition of whole words was considerably better under Condition S than under M, it is significant that the recognition of root morphemes under these two conditions did not differ reliably. It may be concluded that the latter result was due to the equal facilitation of root morphemes in these two pretraining conditions. Furthermore, recognition of root morphemes was not reliably different under Conditions V and O. This would be predicted, since under Condition V the root morpheme of the test word did not occur in pretraining and thus could not have been facilitated.

Even though the root *letter sequences* in pretraining were the same in Conditions M and V, with suffixes differing from the test words in both cases, the recognition of root *morphemes* was better under M ($t = 2.38$, $p < .025$). The facilitative effects of V pretraining were apparent in the intrusion

[3] In order to avoid the "language-as-fixed-effect fallacy" pointed out by Clark (1973), the appropriate quasi-F ratio for the conditions main effect was also calculated: $F'\ (3, 17) = 8.03$, $p < .01$. This provides statistical support for generalizing the effect to any comparable sets of words.

errors containing the root morpheme of the pretraining word. Such errors amounted to 8.7% of the responses under V, a figure comparable with the difference in root morpheme recognition between M and V. This is evidence that response biases of similar magnitude were created under these two conditions.

There appears to be some validity in considering experimental words in terms of root and suffix. The results suggest that, to some extent, free morphemes and suffixes are recognized independently. This is consistent with the linguistic analysis of words into morphemes, and the view that, the response units made available by logogens are morphemes.

It appears that the difference in word recognition scores between Conditions S and M was due to the pretraining with the test word suffixes under S, which did not occur in the other conditions. The scores for recognition of suffix morphemes are shown in Table 2. The difference in suffix recognition between S and O ($t = 2.56$, $p < .025$) demonstrates suffix facilitation. The differences in suffix recognition between M, V, and O were not reliable. The difference between S and M was only poorly reliable ($t = 1.59$, $p = .07$), probably because suffix recognition under M was inflated by the constraint imposed on response suffixes if the pretrained root was correctly produced. Thus, if the test word were "newer," then the likelihood of producing the correct suffix "-er" is zero if the root has been reported as "newt." If "new" has been seen correctly, the likelihood of guessing "-er" is appreciable.

Of the errors which were real words given in response to test words having the zero morpheme (i.e., no suffix), 213 (93.0%) had no suffix. These responses were not counted in the suffix recognition scores of Table 2, which are therefore an underestimate.

It is clear that there was substantially better recognition of suffixes than of roots. It may simply be that the suffixes were more distinctive visual patterns. The suffix "-ing" was correctly recognized on 81.5% of the trials in which it occurred in the test word, including 35.0% of the trials on which the first part of the response was wrong. For the suffix "-ed," there was recognition on 65.1% of its occurrences, including 28.3% error responses. Correct recognition of "-er" was 53.7%, including 15.3% errors.

It may be that "-ing" is more distinctive than "-ed." However, it is an attractive proposition that the suffixes themselves are subject to a frequency effect. If this were so, the relative proportions of trials on which the root and suffix of a test word were recognized would reflect the relative familiarity of the two morphemes to the subject.

This experiment gives grounds for considering a well-known phenomenon in new terms, as "the morpheme-frequency effect."

CONSONANT–VOWEL–CONSONANT RECOGNITION AS A FUNCTION OF GRAPHIC FAMILIARITY AND MEANING [1]

SETH N. GREENBERG [2]

Ohio University-Lancaster

The present research determined whether perception of letter strings is influenced by meaning associated with the string and/or the familiarity of the string's graphic structure. Combining a familiarization procedure which allows graphic familiarity and meaning to be independently associated with unfamiliar consonant–vowel–consonants (e.g., Taylor) and a forced-choice word perception procedure (e.g., Reicher) which eliminates nonperceptual influences, it was demonstrated that only graphic familiarity improves letter sequence recognition. However, it was noted that meaning pretaining influenced the choice of a unitization strategy used in the perceptual task. The results indicate further information about the scope of variables influencing unitization strategy, as well as the importance of unitization strategy in the perception of certain fixed orthographic structures.

Using visual thresholds as measures of perceptibility, Cattell (1885) determined that man perceives letters more easily when the letters form words. A basic question that arises from Cattell's observation is which feature or features associated with words and not with random letter sequences contribute to the superior visual recognition of words? Gibson (1972) classified the distinguishing features of words into four types of information: graphological, phonological, semantic, and syntactic. The two features of interest in the present research include graphological–orthographic features which refer to the physical character and arrangement of letters in a sequence and semantic features. Specifically, this investigation is concerned with whether meaning and/or familiarity of a graphic letter sequence increases a sequence of letters' perceptibility.

Attempts to determine whether graphic familiarity and meaning influence letter sequence perceptibility face two major problems:

1. Employment of an experimental procedure that successfully eliminates nonperceptual factors from biasing results. For example, if the "perceptual task" requires *S*s to report a string of letters, after a brief visual presentation performance may reflect both what *S*s saw and what *S*s were able to recall correctly (Baddeley, 1961; Hochberg, 1968). Thus, a significant effect attributed to a feature might be due to that feature facilitating recall rather than perception. The problem of nonperceptual factors can be circumvented by the use of a forced-choice recognition technique introduced into word perception by Reicher (1969). Reicher's technique calls on *S*s to select from two response alternatives the letter that occupied a randomly designated position in the tachistoscopically presented letter sequence which immediately preceded the response choices. Both response alternatives are equally likely to appear in the tested position. Reicher's procedure successfully eliminates factors of storage load, interference during retrieval, and biased responding which hindered perceptual interpretations of previous experiments.

[1] This study is based on a dissertation submitted to the Ohio State University in partial fulfillment of the requirements for the PhD degree. The research was carried out at the Human Performance Center and was sponsored in part by National Institute of Mental Health Grant 1-R01-MH20495-1 to Harvey G. Shulman. The author wishes to thank Harvey G. Shulman for the time he devoted to reading earlier drafts and the many helpful ideas he contributed.

O ZEL	O ZAL	ZEL O	
U ZEL	U ZED	ZEL U	ZED U

Note. The actual set of perceptual stimuli used incl[illegible] randomly selected intact stimuli [illegible]

[illegible] Manipulation of one feature associated with a letter sequence is normally accompanied [illegible] another feature which is positively correlated with [illegible] in the primary feature. [illegible] better than MBH which is not [illegible] has been to [illegible] perception (Gibson, Bishop, Schiff, & S[illegible], 1964). However, the increased [illegible] of the letters I, B, and M when [illegible] to [illegible] i.e., graphic familiarity [illegible] simultaneous increase in [illegible]

[illegible] perception of [illegible] Taylor's results supported a [illegible]

iarity effect, but failed to [illegible] effect [illegible] meaning. However, use[illegible] threshold technique which [illegible] nonperceptual influences, [illegible] during recall and response [illegible] interpretation of Taylor['s] [res]ults. [In] addition, CVCs were pa[ired] with [illegible] definitions for only 15 trials [prior] to be[ing] employed in the perceptual [t]ask. [This] failure of the meaning varia[ble] [could] be [at]tributed to insufficient asso[illegible]

The present research foll[ow]ed a more extensive version of Taylor'[s] [famil]iarization procedure with a [illegible] recognition task in order [to] [de]termine whether graphic familiarity an[d] meaning are features that enhance a l[etter sequence's] perceptibility.

METHOD

Subjects. Twelve Ohio State Uni[versity] [illegible] served for 13 45-min. sessions at $1 [illegible] The Ss were assigned to three famili[arization] [illegible] (H = high meaning associate, L [illegible] associate, and P = no associate) in o[illegible] ance, thereby providing four Ss per g[roup].

Stimulus material and design. Tw[illegible] meaningful (m) CVCs (Archer, 1960) [illegible] stimuli in the familiarization task a[illegible]

[illegible]

Regarding all aspects of the perceptual [treat]ment, List 1 and List 2 were treated identically. The list used by a given S during familiarization would be the [illegible] stimuli, while [illegible]

[illegible] CVC [illegible] a set of 14 perceptual stimuli [used] in the experimental (visual recognition) task. [An] [illegible] of a perceptual stimulus set is exhibited [in Table] 1.

[The] first and third columns in Table 1 contain [illegible] which were constructed by [illegible] the four vowels that differs from the CVC's [illegible] beginning or end of the familiarization [illegible], each CVC generated eight intact stimuli; six intact [illegible] each set of eight [for] the purpose of testing the [illegible] positions. One stimulus from each set of six [illegible] was used during a session, providing 24 tests of [illegible] positions of intact stimuli. Counterbalancing [illegible] the 24 tests each session produced an equal n[illegible]

[illegible] of each CVC position. A different member [illegible] set of six stimuli was probed in each of six [illegible] sessions. Tests of the CVC positions were counterbalanced within each set so that each [illegible] was probed twice.

In order to meet the requirement of equally likely [illegible] alternatives for the forced-choice probes, [illegible] intact stimulus used for a CVC position probe had a nonintact partner which was derived by replacing the probed letter of the intact stimulus with another letter (second and fourth columns). The replacement letter in the nonintact stimulus and the letter replaced from the intact stimulus [illegible] alternatives for that particular [illegible] the intact stimulus and its [illegible] with an equal [illegible] position.

[illegible] each session, [illegible] of one [illegible] vowel and [illegible] vowel from [illegible] added vowel [illegible] All eight [illegible] that both vowels serving as response alternatives would be used as the correct alternative (i.e., occur as the added vowels with a given CVC equally often).

The rationale behind added vowel testing was that it permitted comparisons between familiar and unfamiliar stimulus conditions. The CVC [illegible] data could not be used for this purpose, since [illegible]

[illegible] perceptibility and upon scanning strategy (unitization).

The order of perceptual stimulus presentation and testing was random within each session (96 trials) except for the following constraints: (a) no successive repetition of stimuli containing the same CVC base was allowed, (b) no more than four successive tests of CVC positions or added vowel positions was allowed, (c) no more than four successive presentations of stimuli generated from CVCs belonging to one of the two lists was permitted, (d) over 32-trial blocks, half of the stimuli were List 1 and half were List 2 generated stimuli, and (e) no CVC appeared as the base of a perceptual stimulus more than twice in a 32-trial block.

[illegible] Ss in the H and L groups [illegible] 12 CVCs belonging [illegible]

[illegible] were used to establish a 90% [illegible] The method for determining [illegible] a short-cut psychophysical procedure [illegible] (1960). The test items [illegible] duration that [illegible] recognition threshold [illegible] was used during the [illegible] in the visual recognition task [illegible]

[illegible] preexperimental tasks, familiarization and [illegible] determination were performed [illegible]

TABLE 2

POSITIONAL ERROR RATES (IN PERCENTAGES)

Condition	Left-added vowel	Left consonant	Center vowel	Right consonant	Right-added vowel
Group P					
Familiar-intact	28	11	17	29	36
Familiar-nonintact		18	33	13	
Unfamiliar-intact	31	15	35	36	39
Unfamiliar-nonintact		16	26	11	
Σ	29.5	15	27.75	[illegible]	37.5
Group L					
Familiar-intact	17	19	15	18	46
Familiar-nonintact		24	32	39	
Unfamiliar-intact	22	17	28	29	49
Unfamiliar-nonintact		25	27	24	
Σ	19.5	21.25	25.5	27.5	47.5
Group H					
Familiar-intact	13	14	8	20	37
Familiar-nonintact		32	25	32	
Unfamiliar-intact	17	16	15	32	44
Unfamiliar-nonintact		8	22	17	
Σ	15	17.5	17.5	24.75	40.5

Note. Error rates listed under added vowel columns were collected over last four sessions only. Analyses [illegible] performed on added vowel data collected over last four sessions and all six sessions produced the same significant effect, [illegible] collected over last four sessions appeared more stable. Added vowel tests were completely counterbalanced within sessions.

forward association trial, while an *S* in the P group pronounced the list of CVCs three extra times. These familiarization trials preceded 18 final pronunciation trials (P group), or 18 forward association trials (L and H groups), as well as a final set of duration threshold trials.

The final six sessions were given to the experimental task, CVC plus vowel recognition. During a perceptual recognition session, an *S* sat 76 cm. in front of a 91 × 61 cm black screen with a 7.6 × 17.8 cm white Lucite area serving as the projection area. The projection area was long enough to hold seven projected letters with a .64-cm. space between the end position letter spaces and the black screen. The field was high enough to hold three rows of letters with a .32-cm. space between rows and a .42-cm. space between the top or bottom row and the edge of the black screen. The *S* pressed a button when he considered himself fixated at the center of the field. Immediately after the button press the stimulus appeared for a duration equivalent to *S*'s 90% recognition threshold for single letters plus 50 msec. The vowel position of the CVC portion of the stimulus coincided with the center of the fixation field. The added vowel appeared in either the leftmost or rightmost position. Thus, there was a space between the CVC base and the added vowel. Following termination of the stimulus display, a masking field was presented containing a series of overlapping Xs and Os, which covered the middle row where the stimulus had just appeared. Occurring with the masking field were two response alternatives which occupied positions directly above (top row) and below (bottom row) the position formerly filled with the stimulus' to-be-tested letter.

During the appearance of the response-alternative-masking field, *S* chose, from the two alternatives, the letter he thought occupied the probed position. Response alternatives remained available for 3 sec. The *S*'s choice was written on an answer sheet, which was covered following the response. The time between successive responses depended upon *S*'s response time, with a normal interval of about 15–20 sec.

The basic projection equipment included two Kodak Carousel RA950 projectors located behind blade shutters which were controlled by a Hunter 1516 six-channel timer.

Eleven of the 12 participants in the perceptual task were contacted 10 wk. after the completion of the perceptual experiment. The twelfth *S*, who had moved, was in the pronunciation group. Two tests were administered; a recall test first and then a recognition test. In the recall test *Ss* were asked to recall as many of the 12 familiar CVCs as they could, while in the recognition task *Ss* chose the 12 familiar CVCs from the total set of 24 CVCs. In both conditions, *Ss* were allowed as much time as they wanted to complete their responses. Each *S* was paid $1.25 for the recall–recognition session.

RESULTS

Error rates for all five tests positions are summarized in Table 2. In examining the influence of graphic familiarity on sequence perceptibility, only added vowel performance was considered. The added vowel results provide evidence that both left and

right [vo]wels were recognized more often when [di]splayed with a familiar CVC than with an unfamiliar CVC. An analysis of variance performed on the error data co[nfir]med this observation revealing a si[gn]ificant effect of graphic familiarity, [F (]1, 9) = 8.40, $p < .05$.

Had meaning influenced stimulus per[c]eptibility, *Ss* in the H and L groups should have performed significantly better than *Ss* in the P group. Examination of the CVC error data in Table 2 appears to indicate that meaning affected CVC per[c]eption. However, an analysis of variance [pe]rformed on CVC position data, as well [as a]n analysis of variance on added vowel [da]ta indicated that the between-*Ss* variable, [me]aning, failed to produce a significant [e]ffect, F (2, 9) < 1 for both analyses. The failure of the main effect of meaning could be due to inclusion of intact unfamiliar CVC tests and nonintact familiar and unfamiliar CVC tests with the intact familiar tests. Since only intact familiar CVC bases were treated differently in the various groups, i.e., used during familiarization, the effect of meaning should be confined to the intact familiar condition within each group, and would be identified as a significant Meaning × Familiarity × Intactness interaction. Analyses of [v]ariance performed on CVC position and [a]dded vowel position data failed to produce [th]is interaction, F (2, 9) < 1 for both [c]omparisons. The lack of an effect of meaning on the total perceptibility of a [se]quence could have also resulted from a [fa]ilure of the familiarization procedure to produce a difference in the CVCs for the various groups. Results from the long-term recall task place doubt on this possibility. The *Ss* in the H and L groups recalled an average of 11 and 9 of 12 CVCs, respectively, while those in the P group recalled 5 CVCs. Recognition performance did not differ betweeen groups. A set of tests performed on the recall results demonstrated that both association groups recalled more items than the P group ($p < .05$ for both comparisons). This information indicates that differential familiarization effectively established differences in the CVCs

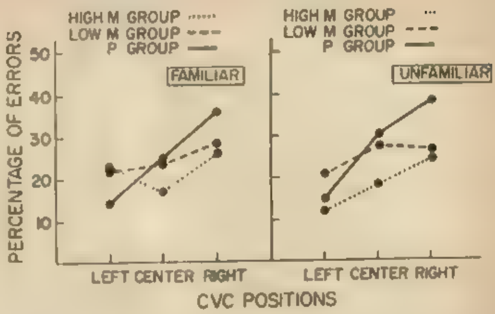

FIGURE 1. Meaning × Consonant–Vowel–Consonant (CVC) Position × Familiarity interaction. (Abbreviations: M = meaningful and P = no associate.)

for the various groups and thus eliminates the failure of familiarization as an explanation of the null effect of meaning.

While meaning failed to effect the level of CVC recognition, a significant Meaning × Position interaction, F (4, 18) = 14.59, $p < .05$, indicated an influence of meaning on the way CVCs were unitized. The interaction displayed in Figure 1 appears to result from the marked increase in errors from the left to center to right CVC position associated with the P group, contrasted with a considerably more moderate left to right increase in errors for the H and L groups. The slopes of the three curves in Figure 1 were compared with a slope of zero (see Draper & Smith, 1966, pp. 15–24). Only the slope describing the increasing errors across positions for the P group differed significantly from a zero slope, t (1) = 6.2, $p < .05$. In addition it should be noted that the positional error trends within each group were similar for familiar and unfamiliar CVC bases.

Discussion

The present results confirmed Taylor's (1958) finding of an effect of graphic familiarity upon letter sequence perceptibility. While meaning pretraining did not produce a similar effect, it did influence the strategies for unitizing the letter sequences. The *Ss* in the P group appeared to treat each letter of a CVC as a unit, and processed the letters in a left to right direction. In contrast, the requirement of making a meaningful association (H and L groups) encouraged *Ss* to treat the whole CVC

as a perceptual unit. Both strategies occurred with unfamiliar CVC-based stimuli, as well as with familiar stimuli. The effect of meaning pretraining, particularly with regard to unfamiliar perceptual stimuli, supported and broadened an earlier finding of Aderman and Smith (1971). Aderman and Smith demonstrated that pretraining involving the consistent presentation of letter strings with a certain orthographic structure could influence the unitization strategy used in processing a succeeding letter string. Two orthographic structures were used during pretraining with half of the *S*s receiving a list of stimuli having one structure, while remaining *S*s received a list with a second structure. In the present study, orthographic structure of both the pretraining stimuli and the base of the perceptual stimuli was held constant, i.e., CVC, while the level of meaningfulness was varied during pretraining. The fact that variations in meaning pretraining led to different unitization strategies is evidence that types of pretraining less closely associated with the physical structure of a letter sequence than orthographic variations can produce changes in strategies for unitizing strings of a fixed structure.

Aderman and Smith's (1971) results also indicated that if the pretraining orthographic structure conformed to the rules of English spelling patterns, *S* would attempt to unitize the succeeding test string into groups of letters identified as spelling units. If the succeeding string also matched an orthographic structure of English, the spelling unit strategy would be compatible with the succeeding string, and *S* performed better in this condition than if pretraining led *S* to use a strategy in which single letters served as units. Aderman and Smith found no advantage, however, to unitization strategies resulting from pretaining sequences either conforming or not conforming to English structure when the succeeding test string did not conform to English structure. Perception of CVCs also appears to be unaffected by unitization strategies resulting from pretraining. Whether CVCs were unitized as wholes or by single letters, the level of recognition was not significantly altered. Thus, various types of pretraining produce different unitization strategies, but whether those strategies influence the perceptibility of a letter sequence depends upon the orthographic structure of the test sequence. It should also be noted that some pretraining variables, such as familiarity in the present experiment, influence sequence perceptibility without affecting unitization (no interaction between familiarity and position was found). Hence, variations in unitization strategies are not necessary to produce changes in the level of perceptibility of letter strings of a fixed structure.

[illegible]FORMATION EXTRACTION FROM DIFFERENT RETINAL LOCATIONS[1]

LESTER A. LEFTON
University of South Carolina

RALPH NORMAN HABER
University of Rochester

Four expe[illegible]ments examined manipulations of retinal location, visual field of presentation, [illegible] response variables in a visual matching task where the re[illegible] speed of judging whether the stimuli were the *same* or *dif*[illegible]. Results showed that (*a*) reaction time increased with retinal eccentricity, [illegible] ally no differences between the two visual fields, (*c*) a [illegible] retinal Location interaction emerged, and (*d*) both judg[illegible] sameness" and of "difference" were responded to in a similar manner, [illegible]rdless of the visual field of presentation.

[illegible] experiments examined an aspect [illegible] effects of retinal location on in[illegible]ation processing of tachistoscopically presented letters. In most of the literature, stimuli have been a horizontal row of letters spread across the fixation point, subtending generally less than 3° or 4° of visual angle. With the assumption that acuity would be sufficiently homogeneous over this region (the evidence summarized in Riggs, 1965, notwithstanding), retinal location has not been considered a particularly significant variable. This has been held even with the general findings in the same literature that accuracy of report, speed of reaction, clarity, apparent contrast, and other variables show variation over this range of locations. Eriksen, in a number of studies from his laboratory (e.g., Eriksen & Hoffman, 1972; Eriksen & Rohrbaugh, 1970) has worried about this sufficiently to avoid horizontal arrays altogether, preferring to place his stimuli in a circular arrangement around fixation. This is not always a feasible procedure, especially when recognition among groups of letters (e.g., words) is of interest.

Harcum (1964) has claimed that spatial organization among items in the array is a far more important variable than absolute retinal location. Hershenson (1969) has challenged this argument, suggesting that under circumstances in which the perceiver is thoroughly familiar with the organization of the material, the distance from fixation determines perceptual clarity and accuracy of report. Harcum (1970), after reanalyzing Hershenson's data, has not been convinced, and the issue is as yet unresolved.

In another line of work (e.g., Bryden, 1967; Heron, 1957), it has been shown that there is an asymmetry of accuracy of report across the fixation point. When a single letter appears either to the right or left of fixation, it is reported more accurately when on the right side, presumably because it projects to the left, language processing cerebral hemisphere. The recent findings of Egeth and Epstein (1972) complicate the issue. They presented a vertically arranged pair of capital letters either 4° to the right or 4° to the left of fixation. The *S*'s task was to respond with a *same* or *different* judgment by pressing a button which recorded re-

action time. When the letters were on the right, the *same* responses were faster than the *different* responses, and the converse was found for letters presented on the left. They attributed this difference to different processing occurring in the two hemispheres. Geffen, Bradshaw, and Nettleton (1972) required *S*s to make name matches as well as visual matches (Egeth and Epstein required only the latter). They found that name matches were faster when the letters were presented on the right visual field as might be expected from the language specialization hypothesis about brain function. However, they did not replicate the *same–different* interaction with visual field side.

This brief review is not intended to be exhaustive but only to show the range of variables relevant to problems of retinal location in information extraction tasks. There are many differences between the procedures of these and other related experiments, some of which are examined in the following studies. In each of the experiments reported, a pair of vertically arranged letters were briefly presented. The *S* had to classify them as rapidly as he could as *same* or *different*. The pair could appear in 1 of 11 locations varying up to 4° on either side of the fixation point. This arrangement permits an examination of the main effect of retinal location and the possible interactions between eccentricity and type of response (*same* or *different*) or visual field (left or right). In one of the experiments, an uppercase and a lowercase letter were always paired; *S* was required to make a name match rather than a physical match, thereby permitting assessment of this variable. Finally, one experiment compared the traditional reaction time procedures of using two response keys with that used by Egeth and Epstein (1972) in which *S* used only one button. There *S* was instructed to press a button for *same* and do nothing to indicate *different*, or vice versa.

GENERAL METH[illegible]

Subjects. In each of the experi[illegible]s, *S*s were undergraduate students at the Univ[illegible] of South Carolina who had normal or corre[illegible] vision and were right-handed. Experiment [illegible]d 4 students, Experiment IB used 60 st[illegible]; Experiments IIA and IIB used 34 an[illegible] students, respectively, and Experiments III [illegible] used 20 and 24 *S*s, respectively.

Stimuli and procedure. The stim[illegible] were pairs of letters presented directly abo[illegible] another. They were black Paratype uppercase [illegible] (11126). At a distance of 86 cm., they e[illegible]ubtended about .35° vertically and horizont[illegible] The vertical distance between the two le[illegible] was .15° (except in Experiment IIA; see below [illegible]e letters chosen were from zero-order appro[illegible]tion lists of letters. On half of the trials, th[illegible]uli were the same two letters; the remainin[illegible]als were two different letters. A background [illegible]nnel was always on except during the presen[illegible] of the letter pair. The luminance level in b[illegible] channels was equated at 2 ftL.

Upon introduction to the laborato[illegible] *S*s were informed about the nature of the tas[illegible] stimuli and were instructed to fixate on th[illegible]entrally located fixation spot. The stimuli [illegible] fixation were presented in a Gerbrands [illegible]stoscope (Model T-4B). Upon initiating a trial, [illegible]50-msec. stimulus would appear and a clock counter (Electronic Research Mfg., Model 2600) would start. The *S*s responded by pushing one of two buttons each 3.12 cm. from the start button and 3 cm. from each other. The *S*s used their index finger of the preferred hand for starting the tachistoscope and stopping the reaction time clock. The *S*s were counterbalanced across response buttons and each received one block of trials which were considered practice and not included in data analysis.

EXPERIMENT I

The main variables of study were the 11 different retinal locations and *same* or *different* judgment. These 22 experimental trials were arranged in blocks in a random order and repeated in a different order 10 times per *S*. The *S*s were first presented with one block of 22 trials which were considered practice, and then tested on the 220 experimental trials. Each *S* participated for seven sessions. The study was then replicated (Experiment IB) using many more *S*s with eight observations per *S* per condition, collected in only one session. In Experiment IA, all letters were used with random assignment to retinal locations. In IB, only the letters

O, A, N, F, I, C, T, R, and S were used, and they were counterbalanced over locations. In Experiment IA, the letters were placed at fixation or at .5°, 1°, 2°, 3°, or 4° either to the left or right of fixation. Experiment IB used the same locations except that the 4° location was replaced with 3.5°.

Results

The Ss made 7% and 5% errors in the two versions of the experiment, respectively; these trials were excluded from the reaction time analyses. Reaction times were scored and summed for each *S* across the conditions and entered into an analysis of variance, a different one for both versions of the experiment. In neither experiment was any main effect or interaction found with visual field side, nor were practice effects significant. The left side of Figure 1 plots these results; the right side collapses over visual field since that variable produced no effects or interactions in either version.

Judgments of *same* or *different* were equally fast—only a 2-msec. difference in both experiments. The different retinal positions, however, produced quite different reaction times, F (4, 12) = 29.2, and F (4, 236) = 36.7, respectively, both $p < .001$. In both experiments, retinal location and *same–different* response interacted, and in virtually the same way, as can be seen on the right-hand side of Figure 1, F (4, 12) = 3.3, $p = .03$, and F (4, 236) = 27.5, $p < .001$, respectively. Three of the reaction times near fixation for the *different* responses were slower than those of the *same* responses. In the eight other cases the *same* responses were slightly faster than the *different* responses.

Trend analysis applied to these data showed significant linear effects in both experiments for the position of the stimulus on the retina, F (1, 3) = 42.6, $p < .001$, and F (1, 59) = 101.6, $p < .001$, respectively. In Experiment IA, retinal location produced a quadratic component, F (1, 3) = 14.3, $p < .001$, and in Experiment IB, a cubic component was evidenced,

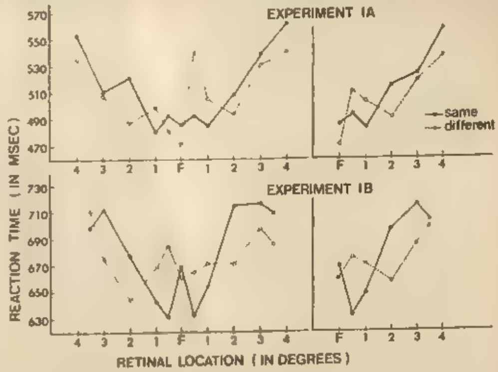

FIGURE 1. The mean reaction time (in milliseconds) is plotted as a function of the retinal location of the stimulus pairs in Experiment I. (The left panels show the data for all 11 locations, the right panels collapse the data over visual field of presentation.)

F (1, 59) = 8.2, $p < .006$. A critical trend is the interaction of the linear components of *same–different* judgments and retinal location—in both experiments these interactions were significant, F (1, 3) = 7.8, $p < .006$, and F (1, 59) = 27.3, $p < .001$. There were other significant and highly complex trends evident—in Experiment IB, the *same–different* linear component interacted with the retinal location quadratic component, F (1, 59) = 25.0, $p < .001$, and the left–right visual field linear component and the retinal location quadratic component also interacted, F (1, 59) = 10.5, $p < .001$. The triple interaction of the *same–different* and left–right linear components interacted with the cubic component of retinal location, F (1, 59) = 4.5, $p = .03$. These two interactions are highly complex, difficult to interpret, and account for a small portion of the variance (3.8%) relative to the linear trend of retinal location (51.8%) and the two-way interaction of *Same–Different* × Retinal Location (14%).

An analysis of the reaction times for erroneous responses was also undertaken. In general, error responses mirrored correct responses in most respects in that longer reaction times were more likely to be associated with errors. Thus, more errors were made for more peripheral locations. In the second experiment, more

errors were made for the *same* responses—8% vs. 2%, F (1, 59) = 62.3, $p < .001$. In both experiments, the frequency of erroneous reaction times produced an interaction between the *same–different* responses and retinal position, just as did the correct responses, F (4, 12) = 5.4, and F (4, 236) = 24.5, ps $< .001$ in both versions. There was a small interaction of Visual Field × Retinal Position in Experiment IB, F (4, 236) = 6.5, $p < .001$. The sum of squares for this interaction accounted for only 1.3% of the total variance.

Discussion

The results from both versions of experiments are consistent. Reaction time increased with peripheral eccentricity. Further, the pattern of errors generally reflected the reaction time data. Thus, where there were increases in reaction time there were corresponding increases in the number of errors. Since the error rate was generally low, *S*s were not making a speed–accuracy trade-off. When the letters were presented 3.5° or 4° in the periphery the processing task was more difficult, *S*s therefore made more errors and, in addition, took longer to process the items.

There was no evidence of an interaction of Visual Field × *Same–Different* responses, the results reported by Egeth and Epstein (1972). However, in Experiment I the letter pairs were separated only by a minimal amount of space. In the study reported by Egeth and Epstein, the letters were separated vertically by 4°. Experiment II was therefore constructed to examine this difference by placing pairs of letters either close together or far apart in either the left or right visual field.

Experiment II

Two vertically arranged letters were presented 3.5° either to the left or right of fixation. They were chosen from the symmetrical letters A, H, I, O, T, U, V, X, and Y. In one condition, the letters were separated vertically by 4°, similar to that procedure used by Egeth and Epstein (1972). In the other, only .15° separated the two letters. In both conditions there were two experimental conditions each with two levels: visual field and the response *same* or *different*. Since there were nine stimulus letters used, there were nine possible *same* combinations. Nine *different* combinations were then arranged and these nine were repeated in the reverse order, that is, with whatever was the top letter being the bottom letter. There were two visual fields, nine different stimuli, two possible responses (*same* compared with *different*), and four replications of each of the possible combinations making a total of 144 experimental conditions. These were arranged in blocks of 36 trials, each block being one replication of the 36 experimental trials. These four blocks were each arranged in a random order. At the end of an experimental session each *S* would have provided 36 measurements for each of the four possible conditions.

Results

There was a great deal of variability with respect to the number of errors made. Some *S*s made many errors, while others made very few. The *S*s were therefore divided into two groups—those *S*s who made 10% errors or less and those who made more than 10% errors. In data analysis, these two groups have been treated separately. However, except in the one instance to be noted, the pattern of results was so similar across error rates, that *S*s have been combined with respect to the presentation of results.

In general, no significant effects or interactions were found with either the wide (3.5°) or close (.15°) vertical separations. Specifically, no hint of a Visual Field × *Same–Different* interaction was apparent in either version, regardless of the error rate. These data are presented in Table 1. There were significantly more errors made on the *same* response for both error groups for both separations.

The results of this experiment confirm those of the first experiment. In this study, when the letters were presented close together so that *S*s could make a physical match, or far apart such that a name match might be made, there was no Visual Field × *Same–Different* interaction.

There [...] been no clear evidence in Experim[...] I, II, or in the Egeth and Epstein (1972) [...]udy that Ss were indeed naming the s[...]uli. Experiment III examined the nam[...] process by using capital and small lett[...] as paired stimuli.

Experiment III

The stimuli for this experiment (A, B, C, D, E, G, T, N, F, P, R, H, V) were [...] different set of letters chosen to reduce [...]he visual similarity between the upper- [...]d lowercases. The *S* was now to indicate [...]he letters had the same name or not. [...]ll other respects this study was iden[...]l to that of Experiment II. The [...]rtical separation was .15°.

Results

All *S*s tested in this experiment produced high error rates, averaging 27%. As in the other studies, the error rate was significantly greater for the *same* responses than for the *different* responses, F (1, 19) = 60.5, $p < .001$.

The reaction time data were treated as in the other experiments. There was a [...]ignificant left visual field superiority, [...] (1, 19) = 5.8, $p < .05$. Overall, the [...]t visual field was responded to 29 msec. [...]ster than the right visual field. There [...]as no difference between the *same* and *d[...]erent* response, nor any Visual Field [...] *Same–Different* interaction. These data are presented in Table 1.

[...]he critical interaction of Egeth and Epstein (1972) remains elusive. When *S*s were presented with stimuli that were named (Experiment III) or not named (Experiments I and II), or when stimuli were close together or far apart (Experiment II), this interaction did not emerge. There is one further methodological point that may be relevant. Egeth and Epstein used a go–no-go technique, in which half of their *S*s were asked to respond by pressing a single button as fast as they could if the letters were the *same* and do nothing if the letters were *different*. The other *S*s pressed if the two letters were *different* and did nothing if they were the *same*.

TABLE 1

Reaction Time (in msec.)

Experiment and condition	Visual field: Left	Visual field: Right
Experiment IIA		
Same	792	788
Different	774	768
Experiment IIB		
Same	783	801
Different	769	786
Experiment III		
Same	988	1,026
Different	967	987
Experiment IV		
Same	567	574
Different	603	600

Experiment IV

Experiment IV is a replication of Experiment II, differing only in that half of the *S*s were told to press the *same* button if the letters were the same and do nothing if they were different. The other half of the *S*s were told to press the *different* button if they were different and do nothing if the letters were the same. The letters were separated by .15°.

Results

The data were treated in the same manner as in the other experiments. Overall, there was a 10% error rate. The analysis of variance showed that there was neither a main effect of *same* compared with *different* nor of the visual field of presentation. The Visual Field × *Same Different* interaction was not evident ($F < 1$). The error rates showed no significant differences or interactions. Thus, except for the overall reduction in reaction time between this experiment and the two-button ones, this methodological change cannot be responsible for the overall pattern of results in these experiments.

General Discussion

One of the main findings of the present experiments was the change in reaction time

that was associated with changes in the retinal location of the stimuli. Experiment I showed that with increases in retinal eccentricity from fixation, judgments of sameness and of difference required more processing time. Both Harcum (1964) and Hershenson (1969) would predict this to be the case—both accuracy and reaction time data should reflect one another. These data do not directly converge on the notion of sensitivity compared with saliency as put forth by Harcum (1970). They do provide data that can be used to estimate the effects of manipulating fixation in other reaction time tasks that have spread letters across a fixation point. For example, a certain number of milliseconds might be subtracted from different retinal locations to examine visual processing uncontaminated by varying retinal locations.

The data provide evidence for a change in processing strategy depending on the locus of stimulation. The *Same–Different* × Retinal Position interaction found in Experiment I shows that at near foveal positions *same* responses are faster than *different* responses; this is a result that has been found many times (e.g., Posner, 1969). As the retinal eccentricity increases, however, the *different* responses come to be faster than the *same* responses. These results, the obtained interactions, and trend analyses support the conclusion that *S*'s strategies may shift to a criterion of sameness or difference as a function of the location of stimulation.

None of the other variables examined by the experiments seemed to be critical. The previously reported interaction of visual field with *same–different* responses was never observed. The only visual field effect found occurred when *S*s had to make a name match, and this was equally strong for both responses. The amount of the vertical separation of the letters did not seem important, nor whether *S*s used two response buttons, or only one with a go–no-go criterion.

Overall the results of the present studies present data to support five main conclusions: (a) When *S*s are engaged in a visual matching task, performance is slower the further the stimuli are from fixation; (*b*) there is a change in the speed of responses for [illegible] responses compared with *different* respon[illegible]e to the fovea; (*c*) there is no differ[illegible] between judgments of sameness or di[illegible]ce with respect to visual field of present[illegible]; (*d*) the only hint of a visual field effect [illegible]ars when *S*s are forced to name the stim[illegible] and (*e*) neither spacing arrangements [illegible] response key arrangements seem to ex[illegible] critical influence on the results.

LINGUISTIC INTERDEPENDENCE OF BILINGUALS [1]

MIKE LÓPEZ [2] AND ROBERT K. YOUNG

University of Texas at Austin

Spanish English bilinguals were first familiarized on a list composed of Spanish or English words. Next they learned a Spanish or an English list consisting of words that were the same as (or translated) or different from those in the familiarization list. Familiarization effects were uniform both between and within languages in that the amount of positive transfer obtained was the same for all groups. The data were interpreted as being supportive of the language interdependence hypothesis.

The unique ability of bilinguals to process information presented in two different linguistic systems has given rise to differing ideas as to the nature of bilingual organization of memory. One of these, the independence hypothesis, assumes that the bilingual has two distinct memory stores, one for each language, with information presented in one language not being readily available to the other system. A contrasting position, the interdependence hypothesis, holds that bilinguals store information in one memory store only (Kolers, 1966). An interdependence hypothesis would assume that bilinguals store words in terms of their semantic features only, with some means of "tagging" the items with the proper language at the time of output.

Although several studies of bilingualism have supported the interdependence hypothesis, support for this position has not been unanimous. Most studies supporting the interdependence viewpoint have demonstrated a bilingual equivalence effect, wherein the presentation of an item in one language produces the same effect on recall of that item in the other language as if it had been originally presented in the other language (e.g., Glanzer & Duarte, 1971; Kolers, 1966). Tulving and Colotla (1970), supporting the independence hypothesis, maintain that this equivalence effect is probably due to a well-established habit of translating. Facilitation in the recall of translated items would not be evident were it not for an automatic translation of these items by *S* at the time of presentation. Presumably, this translation habit would be strongest in bilinguals who are not equally proficient in each language, translating from the weaker to the dominant language (Goggin & Wickens, 1971).

The present study was designed to test this translation hypothesis by giving *S*s familiarization trials on items in one language and then having them learn, by free recall, the same items in translation. If the bilingual's two languages represent two independent systems, there should be no familiarization effect at all, unless *S*s actively translate the items. However, this translation should result in facilitation of learning of items in the stronger language only, after they have been familiarized in the weaker language. There should be no facilitation effect for items familiarized in the strong language and learned in the weak language, since *S*s would have no reason to translate in this direction during familiarization.

The interdependence hypothesis would predict facilitation of learning in all cases. If the familiarization of a word or its translation results in the activation of the same semantic representation, then this familiarization should result in an equal facilitation of learning, regardless of whether or not learning is in the same language as familiarization, and regardless of which language is dominant.

TABLE 1

Mean Numbers of Items Recalled Per Trial

List language	Familiarization language: English	Familiarization language: Spanish
Experimental		
English	12.38	11.91
Spanish	10.25	11.39
Control		
English	11.15	11.35
Spanish	9.16	8.79

Method

Subjects. The *Ss* were 64 Mexican-American high school juniors and seniors, bilingual in English and Spanish, who volunteered to serve in the experiment. These *Ss* were asked to rate themselves on a number of variables related to language learning and fluency. Assignment of *Ss* to conditions was by a predetermined random sequence according to order of appearance in the experimental room.

Design. The *Ss* first read a 16-word list in English or Spanish and then learned a 16-word list in the same or the other language. In the experimental conditions, the second list consisted of the same words that were in the familiarized list, in the same language or translated to the other language. In the control conditions, the first-list words were unrelated to the words to be learned. Two *Es* tested the *Ss*. The design can thus be summarized as a 2 × 2 × 2 × 2 factorial design with a within-*Ss* variable of 10 free-recall trials (n = 4/cell).

Materials. The verbal materials used in the experiment were selected by asking 51 students from the same school as the experimental *Ss* to translate 100 common adjectives from English to Spanish or vice versa. Two different forms were used to counterbalance for direction of translation of the adjectives. The 32 adjectives most often translated correctly composed the four lists used in the study. None of the students asked to provide these translations served in this experiment.

Procedure. Each of the four 16-item lists was typed on a plain sheet of typing paper. As each *S* entered the experimental room, he was told by *E* that before the experiment started, *E* would like to hear *S* read a list of words. The *Ss* were then required to read the list aloud for six repetitions. Following the sixth repetition, *S* was told that the experiment could now begin and was read standard free-recall instructions. All *Ss* were then given 10 trials on the list. Stimuli were presented auditorily on tape at a 2-sec. presentation rate. Recall was oral with a 90-sec. recall interval. Order of presentation of the words was randomized across the 10 trials, and none of these orders corresponded to the order of the or al list read by *Ss* in the experimental conditio

Results

The *Ss* rated their fluenc each language on a 1–7 scale. The n English rating was 4.97, and the m rating of Spanish fluency was 3.77. addition, *Ss* indicated that they had sp English and Spanish for 13.27 and 53 years, respectively. Fifty-eight of the 64 *Ss* indicated that they thought English, χ^2 (1) = 34.51, $p < .01$. Th s appear to be compound bilinguals (c Ervin & Osgood, 1965) with English as ir dominant language. That is, these learned both languages at the same ti and in the same context, yet (probal due to a deemphasis of Spanish and a co esponding emphasis on the use of E glish in school) they presently consider th mselves to be more fluent in English.

An analysis of variance was performed on the number of items recalled o er trials. The experimental *Ss* recalled sig ficantly more items than did the controls, (1, 48) = 10.20. English lists were easier to learn than Spanish lists, F (1, 48) = 1 .3. In addition, the trials main effect ached significance, F (9, 432) = 124 All these *Fs* were significant at the .01 level. The Learning Language × Trials interaction was significant, F (9, 432) = 2.54, $p < .05$, as English lists were learned faster than Spanish lists. This is not surprising in view of the fact that for this group of bilinguals English is highly dominant.

A facilitation effect of familiarization was found for all language conditions, and this enabled experimental *Ss* to recall significantly more words than control *Ss*, as previously noted. Inspection of Table 1 reveals that there was not the expected differential facilitation that would have been predicted by a translation hypothesis. That is, familiarization of a Spanish list followed by learning the English equivalents does not result in a greater facilitation, relative to control items, than does familiarization of an English list followed by learning of the Spanish equivalents.

This differential facilitation would have been manifested in significant Familiarization Language × Learning Language and Familiarization Language × Learning Language × Condition interactions. These interactions were not significant, $Fs\ (1, 48) = .36$ and 1.62, respectively.

DISCUSSION

The results of the present study support an interdependence hypothesis of bilingual organization of memory. A positive transfer effect of familiarization was produced in all combinations of familiarization list language and learning list language, both intralingual and interlingual. The positive transfer in the interlingual combinations is especially revealing in view of the fact that there was no significant Familiarization Language × Learning Language interaction. That is, these English-dominant bilinguals did not show a significantly greater facilitation in the Spanish to English conditions vs. the English to Spanish conditions, as they should have if a translation hypothesis of the bilingual equivalence effect is to be accepted.

The greater difficulty *Ss* have in learning Spanish lists relative to English lists can be attributed in part to the learning history of these *Ss*. In school they are expected to learn in English, not Spanish. Consequently, they have not developed the elaborate coding strategies in Spanish that are necessary for rapid acquisition of verbal material.

Finally, it should be noted that a single semantic store for bilingual memory that is supported by this experiment does not exclude the possibility that other components, notably the syntactic and phonological components, of a bilingual's linguistic systems are independent. This aspect of bilingualism has been closely investigated by Macnamara (1967).

ROLE OF HIGHER ORDER RULES IN PROBLEM SOLVING[1]

JOSEPH M. SCANDURA[2]

University of Pennsylvania

Why do some problem solvers succeed on problems for which they have all the necessary component skills, whereas others do not? It was assumed that a major portion of problem-solving ability can be traced to the presence or absence of higher order rules which make it possible to generate solution procedures. Experiments I and II were designed to test a simple problem-solving mechanism by which lower and higher order rules interact. Experiment I involved a composition higher order rule and Experiment II, a higher order generalization rule. Results were over 98% consistent with theoretical predictions concerning the behavior of individual *Ss* on specific problems. In Experiments III and IV the presence or absence of higher order rules was determined indirectly through testing. The overall percent correct predictions were 85 and 92 respectively.

One of the most crucial questions in problem-solving research is why some problem solvers succeed on problems for which they have all of the necessary component skills, whereas others do not. In dealing with this question, most studies of problem solving have attempted to deal with the process in its full complexity (e.g., Duncker, 1945; Newell & Simon, 1972). That is, most studies have employed problem situations that involve problem definition (the formation of subgoals), memory, the derivation of solution procedures, and the use of such procedures. The situation is further complicated because existing theories of problem solving are either extremely limited in scope (i.e., to specific kinds of problems) or, if general, are more like overall schemas than strong theories (cf. Greeno, 1973).

The present research has adopted a somewhat different strategy. It seeks to deal separately with the various aspects of problem solving (e.g., the derivation of solution procedures) but in a way which generalizes over tasks. Specifically, this research is not concerned with the role of memory or with problem definition. Precautions were taken to insure that *Ss* fully understood the problems (goals and givens) presented and that they were understood in the way *E* intended. Further, the ongoing research is concerned with a specific falsifiable theory (Scandura, 1973) concerning the behavior of individual *Ss* in particular problem situations, and not with either the performance of groups or of individuals averaged over tasks.

The general point of view adopted is that rules underlie all behavior (e.g., Scandura, 1970). More specifically, this research is based on the assumption that, when the goal adopted by *S* is known, a major portion of problem-solving ability can be traced to the presence or absence of higher order (HO) rules. These rules may be used to combine constituent parts of a problem solution into a coherent whole adequate for solving the problem (cf. Saugstad, 1955) and/or to otherwise generate solution procedures from known rules.

In this context, the question arises as to how known rules interact in problem solving. It is hypothesized that in problem solving (as in all learning) rules interact according to a fixed mechanism, which is presumed to be innate rather than learned (Scandura, 1973). This mechanism is

[1] This research was supported in part by National Science Foundation Grant GW-6796 and U.S. Office of Education Grant OEG-3-71-0136. Experiment I was conducted with Louis Ackler, Experiment II with Francine Endicott and John Durnin, and Experiments III and IV with Durnin and Wallace Wulfeck. The author would also like to thank Joe Karabinos and Diane Triman, who helped proctor the experimental sessions.

[2] Requests for reprints should be sent to Joseph M. Scandura, University of Pennsylvania, 3700 Walnut Street, Philadelphia, Pennsylvania 19174.

assumed to operate as follows: Given a goal situation ⟨S, G⟩, *S* tests to see if the problem solution is immediately available (i.e., to see if he knows the solution). If not, control shifts to the solution goal (SG), consisting of the set of potential solution rules, and *S* tests the rules available to him to see if any includes S in its domain and the goal in its range.[3] If such a rule is available, control reverts to the original goal and the rule is applied to S. If not, control shifts to the higher level goal (HG), [illegible] of HO rules which apply in the [illegible]n goal situation ⟨S, G⟩ and whose [illegible] contain a potential solution rule. With this higher level goal in force, *S* is assumed to test his available rules as before. If one is found, control reverts to the next lower level goal and the HO rule is applied to other available rules, thereby generating a new (potential) solution rule. If the lower level goal is satisfied by the new solution rule, control reverts to the original goal and the solution rule is applied to S. The problem is solved if the (potential) solution so generated satisfies the goal situation.

It should be noted that testing, goal shifting, and rule application are essentially the same at *all* goal levels. Generalization and formalization of the mechanism is given in Scandura (1973). Furthermore, HO rules are formally identical to other rules and obey the same laws of behavior. The descriptor "higher order" refers to the role of a rule in a particular instance of problem solving, not to its basic nature. This differs from common usage. The term "higher order rule" as used by Gagné (1970), for example, corresponds to the *output* of what is referred to here by this term.

Suppose, for example, that *S* adopts goal G in situation S and has only the following rules available: r_1, r_2 (neither of which satisfy SG), and h, where h (r_1, r_2) = p and p satisfies SG. What can we say about what *S* will or will not do? Given that *S* has adopted goal G in situation S, and only has rules r_1, r_2, and h available, Table 1 shows that the above mechanism provides a sufficient basis for predicting *S*'s behavior. If we changed the situation by eliminating any one of r_1, r_2, or h, we could conclude that *S* would fail. In order to make predictions where training on rules is not a central variable, it is essential to determine what rules *S* knows. Indeed, the general importance of prior knowledge in research on complex human behavior is becoming increasingly clear (e.g., Bourne, Ekstrand, & Dominowski, 1971; Scandura, 1973).

The major purpose of this research was to test this mechanism empirically, both by manipulating HO rules and by testing to determine their availability prior to problem solving.

TABLE 1

SEQUENCE OF EVENTS IN IDEALIZED PROBLEM SOLVING

Event	Theoretical justification
SG = $\{r_i \mid S \epsilon \text{ Domain } r_i, G \subset \text{Range } r_i\} = \phi$ (is empty)	Assumption
∴ Control shifts to HG	Higher level hypothesis
HG contains h	Assumption
∴ Control reverts back to SG and *S* applies h to r_1, r_2 (to get p)	Reversion and performance hypotheses
p satisfies SG	Assumption
∴ Control reverts to G and *S* applies p to S (to get R) R may satisfy G	Reversion and performance hypotheses

Note. See text for explanation of abbreviations used.

[3] This condition is slightly different from that in an earlier formulation (Scandura, 1973). Instead of requiring that the range of the rule contain the goal, I had initially proposed that the range be contained in the goal. While the latter condition works equally as well with initial goals, it is not fully adequate. For example, in the trading game experiment requiring the range of a composition rule to be contained in the higher level goal is overly restrictive because this goal only contains A → Y → C rules (Y variable and A and C constants), whereas the range of the composition rule more naturally includes all composite rules of the form X → Y → Z (where X and Z are also variables).

Experiment I

Experiment I provided a test of the mechanism involving an HO composition rule.

Method

Materials and tasks. The experimental material consisted of tasks involving trading stimulus objects of one kind (e.g., red chips) for response objects of another (e.g., pencils). Each task can be characterized as a set of stimulus-response pairs in which n stimulus objects are mapped into $(n + m)$ response objects (e.g., n red chips into $n + 3$ pencils). Throughout the experiment, $n + m \leq 10$, with $n \leq 7$ and $m \leq 4$.

There were two kinds of rules, *simple* and *composite*, for solving such tasks. Simple rules were represented on 5×8 in. cards. To represent the simple rule which maps n paper clips into $n + 1$ blue chips, for example, a paper clip was glued on the left and a blue chip on the right of the card. Composite rules generate trades in two steps. One composite rule, for example, first changes pencils into paper clips and then paper clips into white chips. Composite rules were represented by taping together two simple rule cards.

A pair of simple rules was said to be *compatible* if the outputs of one of the rules were of the same type as the inputs of the other. Compatible rules can be combined to form composite rules (e.g., the rules denoted "n caramels $\rightarrow n + 1$ toy soldiers" and "n toy soldiers $\rightarrow n + 2$ pencils" can be combined to form a composite rule which maps n caramels into $n + 3$ pencils). The set of compatible pairs of simple rules comprises the domain of an HO rule which maps such pairs into corresponding composite rules. This HO rule was used to define a second, higher level task in which, given a compatible pair (e.g., "n caramels $\rightarrow n + 2$ white chips," "n white chips $\rightarrow n + 1$ pencils"), the goal was to devise the corresponding composite rule (i.e., for converting caramels into pencils).

Subjects, design, and procedures. The *S*s were 31 boys and girls between the ages of 5 and 9. They were run individually and given 25¢ for participating. Seven *S*s were excluded from the experimental comparison, 6 because they passed the pretest and 1 because she failed to learn how to interpret the composite rule cards. At the start of the experiment, each *S* was told that he was going to play a trading game with *E* and was given several sets of objects to trade. The *S* was then taught to interpret simple rule cards and to make trades using the rules represented by the cards. For example, *S* was shown a rule card for trading paper clips for blue chips and *E* explained "no matter how many paper clips I give you, you must give me the same number of blue chips and then add one more." Practice was provided and, if necessary, *E* showed *S* how to make trades of this sort and asked him to repeat what he had been shown. The criterion was three consecutive successful trades. The *E* then gave *S* a set of objects not in the domain of the rule (e.g., two pencils) and asked *S* if he could use the rule to trade pencils for blue chips. Regardless of *S*'s response, *E* emphasized that the rule could be used only to trade paper clips for blue chips.

The *E* then showed *S* a different rule card and asked him to interpret the rule, providing assistance if necessary. Practice continued until *S* reached criterion. Again, *E* emphasized that the rule was restricted to objects on the card. This procedure was repeated using different rules until *S* was able to interpret three consecutive rule cards and use them without assistance. At this point, it was assumed that for *S* simply seeing a simple rule card was equivalent to knowing and being able to apply the rule.

During Phase 2, *S* was taught to interpret and use the composite rules. For example, *S* was presented with a composite rule for trading pencils for white chips together with two pencils. He was told to use the first part (*E* pointed at the first card) to trade the pencils for paper clips. The *S* was required to place the correct number of paper clips on the table. The *E* continued, "Now, use the second part to trade these four paper clips for white chips." This procedure was repeated with different stimuli until *S* performed three consecutive trades correctly. Practice continued with similar rules until *S* interpreted and correctly applied three consecutive composite rules.

The *S* was then given a *pretest* consisting of two parts. First, *S* was presented with new cards representing a pair of compatible rules. Then, *S* was asked to make three trades requiring use of the corresponding *composite* rule. (The *S* was never shown this rule directly, either before or after testing.) For example, an *S* who was presented with the rules "n pencils $\rightarrow n + 2$ pieces of bubble gum" and "n pieces of bubble gum $\rightarrow n + 1$ paper clips" would be presented in turn with various numbers of pencils (e.g., two, four, and one) and asked to trade the appropriate numbers of paper clips. No reinforcement was provided on the pretest.

Those *S*s who consistently failed on the pretest were randomly assigned, in matched pairs, to one of two treatment groups, Group HR, which received training on the HO rule, and Group C, which was the control group. Those *S*s who succeeded on two or more instances of the pretest were given 5 min. of irrelevant instruction (reading a comic book) and were given a posttest, which involved new rules but paralleled the pretest in every other respect.

Each *S* in Group HR was taught the HO rule. The *S*s were first shown two compatible rule cards and asked to interpret each. The *E* then demonstrated how to combine the rules by sliding the rule cards together in the appropriate manner. The *S* was then asked to interpret this newly formed rule, and *E* emphasized that the rules could be combined only because the output of one was the same as the input of the other. Next, *S* was presented with several pairs of rules, some of which were not com-

patible. [illegible] each pair, *S* was required to form the compo[illegible] rule, if possible, and to interpret the newly [illegible] rule but *S* did not actually make trades. [illegible] the randomly interspersed incompatible pairs [illegible] had to indicate that the rules could not be so co[illegible]ned. After performing successfully on five co[illegible]ive (compatible and incompatible) pairs of rul[illegible] *S* was given the posttest. The time required [illegible] *S* on the HO rule was recorded. Each G[illegible] C *S* was asked to read a comic book for the [illegible] amount of time as his matched partner in [illegible]roup HR required to learn the HO rule. Finally, the posttest was administered in the same manner as the pretest to all *Ss*.

[illegible]esults

[illegible] experimental results were relatively [illegible]. Eleven of the 12 HR *Ss* solved [illegible] ree transfer problems. The one *S* who [illegible] after reaching criterion on the HO [illegible] was put through the experimental [illegible]ocedure 1 wk. later. This time he performed perfectly on the posttest (only). All 12 control *Ss* failed uniformly on the posttest. The individual results are summarized in Table 2.

Although statistical comparisons between groups seem inappropriate, reliability of the percent correct predictions may be expressed in terms of confidence intervals (for the HR group). Based on the assumption that correct and incorrect predictions [illegible]re binominally distributed and using the [illegible]tained mean of 91.7% to estimate the [illegible]pected percentage of correct predictions [illegible] Group HR, the 68% confidence interval [illegible] between 83.9% and 99.5%.

Note. The + indicates that *S* reached criterion [illegible] that he did not. The *Ss* are identified according to age (5, 7, 8, and 9) and sex (B, G).
a Upon readministration of the HR treatment, this *S* required 2 min of instruction [illegible] reached criterion.

EXPERIMENT II

The purpose of this experiment was to test the mechanism proposed above with two different and more complex HO rules of varying generality. Both involved generalization from a restricted rule to one that was more general. To help make it easier to identify common and disparate features, the method description parallels that of Experiment I.

Method

Tasks and materials. The experimental tasks involved responding with appropriate numerals to given stimulus numerals. Each task can be charac-

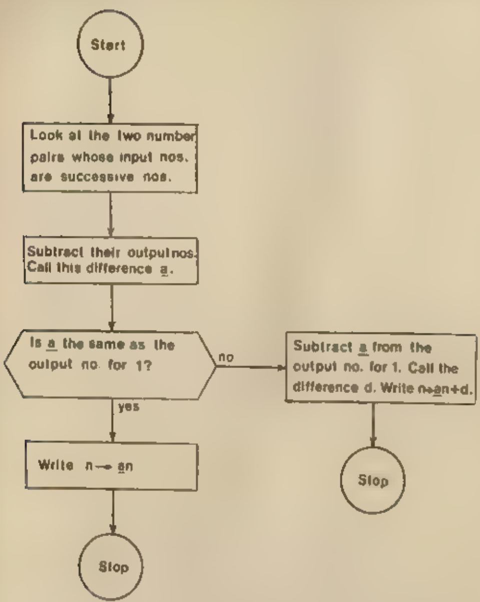

FIGURE 1. Flow diagram for the higher order finite differences rule which acts on restricted rules and generates rules of the form $n \rightarrow an + d$.

terized as a set of stimulus–response pairs in which each number n is mapped into a number of the form $an + d$, where a and d are whole number constants (e.g., n into $4n + 13$). In addition to the above, the domains of the *restricted* tasks contained exactly three numbers, 1 together with (any) two consecutive numbers (e.g., 8 and 9). Restricted tasks were represented as triples which also designated the underlying rules. Triples were always presented to *S*s together with the three input numbers; the pairs were printed on the left of a sheet of paper and the inputs on the right. The rules underlying the *unrestricted* tasks were of two types. The an rules simply involved multiplying the input numbers by a (i.e., $d = 0$). The $an + d$ rules involved both multiplication and addition (of d).

Two HO generalization rules were identified. Both HO rules act on restricted rules (triples) and generate output rules of types an and $an + d$, respectively. A flow diagram for the more general finite differences (F) rule is given in Figure 1. The division (D) rule is similar. Both HO rules partition the class of restricted rules into two equivalence classes consisting of an rules and $an + d$ rules, respectively. The D rule only generates an rules, whereas the F rule generates $an + d$ rules. (The D rule may also be viewed as having a limited domain consisting of only those restricted rules in which the output of 1 equals the quotient of the output in one of the other pairs divided by its input.)

Subjects, design, and procedure. The 80 *S*s were students in Grades 5–12 of Catholic and public schools of Philadelphia. They were run individually. Eight *S*s were eliminated because they were unable to do simple arithmetic computations. The experiment was also terminated early (to ensure equal n in experimental groups and save *E* time) with 12 more *S*s who were able to solve an problems but not $an + d$ problems on the pretest (Phase 3 below).

Experiment II was also run in the following five phases:

1. *S* was presented with triples of number pairs and shown how to interpret them. He was instructed "to write the output that goes with each input according to the triple." The criterion was two correct solutions in succession.

2. The *E* introduced rules of the form $n \rightarrow an + d$, gave one example of a general rule where $d = 0$ and one where $d > 0$, and stated that for every triple there is a rule of the form $n \rightarrow an + d$, which "fits" the triple. The *S* was told: "A general rule fits a triple if, when you use the rule on the input numbers...you get the same outputs as in the triple." The *S* was taught how to check whether a rule fits a triple and practiced checking with four different rules, two $an + d$ and two an. Then *S* was presented in turn with 6 pages, each containing a rule, a triple, and two–four inputs not in the triple. He was told to "find what output goes with each new input number according to the rule." This involved first checking to determine whether the given rule fits the triple and, if so, to use it to compute the output for each new input. The criterion was four consecutive correct problems.

Just prior to the pretest *E* summarized for *S* what he had learned. That is, there are two ways to find the output for a given input of a triple: (*a*) look at the triple to see what the output for that input is, and (*b*) use a rule, which fits the triple, to compute the output for the input. The *S* also was reminded how to check whether a rule fit a triple; and, that, given a triple and a rule that fits the triple, the outputs for new inputs can be computed via the rule.

3. The *S* was given a pretest consisting of four randomly sequenced transfer problems, two an and two $an + d$. Each problem consisted of a triple and three new inputs (but no rule). The *S* was instructed to "find out what output goes with each new input according to a rule...which fits the triple." If *S* solved one but not both problems of Type an ($an + d$), he was given another problem of that type. If he solved it, he was given the unsolved problem again. Under these conditions, if *S* solved the original two problems, he was considered able to solve that type in general, otherwise not. When *S* encountered difficulty on the pretest, *E* explained that the task was difficult and provided encouragement. Based on pretest results, *S*s were categorized into three classes: none—unable to solve either type of problem; AN—able to solve an but not $an + d$ problems; and AN + D—able to solve both an and $an + d$ problems. The none class was randomly divided into three groups: C—*S*s receiving no HO rule training; D—*S*s taught the D rule; and F—*S*s taught the F rule. Class AN was

rand[illegible]ided into Treatment Groups D and F. The AN + D Ss effectively knew the identified HO rules and were unassigned.

4. Each S assigned to Groups D or F was told, "I will teach you a procedure which can be used for some kinds of triples to find a general rule... which fits the triple." On each HO task S was presented with a triple and required to construct a rule that fit the triple. A description of the appropriate HO rule was placed on a stand in front of S, and E worked through two HO practice tasks with S. Then S was presented in turn with six more HO tasks and required to reach a criterion of four correct solutions in a row. The Classes C and AN + D Ss (the latter solved all pretest problems) received no treatment. Just prior to the posttest E again summarized what S had learned, adding for Ss in the HO treatment groups: "You know a procedure which can be used for some kinds of triples to find a general rule... which fits the triple... refer to this procedure whenever you wish." The HO rule remained in front of S during the posttest.

5. The posttest involved new transfer problems but paralleled the pretest in every respect.

Results

Of 60 Ss admitted, 50 were placed in the five experimental groups; 10 passed both the *an* and *an* + *d* problems on the pretest (and the posttest). The experimental results for the 50 Ss were exactly as predicted. No S in Group C of the none class was successful on either the *an* or *an* + *d* posttest problems. All 10 Ss in Groups D and F, of Classes AN and AN + D, were successful on the AN problems of the posttest and all Ss in Group F of both classes were successful on the *an* + *d* problems.

In short, Ss were successful on posttest problems if and only if they knew how to solve the problems before entering the experiment (given only the restricted rules) and/or they were taught an appropriate HO rule.

Experiments III and IV

Experiments III and IV were conducted to determine the feasibility of predicting the performance of individual Ss on specific problems by assessing Ss' knowledge relative to the HO generalization rules identified. Specifically, could the methods developed in Scandura (1973) be used to determine which parts of the HO rules used in Experiment II were available to individual Ss? And, could this information be used to predict the performance of individual Ss on new problems?

Method

The tasks and rules were as in Experiment II. The materials were six booklets. Booklets 1–3 covered the same material as Phases 1 and 2 of Experiment II. Material for Phase 3, pretest on criterion problems, and Phase 4, training on HO rules, were eliminated. Booklets 4 and 5 were substituted for this material. These booklets made it possible to assess knowledge relative to the HO rules. Because outputs of HO rules are themselves rules, Booklet 4 was used to provide instruction in how to write rules of the form $n \to an + d$. Page 1 read, "to write a rule... in which we multiply the input number by 3 and add 4 to the product, let n be the input number. To multiply n by 3 write $3 \times n$. To add 4 to the product write $3 \times n + 4$." Eight practice problems were given. Booklet 5 tested for the HO rules, "On each page . . . is a triple. Find and write . . . a rule of the form $n \to an + d$ which fits the triple." Four problems followed. Two problems required use of an HO rule for deriving $n \to an$ rules and two problems for deriving $n \to an + d$ rules. Booklet 6 corresponded to Phase 6, the posttest.

Experiment III was run with 17-first year algebra students and Experiment IV, with 9 general math and 11 algebra students, all from West Philadelphia. In Experiment III, Booklets 1–6 were administered during a 1-hr. class period. In Experiment IV, Booklets 1–4 were administered on one day, and a short review booklet and Test Booklets 5 and 6 on the next. Both class periods were 40 min. long. In contrast to Experiment II, instructions were read to classes instead of individuals. Each S had to work at least four problems correctly in each booklet. From 3–5 proctors were available in each classroom. In scoring Test Booklets 5 and 6, problems were divided into two categories, according to whether an *an* + *d* or an *an* rule was involved. If S got both problems of one type in a booklet correct, he was considered successful; otherwise not. Although Tests 5 and 6 both involved HO rules, the difference between them is critical. Predictions were based on the prior availability of appropriate HO rules. An S who could derive *an*, but not *an* + *d*, rules in Booklet 5, for example, was assumed able to solve only transfer problems involving *an* rules.

Results

The results of Experiments III and IV are summarized in Table 3. In all cases, the number of correct, as opposed to incorrect, predictions differed significantly from chance ($p < .05$ for both *an* and *an* + *d* problems in Experiment III; $p <$

TABLE 3

SUMMARY OF GENERALIZATION ASSESSMENT RESULTS

Group	No. successful on assessment test (5)	Proportion correct predictions on transfer test (6)	No. of *S*s *not* successful on assessment test (5)	Proportion correct predictions on transfer test (6)	Total no. of correct predictions	Overall percent correct predictions
Experiment III ($Ns = 17$)						
an problems	7	4/7	10	10/10	14	82
an + *d* problems	2	2/2	15	13/15	15	88
Experiment IV ($Ns = 20$)						
an problems	13	11/13	7	7/7	18	90
an + *d* problems	3	2/3	17	17/17	19	95
Combined ($Ns = 37$)						
an problems	20	15/20	17	17/17	32	86
an + *d* problems	5	4/5	32	30/32	34	92

Note. The numbers in parentheses refer to Booklets 5 and 6.

.001 and $p < .05$, respectively, for *an* and *an* + *d* problems in Experiment IV; and $p < .001$ and $p < .005$, respectively, for *an* and *an* + *d* problems in the combined study; exact probability, Finney, 1948). Although the difference was not reliable, the additional 20 min. provided in Experiment IV appeared to increase precision of prediction on both *an* and *an* + *d* problems (8% and 7%, respectively). Whether or not level of prediction could be further increased is not clear, but this observation tends to support the notion that results of such experiments may be expected to conform to prediction just to the extent that memory-free conditions are realized.

DISCUSSION

Overall, the results of Experiments I and II provide strong support for the postulated mechanism. When the effects of memory are minimized, and *S*'s goals are known to *E*, availability of appropriate higher and lower order rules appears to be both a necessary and sufficient condition for solving transfer problems. Although its importance was not emphasized, ability to determine whether or not a given or derived rule satisfies a higher level goal is also crucial (Scandura, 1973). The results of Experiments III and IV show further how availability of HO rules may be determined through testing and used as a basis for explanation and prediction in problem solving. These results, however, apply only in situations where memory and problem definition are not likely to be involved. Extension of the proposed mechanism to include memory and to some extent problem [illegible]inition is given in Scandura (1973). Empiri[illegible] testing should be a first order of business.

Another feature of this research [illegible]h deserves mention is the possibility of [illegible]matically identifying the basic rules un[illegible]ing a set of problems (cf. Scandura, [illegible]n, & Wulfeck, 1972). In general, the [illegible] (including HO rules) underlying a set o[illegible]blems may be determined as follows: (*a*) [illegible]ect a broad (finite) sample of problems in [illegible]he set and identify solution rules for each problem. These rules provide a sufficient basis for solving not only the sampled problems but all other problems "like" them. The use of such rules corresponds to *reproductive* problem solving (Wertheimer, 1945) and, aside from relative complexity, to performance theories in computer simulation (e.g., Newell & Simon, 1972). (*b*) Identify parallels among the identified rules (e.g., they may involve successive application of simple trading rules, or they may be of the form (*an* + *d*). These "parallels" indicate the presence of higher (and lower) order rules from which the solution rules may be constructed. The composition and simple trading rules of Experiment I (from which the composite rules may be derived) and the generalization and restricted rules of Experiment II (from which the *an* and *an* + *d* rules may be derived) provide examples. This type of analysis (of rule sets) may be repeated as many times as desired. In general, the more basic rule sets obtained in this way make it possible, according to the postulated mechanism (Scandura, 1973), to solve a set of problems larger than originally envisioned and correspond to *productive* problem solving (Wertheimer, 1945).

MEMORY SEARCH OF CATEGORIZED LISTS: A CONSIDERATION OF ALTERNATIVE SELF-TERMINATING SEARCH STRATEGIES [1]

MARY J. NAUS [2]

Wellesley College

The two three-stage memory search models for categorized lists described by Naus, Glucksberg, and Ornstein were investigated in three experiments. Both models assume that memory search is serial and terminates after the probed category has been exhaustively searched. The models differ only in whether memory entrance is assumed to be directed to the probed category or to occur randomly. The latency data in Experiment I support random entrance for two-, three-, and four-category lists. When trained in directed entrance, *S*s in Experiment II showed that along with the greater reduction in search time they obtained with random entrance, additional intercept time is required to locate the probed category in the list. Results from Experiment III indicated that *S*s only use random entrance when the categories in memory are blocked. Sternberg's exhaustive model for single-category lists is proposed to be a special case of this three-stage model.

Sternberg (1966) proposed that the retrieval of information from short, single-category lists in recognition memory is serial and exhaustive. Since memory search is obviously not always exhaustive, what are the characteristics of this exhaustive search?

The task in which Sternberg provides evidence for an exhaustive memory search requires *S* to memorize a short set of items (called the *positive set*). A test item (*probe*) is then presented and *S* is asked to decide if the probe was a member of the positive set. If the probe is a member of the set, a positive or *yes* response is correct; if not, a negative or *no* response is required. Reaction time (RT) is measured for these *yes* and *no* responses. Memory search was considered exhaustive because the slopes for the positive and negative responses were equal. Recently, however, there is some evidence that an exhaustive model of memory search may not adequately describe information retrieval in this task. When the items in the positive set are not members of the same category but can be grouped perceptually (Williams, 1971), syntactically (Clifton & Gutschera, 1971), semantically (Naus, Glucksberg, & Ornstein, 1972), or symbolically (Milles, 1969), *S*s are able to use the categorization to modify the exhaustive nature of their memory search.

In an attempt to precisely describe the search of multicategory sets, Naus et al. (1972) proposed two nonexhaustive search models. Both of these models consider memory search to be a three-stage process rather than the single-stage one Sternberg (1966) implied. Both models assume that (*a*) memory entrance includes both the selection of the to-be-searched categories from the positive set and the transfer of these categories into short-term memory for search (*b*) search is serial, and (*c*) search terminates as soon as the probed category has been exhaustively searched. The two models differ only in their rule for the selection of the to-be-searched categories from the set. In the Directed Entry Model, the category of the probe is used both

[1] This research was submitted in partial fulfillment of the requirements for the PhD degree at Princeton University. Appreciation is expressed to the members of the dissertation committee: Sam Glucksberg, Chairman, Peter Ornstein, Carl Sherrick, Tom Trabasso, and Walter vom Saal for their kind encouragement and many helpful suggestions. This research was supported by U. S. Public Health Service Predoctoral Fellowship 5-F01-MH-44648-02 and by Grant MH-10742 administered through Princeton University with Sam Glucksberg as principal investigator.

to *begin* and to terminate search, such that the number of items searched equals the number of items in the probed category. The Random Entry Model proposes that the categories entered for search are independent of the category membership of the probe. If the items searched first are from the probed category, search terminates after this category has been exhaustively searched. If the items searched first are from a nonprobed category, search continues until the probed category has been completely searched. When Naus et al. (1972) presented *S*s with sets of both one and two semantic categories, the two-category sets showed a slope reduction of 24.8%. This is consistent with the Random Entry Model's predicted 25.0% slope reduction for two-category sets.

The experiments presented here further investigate memory search of multicategory sets. Experiment I extends the number of semantic categories in the sets to three and four to determine whether *S*s continue to use a random entrance process. Experiment II is designed to teach *S*s to use the Directed Entry Model in order to specifically compare the results of a directed vs. random search. Finally, whereas in the first two experiments the categories in the sets were presented in blocked order, Experiment III presents them in random order to determine the generality of random entrance.

Experiment I

The Random and the Directed Entry Models make differential predictions for the number of items searched as a function of the number of categories in the set (K). For the Random Entry Model the predicted percent reduction in multicategory slope equals $[(1.00 - (K+1)/2K)\cdot(100)]$, while for the Directed Entry Model the predicted percent reduction in slope for multicategory sets is $[(1.00 - 1/K)\cdot(100)]$ (Naus et al., 1972). This experiment was designed to determine whether *S*s continue to use random entrance for three- and four-category sets.

Method

Experimental design. A mixed experimental design with three groups of *S*s was used. Group 1C/2C was presented sets of 2, 4, 6, and 8 words, with half of the sets containing words from one category and half containing words from two. Group 1C/3C received sets of 3, 6, and 9 words, with half of the sets containing words from one category and half containing words from three. Finally, Group 1C/4C saw sets of 4, 8, and 12 words, with half of the sets containing words from one category and half containing words from four. Each *S* received all combinations of positive set sizes, response types, and number of categories for his group.

In each multicategory set there was an equal number of words from each category. This restriction, together with the different number of categories in each group, yielded the different set sizes across the three groups. The categories in the multicategory sets were presented in blocked order. Half of the tests were negative and half were positive. Negative probes were only selected from categories represented in each set. The sequence of set sizes, the number and order of categories, the positive or negative test trials, and the serial position of the probes were randomized and counterbalanced over trials.

Stimulus materials. The total ensemble of stimulus words varied across the three groups: Group 1C/2C had a total ensemble of 32 words, 16 animal and 16 girls' names; Group 1C/3C had a total of 48 words, adding 16 musical instrument names to the ensemble for Group 1C/2C; and Group 1C/4C had a total of 64 words, adding 16 vegetable names to the ensemble for Group 1C/3C. The instances of these four taxonomic categories were obtained from the Battig and Montague (1969) category norms, equating the categories for "cohesiveness" based on the mean rank of the words eliciting the categories. The instances of these categories were also equated for mean frequency, number of syllables, and length on the basis of the Thorndike and Lorge (1944) word frequency count. The stimulus words were made into slides and were also printed on index cards for presentation in the free recall learning.

Apparatus. A Kodak Carousel projector, equipped with a Lafayette tachistoscopic shutter, displayed the slides on a translucent screen between the control room and *S*'s Industrial Acoustic Company chamber. Beneath the screen in *S*'s room were a "Y" indicating the position for the *yes* response and an "N," the position for the *no* response. The *S* sat at a small table facing the screen. On the table was an intercom connecting *S*'s room with the control room and a response box containing a small ready light, two microswitch response keys, and two feedback lights. The feedback lights were located 5 in. behind each key. The ready light was mounted between the two response keys. The response keys were connected to a digital klock-

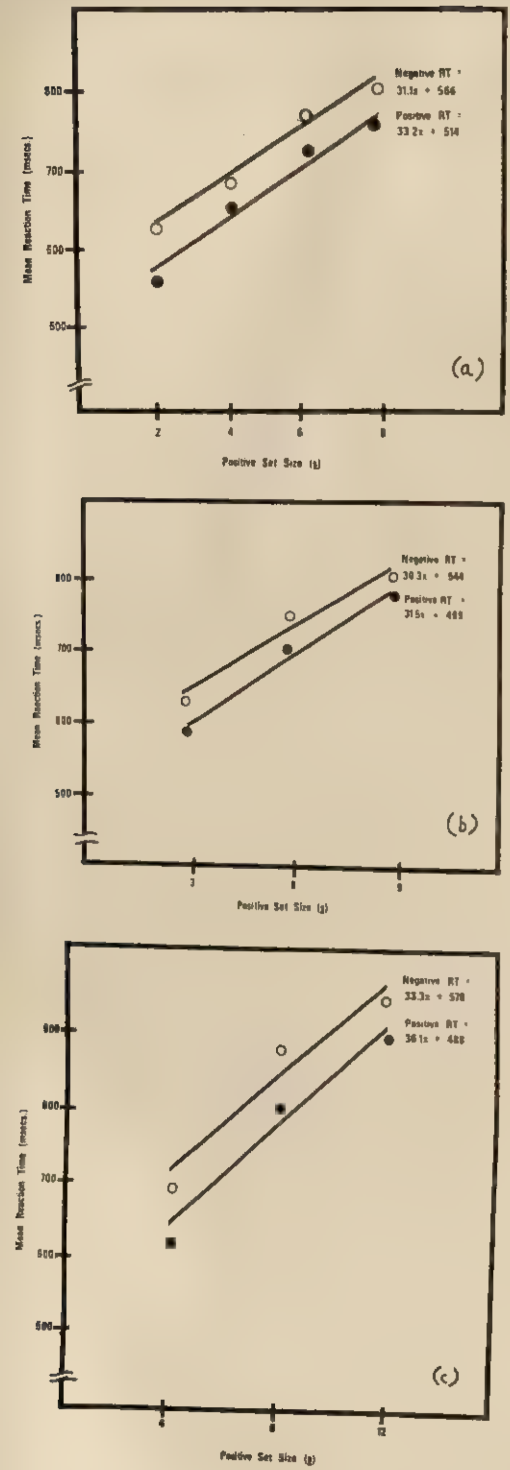

FIGURE 1. Mean reaction time (RT) as a function of positive set size for one-category sets for (a) Group 1C/2C: Experiment I, (b) Group 1C/3C: Experiment I, and (c) Group 1C/4C: Experiment I.

kounter and two signal lights to i e to *E* which key was pressed. The projector, r, and ready and feedback lights were controll Tally Tape Reader. All presentation interva l light durations were controlled by electro ical timers.

Procedure. The procedure wa same for all three experimental groups. In ea ur sessions, *Ss* were initially shown the stimul rds on cards and were instructed to memori recall the words in any order. At least 90 call was required. The *S* then received t recognition–memory instructions used by Stern (1966), and was also told that the categorized rds he had just memorized would be used in t e sets. Each trial of the RT task followed a fication of Sternberg's fixed-set procedure, wit set changing after every eight tests.

The number of tests per 60-min ion varied across the groups: Group 1C/2C re l 280 tests per session, Group 1C/3C received nd Group 1C/4C, 224.

Subjects. Eighteen right-handed me om Princeton University were paid $10 each t as *Ss*.

Results and Discussion

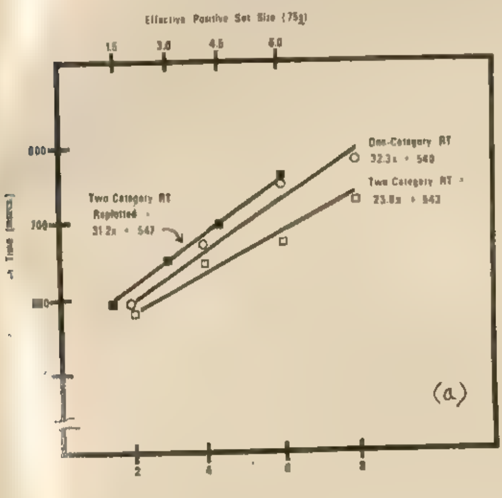
Since primary interest was in mptotic, error-free performance, only sion IV data for correct responses are eported. The error rates were between .9% and 2.2% for both the one- and mul ategory sets for all three groups. These e ror rates did not significantly differ from on another. There were also no differences in error rates for positive and negative respons

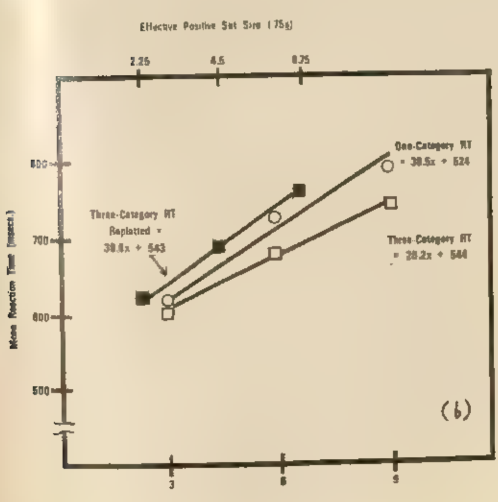
One-category results. The one-category results were consistent with those reported by Sternberg (1966) for all three groups. These data are summarized for Groups 1C/2C, 1C/3C, and 1C/4C in Figure 1a, 1b, 1c, respectively. Mean RT increased significantly with positive set size, the positive and negative slopes were equal, and the positive RTs were reliably faster than the negative RTs.

Category effect: Means and variances. To assess the effect of taxonomic categories on RT, the one- and multicategory sets in each group were submitted to separate analyses of variance. For all groups, the mean RTs for multicategory sets were reliably faster than the mean one-category RTs, indicating that *Ss* used the categories to modify their search strategies. Specifically, these one- and multicategory differences in mean RT were a decrease in the multicategory slopes, as reflected by significant Number

of Categories × Positive Set Size interactions for each group.

To determine if *S*s were specifically using the Random Entry Strategy, the slopes and intercepts for the one- and multicategory sets were directly compared. These comparisons were applied to data pooled over positive and negative trials because there were no reliable Positive–Negative × Categories interactions. These data are summarized in Figure 2a, 2b, and 2c. When the one- and multicategory data are based upon the size of the set actually presented (*s*) the one- and multicategory slopes differed reliably from one another for all of the groups: for Group 1C/2C, $t\ (5) = 8.86$, $p < .01$; for Group 1C/3C, $t\ (5) = 12.80$, $p < .01$; and for Group 1C/4C, $t\ (4) =$





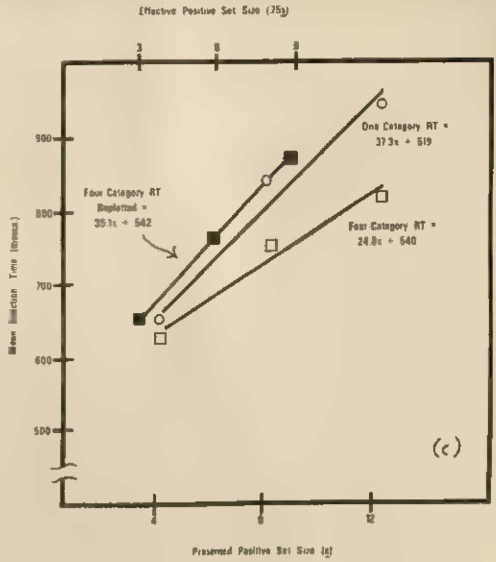


FIGURE 2. Mean reaction time (RT) as a function of presented positive set size for (a) one- and two-category sets and mean RT as a function of effective positive set size for two-category sets: Experiment I, (b) one- and three-category sets and mean RT as a function of effective positive set size for three-category sets: Experiment I, and (c) one- and four-category sets and mean RT as a function of effective positive set size for four-category sets: Experiment I.

15.83, $p < .01$. The obtained percent slope reduction was 26.3 for two-category sets, 33.8 for three-category sets, and 35.7 for four-category sets. These obtained percent slope reductions are consistent with the predictions of the Random Entry Model.

While the average data are consistent with the Random Entry Model, it is important to determine if this model was used by the majority of *S*s. In Group 1C/2C, four of the six *S*s had one-category–two-category slope differences which were within the 95% confidence limits of a 25.0% slope difference. In Groups 1C/3C and 1C/4C only S_6 in Group 1C/4C did not show results consistent with the Random Entry Model.

Further evidence in support of the Random Entry Model may be obtained from the distribution of RTs. Since the Random Entry Model asserts that the RTs for multicategory sets are an additive combination of the time required to search proportions of the set ranging from one to

K categories, the multicategory variances can be predicted based upon the obtained one-category variances for sets of different sizes. The equation for predicting two-category variances presented by Naus et al. (1972) can be extended to three- and four-category sets. When an F test was used to compare the obtained and predicted multicategory variances, no differences were obtained for any of the groups.

Category effect: Intercepts. Since the number of items actually presented in the sets does not represent the number of items actually searched given random entrance (Naus et al., 1972), the multicategory sets have been replotted as a function of *effective* set size (see Figure 2a, 2b, and 2c). Given that these replotted slopes and the one-category slopes do not differ, the intercepts can be directly compared. Although the multi- and one-category intercepts did not reliably differ for any of the groups, the magnitude of the difference seemed to be a direct function of the number of categories in the set: on the average 7 msec. for two-category sets, 22 msec. for three-category sets, and 34 msec. for four-category sets. A linear regression analysis on the intercept differences as a function of the number of categories in the set yielded a slope of 13.5 which significantly differs from zero, $t\ (30) = 2.14$, $p < .05$. This increase in multicategory intercept as a function of the number of categories in the sets implies that there is an additional constant operation involved in a Random Entry Search which is directly related to the number of categories in the set. This operation could be the en bloc transfer of each of the to-be-searched categories to short-term memory for search. This proposed transfer process suggests a possible mechanism for the random selection of at least the first category searched: the category in short-term memory when the probe is presented is the category that is searched first. Since the category in short-term memory when the probe is presented has the probability of $1/K$ of being the probe category this hypothesis predicts that the Random Entry Model requires $\sum_{i=0}^{K-1} i/K$ transfers, each costing 13.5 msec. in intercept time. The multicateg[illegible] intercepts predicted by this hypothesis[illegible]wever, are smaller than those actuall[illegible]tained for three- and four-category s[illegible]suggesting that another "constant" op[illegible]ion is also involved.

Given that the Directed [illegible] Model is more efficient in reducing t[illegible]umber of memory comparisons and th[illegible]s seem to use a directed entry search f[illegible] large categorized sets (Okada & Burrow[illegible]1973), why do Ss use the Random Ent[illegible] Strategy? The data from S_6 in Group 1[illegible]C suggest that a thorough comparison of the two models may provide an ans[illegible] to this question. This S's mean da[illegible]upport a directed search. In addition, [illegible]ifference between the one- and four-ca[illegible] intercepts, where the four-category[illegible]ercept is determined as a function of [illegible] Directed Entry Model, is 130 msec[illegible]hus, the Directed Entry Model seems [illegible]chieve a larger reduction in the numb[illegible] items searched only at the cost o[illegible]dditional intercept time, such as the ti[illegible]equired to select the probe category f[illegible] the set prior to search.

Experiment II

Method

Experimental design. The Ss were either in Grou[illegible] 1C/3C or 1C/4C. These groups were divided into the regular and the directed-entry instruction conditions. The regular instruction Ss were given the same instructions as in Experiment I. The directed entry Ss were instructed and taught to use the Directed Entry Model. The instructions stressed directed selection of the probed category prior to search onset. To aid Ss in using the Directed Entry Model, they were also provided with an auditory presentation of the probe category prior to the presentation of the probe. This auditory category cue occurred simultaneously with the onset of the warning signal, about .8 sec. prior to the presentation of the probe.

Procedure. Initially both instruction conditions received the free recall task and the recognition memory instructions described in Experiment I. In addition, for the first three sessions, Ss in the directed-entry instruction condition received instructions that stressed the direct selection of the probed category prior to search onset and that informed them that the probe category would be auditorily presented prior to the presentation of the probe to aid in their memory search of only the probed category. Session IV did not differ for directed-entry and regular instruction Ss.

Subjects. [T]welve right-handed undergraduate men from [Prin]ceton University were paid $10 each for servi[ng as] [S]s.

Results [an]d Discussion

Bot[h] [S]essions III and IV data are considere[d] [b]ecause of the differential treatment in th[e] [d]irected-entry instruction condition. The [e]r[r]or rates for these sessions for one- and [mu]lticategory sets ranged 1.9%–2.7% for [bot]h positive and negative trials. These err[or] [r]ates did not reliably differ for any of th[e] [ce]lls of the design.

[One-]category results and category effect for re[gu]lar instructions. The one-category re[s]u[lts] for both groups and instruction c[on]ditions supported those reported by [Ste]rnberg (1966). The regular instruction [con]dition was a control condition and repli[ca]ted Experiment I, showing a slope reduction of 33.9% for Group 1C/3C and 38.0% for Group 1C/4C.

Category effect: Directed-entry instructions. In order to determine if *S*s in the directed-entry instruction condition used the Directed Entry Model to search the multicategory sets, separate linear regression analyses were conducted for Groups 1C/3C [a]nd 1C/4C for Sessions III and IV. Session [I]II data summarize the effect of directed-[en]try training while it occurred. The ob[tai]ned one- and multicategory slopes dif[fe]red reliably for each group: for Group 1[C/]3C, t (2) = 36.6, $p < .01$, and for Group 1C/4C, t (2) = 39.6, $p < .01$, with the obta[i]ned slope reductions of 70.8% for Group 1C/3C and 76.6% for Group 1C/4C consistent with a Directed Entry Search. Individual *S*'s slope reductions were also consistent with the Directed Entry Model. The variance data, when the predicted multicategory variances are based on the obtained one-category variances for Set Size s/2, were also consistent with directed entrance.

During Session IV, *S*s no longer received instruction or training in the use of the Directed Entry Model. Although the obtained one- and multicategory slopes differed reliably for both groups—for Group 1C/3C, t (2) = 9.4, $p < .01$, and for Group 1C/4C, t (2) = 39.11, $p < .01$—there was a difference in obtained slope reductions between the groups. The obtained slope reduction of 34.0% for Group 1C/3C was consistent with the Random Entry Model, whereas the obtained slope reduction of 76.4% for Group 1C/4C supported a Directed Entry Search. For both groups, individual *S*'s slope reductions were consistent with these averaged results and the variance analyses supported the findings obtained with mean data. Thus, in contrast to Group 1C/3C, where *S*s returned to the use of the Random Entry Model when training and instruction were discontinued, Group 1C/4C *S*s continued to use the Directed Entry Model during Session IV.

Direct comparison of the one- and multicategory intercepts again requires that multicategory intercepts be reestimated as a function of effective set size based upon either directed or random entrance. The one-category and reestimated multicategory data are summarized in Table 1. Since there were no reliable differences between one-category and reestimated multicategory slopes, the intercepts can be directly compared. When *S*s used the Directed Entry Model, there was a large increase in multicategory intercept: on the average 140 msec. for three- and 185 msec. for four-category sets.

Comparison of the models. An in-depth comparison of these models may answer two important questions. Why do *S*s not always use the Directed Entry Model to search the multicategory sets since it leads to a greater reduction in memory comparisons, and why is there a differential effect for Groups 1C/3C and 1C/4C during Session IV of this experiment?

The Directed Entry Model leads to a large increase in multicategory intercepts as well as to a large reduction in the number of memory comparisons. Two processes seem to be included in these multicategory intercepts. First, the Directed Entry Model requires time to transfer the probed category to short-term memory. Assuming that this transfer only occurs if the probed category is not already in short-term memory when the probe is presented, on the average $1 - 1/K$ transfers are required. Second, the additional intercept time could

TABLE 1

* $p < .01$.
** $p < .001$.

be the time required to select the probed category from the set prior to search. If this category selection is considered to be a serial matching operation between the category of the probe and the categories in the set, this operation would be represented by an increase in intercept which is a direct function of the number of categories in the set, approximately 45 msec. per category. Although Williams (1971) has found evidence for a serial and exhaustive category comparison process for perceptual categories, the present experiment does not indicate whether the category comparison process for semantic categories is exhaustive or self-terminating. Together, these two operations add $(1 - 1/K) \cdot 13.5 + (K) \cdot 45$ msec. to the one-category intercept resulting in a predicted three-category intercept increase of about 145 msec. and a four-category intercept increase of about 190 msec. These results support a net-savings hypothesis (Naus et al., 1972) which suggests that *S*s spontaneously use the Random Entry Model because in this experiment it is more efficient in *overall* time savings. However, one would suspect that, with additional categories and larger set sizes, the Directed Entry Model would become the more efficient.

In addition to the Random Entry Model's overall time savings in the present experiments, the demands of this experimental procedure, such as temporal sequences and *S*'s instructions, may impose a rapid search onset over selective entry. Together with the net-savings hypothesis this reason might provide an explanation for the differences between Groups 1C/3C and 1C/4C in Session IV. In the regular instruction condition, this task may favor a random search onset for both Groups 1C/3C and 1C/4C, even though the set sizes in the [illegible] condition are large. The training [illegible] in the directed-entry instruction condition modified the task demands sufficiently to favor directed entrance for both groups. However, after training was discontinued, the strategy used to search the multicategory sets depended upon the size and number of categories in the sets.

This experiment raises the question of the generality of the Random Entry Model, suggesting the importance of precise specification of the conditions under which it is used. Experiment III was designed to determine if *S*s will continue to use the Random Entry Model if the category exemplars are presented in random order rather than in the blocked order.

EXPERIMENT III

Method

Experimental design. All *S*s were in Group 1C/2C. The stimulus materials, instructions, and number of trials were the same as in Experiment I with the addition of a postexperimental questionnaire at the end of the last session.

Subjects. Six right-handed undergraduate Princeton males were paid $10 each for their participation in the four sessions of the experiment.

TABLE 2

INDIVIDUAL *Ss*' SLOPE ANALYSES FOR GROUP 1C/2C: EXPERIMENT III

[a] Consistent with the Random Entry Model's predicted slope difference.

Results and Discussion

One-category results. As in the first two experiments, the Session IV error rates for one- and two-category sets, which ranged 1.0%–.8% did not reliably differ, and the one-category latency data were consistent with those previously reported by Sternberg (1966).

Category effect. When an analysis of variance was completed to assess the effect of taxonomic categories on RT, the mean RTs for two-category sets were reliably faster than the mean one-category RTs, $F(1, 5) = 17.73$, $p < .001$. To determine whether *Ss* were using the Random Entry Model to search the two-category sets, regression analyses were applied to data pooled over positive and negative trials because there was not a reliable Categories × Positive–Negative interaction. The one-category sets had a slope of 31.3 and an intercept of 498 msec. The two-category sets had a slope of 27.8 and an intercept of 505 msec. When the one- and two-category slopes were compared, they did not reliably differ, showing a slope reduction of 11.2%. However, analysis of the postexperimental questionnaire indicated that *Ss* could be divided into two groups. Four of the six *Ss* (*Ss* 1, 2, 3, and 6) reported actively operating upon the random two-category sets to reorganize them into category blocks. Instead of rehearsing the items in the presented order, these *Ss* described reorganizing the positive set items into category groups and rehearsing the items in these blocks. In contrast, the remaining two *Ss* wrote that they did not reorganize the positive set items into groups by category, but memorized the items in their presented order. The individual *S*'s Session IV data with *Ss* grouped as "reorganizers" and "nonreorganizers" are presented in Table 2. The reorganizers one- and two-category slopes differed reliably, $t(3) = 7.23$, $p < .01$, yielding a slope reduction of 25.6%. All individual *S*'s results were also consistent with the Random Entry Model's predictions. In contrast, neither of the nonreorganizers had one- and two-category slopes which reliably differed from one another.

This experiment suggests that memory search strategy selection, at least the use of the Random Entry Model, is influenced by the form of the input. Clifton and Gutschera (1971) showed that presenting two-digit numbers in blocked order, where the category is defined by the tens digit, greatly facilitated the use of a hierarchical search. However, randomizing the digits did not completely eliminate a hierarchical search. The Random Entry Model differs from a digit hierarchical search in that it seems to *require* that the items be stored in memory in blocked categories. Speculatively, this blocked storage might be required for the en bloc transfer of the categories to short-term memory for search. Since all *Ss* did not block the categories in the set in order to use the Random Entry Model, this implies that the selection of a memory search strategy is an option available to *S*, i.e., an *S*-controlled process rather than a structural memory feature (Atkinson

& Shiffrin, 1968). This indicates, as recently demonstrated by Hunt, Frost, and Lunneborg (1973), that individual difference variables may be very important in investigations of memory search.

General Discussion

These experiments suggest that memory search is a three-stage process. When the number of items in memory is small and the items are all members of the same category, results are consistent with Sternberg's (1966) exhaustive search model. This model, however, is proposed to be a special case of the more general three-stage model presented here. The single stage results because with small, one-category sets memory entrance is unnecessary and search always terminates after the complete positive set has been searched. In contrast, when the sets are large or can be organized into categories, memory entrance becomes necessary and search can be nonexhaustive through the use of category boundaries.

The Random Entry Model requires speculation as to how random entrance might occur. It seems reasonable to suppose that the category which is in short-term memory at test is the category which is searched first. It is more difficult to propose a mechanism for the random selection of the remaining categories for search. Random entrance requires that S knows when he has searched a nonprobed category, but does not use this information to select the probed category from the set. It is as if once S is in a "searching mode" it costs more in either time or effort to switch to a "selection mode" to locate the probed category in the set than it does to search additional categories.

In addition to the two nonexhaustive, three-stage search models presented here, the slope reductions for multicategory sets could be interpreted in terms of a faster comparison model. In this class of models, memory search of the multicategory sets is considered to be exhaustive, but some or all of the memory comparisons are proposed to be made more quickly than in the one-category sets. Assume that the members of the probed category are compared to the probe at the one-category rate (x msec. per item), but the items in nonprobed categories can be compared more quickly (y msec. per item). Thus, when the positive set consists of K categories of equal size, the average search time per item is $x + (K-1)y/K$ msec. The decrease in the time required for search of the [illegible]ed category items would be represented [illegible] decrease in multicategory slope. If it is [illegible]her assumed that the items in the nonprob[illegible]ategories are searched at twice the rate as [illegible]tems in the probed category, this model m[illegible]s the same prediction as the Random Ent[illegible]odel. The nonexhaustive models are curr[illegible]ly favored, however, given that the fast[illegible] comparison models cannot adequately ac[illegible]nt for the intercept and variance parame[illegible] in Experiment I and the increased sl[illegible] reductions obtained in Experiment II. E[illegible]imentation is currently under way to direct[illegible]ifferentiate between these two classes of m[illegible]

DIRECTED FORGETTING AS A FUNCTION OF EXPLICIT WITHIN-LIST CUING AND IMPLICIT POSTLIST CUING[1]

ADDISON E. WOODWARD, Jr.[2]

Governors State University

DENISE CORTIS PARK[3] AND KAREN SEEBOHM[4]

Albion College

Explicit within-list instructions to forget, as well as postlist implicit instructions to forget, were presented within the same list structure to 60 *S*s. The results indicated that explicit forget items were far less likely to be intruded in immediate recall, recalled finally, or recognized on a final recognition test than implicit forget items. These findings support the notion that explicit forget items differ from implicit forget items. Furthermore, while search and retrieval mechanisms may be a viable explanation for phenomena involving implicit forget instructions, differential rehearsal is the most likely explanation for directed forgetting resulting from explicit forget instructions.

The ability of *S*s to differentiate between items that are to be remembered and items that are to be forgotten has merited a significant amount of research (Bruce & Papay, 1970; Elmes, 1969; Epstein, 1969, 1970; Woodward & Bjork, 1971). Various experimental designs have incorporated either implicit (Epstein, 1969, 1970; Shebilske, Wilder, & Epstein, 1971) or explicit (Davis & Okada, 1971; Woodward & Bjork, 1971) instructions to forget in order to investigate directed forgetting in memory. Implicit forget instructions typically ask *S* to exclude some portion of the input from output at the time of recall (Epstein, 1969, 1970). Usually, *S*s are not asked to recall those excluded items, thus the implicit forget label.

Explicit forget instructions are most often incorporated in experiments using item-by-item cuing. The *S*s are presented list items, with each item being followed by either an instruction to remember or an instruction to forget. A final recall test is used to determine the effectiveness of the forget instruction.

Both kinds of paradigms have generated phenomena that have been labeled instances of intentional forgetting or directed forgetting. Presumably, a search for the mechanisms underlying forgetting as a result of implicit forget instructions would also explain forgetting as a result of explicit forget instructions. It is the contention of the present authors, however, that the basic phenomena resulting from implicit or explicit forget instructions are markedly different and, although each paradigm may tell us something about the memory process, neither tells us much about the other.

The present study brings together within a single experiment both implicit and explicit forget instructions. Implicit cuing to forget is defined as any cue that instructs *S*, at the time of output, to disregard part of the input—a situation very similar to the procedures employed by Epstein (1969, 1970). Explicit cuing to forget is defined as any signal or cue, occurring after input but before output, instructing *S* not to remember the item(s) in question. The focus is on the fate of those items with forget instructions at

immediate recall, at final recall, and at final recognition.

The explicit cuing is within-list, while the implicit cuing is postlist. Thus, time of cue is being manipulated in a way similar to Bjork's (1970) Experiment III. The implicit forget (F) items in this experiment are similar to items followed by Bjork's remember yellow:forget yellow instruction which urged *S*s first to remember the yellow items and then later to forget those items. Bjork's forget yellow:remember green instruction is equivalent to items followed by an explicit forget instruction. The present experiment differs from Bjork's in that item-by-item cuing was used, the task was free recall, not paired associates, and a final recall test as well as a final recognition test were administered.

Within each of six lists there were three classes of items: items followed directly by a forget instruction, and two remaining sets of items followed by remember instructions but functionally separate. Each list was followed by one of six recall instructions. If one set of remember (R) items is labeled A, the other B, then the recall instructions include recall only A, recall only B, recall A then B, recall B then A, free recall A and B, and finally, after one list, *S*s were asked to recall all the items, even those followed by explicit forget instructions. Every list then contained a set of items followed by explicit forget instructions. Lists that incorporated implicit forget instructions included the recall-only-A instruction (B items were the implicit F items), and the recall-only-B instruction (A items were the implicit F items). At the conclusion of the experiment a final recall test was administered followed by a final recognition test.

The data of interest include the following comparisons: (*a*) the probability of immediate recall, final recall, and final recognition of explicit F items vs. implicit F items (A items from the only-B condition, and B items from the only-A condition); (*b*) the probability of immediate recall, final recall, and final recognition of explicit F items vs. A items and B items in the recall-all condition; (*c*) the probability of immediate and final recall and final recognition of A items in the o[illegible] A condition vs. the probability of recal[illegible] A items in the A then B condition and [illegible] items in the only-B condition vs. B item[illegible] the B then A condition.

METHOD

Subjects. The *S*s were 60 under[illegible]ate students at Albion College. They partic[illegible]d in order to fulfill introductory course requirem[illegible]

Materials and apparatus. All *S*s were presented six 24-item lists. Words were co[illegible]on unrelated four-letter nouns. Eight randomly [illegible]ected words were followed by a red dot, eight b[illegible] a black dot, and eight by a blue dot. In each li[illegible]uarter, two words each were followed by one of th[illegible]olored dots and the same colored dot did not ap[illegible] more than twice consecutively. The distract[illegible]ns used in the final recognition test were selecte[illegible]m the same pool of words as were the target wor[illegible] The words, the cues to remember and forget, [illegible] the recall instructions were presented on a high[illegible]d memory drum (change time less than .05 se[illegible]ated by a prepunched paper tape which determi[illegible] the length of item presentation and recall time[illegible]

Design. All *S*s saw the same lists o[illegible]ms. Each list was followed by a different outpu[illegible]nstruction. The six instruction conditions were r[illegible]l only A, recall only B, recall A and B, recall A t[illegible]n B, recall B then A, and a special list after which *S*s were to recall all items—A, B, and F.

Item sets were designated by th[illegible] different colors. Each word was followed by either a red, black, or blue dot. Hence, there were two sets of remember items and one set of forget items differentiated by color. Each *S* was initially instructed that two colors designated remember items and one color designated forget items.

Counterbalancing techniques were employed so that, across *S*s, each item served in each of the three conditions. This manipulation occurred as a result of changing the instruction associated with a particular color cue from one *S* to the next. Also, across *S*s, each output instruction occurred at each list position with the exception of the recall-all list which was always paired with the third list. Each list began with a 3-sec. ready signal and ended with a 30-sec. recall period. Each item was shown for 3.3 sec. and each instruction for 1.0 sec.

Procedure. The *S*s were run individually, and in the initial set of instructions they were told that they would see lists of words and that each word would be followed by a colored dot which designated whether the item was to be remembered or forgotten. Their task was to try to recall as many of the to-be-remembered items according to the instructions following each list. They were informed that, following each list, there would be one of six possible recall instructions and were told what these instructions would be and that it would be their

best st… to try to remember R items and to forget … and not to try to anticipate when the spec… recall list would occur—a procedure employ… Reitman, Malin, Bjork, and Higman (197… Bjork and Woodward (1973). Such a proced… was deemed successful by Bjork and Wood…ard in that their *S*s did not appear to antic…te the occurrence of the special list. Explicit …rget instructions existed at the onset of the exper…ent when *S*s were told which of the three colo… designated forget items. Implicit forget instru…ns existed for A items in the only-B condition and … B items in the only-A condition. Although the …itial instructions to *S*s indicated what the lik… recall conditions would be, they did not in… which recall instruction was paired with w… list. Since *S*s did not know how many lists w…d be seen, it seemed unlikely that they would b… able to accurately ascertain what a particular …ll instruction would be.

…he *S*s were given three practice lists, each con…ting of 12 two-digit numbers in order to familiarize …hem with the procedure. The recall conditions …aired with the practice lists included recall A then B, recall A and B, and recall only A. After all of the experimental lists had been presented, *S*s were given a final recall test of both R and F items for as much time as they needed. At this point, *S*s were asked to write down each and every word from the experiment that they remembered, regardless of the items' previous instruction. Following final recall, they were then given a final recognition test consisting of the original 144 items and 144 distractors. Their task was to circle any item previously presented to them again regardless of the item's previous instruction. The immediate recall tests, …he final recall test, and the final recognition test …ere all written. The *S*s were instructed in the …dered recall conditions (A then B, B then A) to …rite down as many of the words to be recalled first … they could, to then draw a line and write down … many of the words to be recalled last as they …uld. The *E* attempted to monitor the recall process in those instances providing a partial safeguard against *S*s who wished to circumvent the instruction.

RESULTS

Table 1 presents the probability of immediate recall, final recall, and final recognition of A, B, and F items. Recall of explicit F words is consistently lower than implicit F words. The probability of intruding F items immediately in the only-A condition was .040, while the probability of intruding B items, items that were not to be recalled either, was .119. A correlated t test indicated this difference to be significant, t (59) = 4.12, $p < .001$. In the only-B condition, explicit F items were intruded with a probability of .031, while A items were intruded with a probability of .117. This difference was also significant, t (59) = 4.24, $p < .001$. When *S*s were asked to free recall all items from the list, F items were recalled with a probability of .081, while A and B items were recalled with probabilities of .272 and .254, respectively. A one-way analysis of variance indicated that indeed these differences were real, F (2, 177) = 25.66, $p < .001$.

A 6 × 3 analysis of variance (Recall Conditions × Item Types) on the immediate recall data indicated a significant item effect, F (2, 1062) = 228.36, $p < .001$, a significant effect of recall instruction, F (5, 1062) = 4.98, $p < .001$, and a significant Item Type × Recall Instruction interaction, F (10, 1062) = 10.57, $p < .001$. To summarize the immediate recall data, we can say that explicit F-item recall remains invariant over recall instruction, with the possible exception of the free-recall-all condition; A- and B-item recall

TABLE 1

PROBABILITY OF IMMEDIATE RECALL, FINAL RECALL, AND FINAL RECOGNITION AS A FUNCTION OF RECALL INSTRUCTION AND ITEM TYPE

Immediate recall instruction	Item type		
	F	A	B
Immediate recall			
A only	.040[a]	.292	.119[a]
B only	.031	.117[a]	.327
A and B	.038	.271	.302
A then B	.039	.271	.250
B then A	.033	.300	.283
Free recall all	.081	.275	.254
Final recall			
A only	.048	.121	.123
B only	.031	.123	.158
A and B	.051	.135	.125
A then B	.065	.144	.152
B then A	.042	.187	.131
Free recall all	.060	.100	.087
Final recognition[b]			
A only	.275	.435	.419
B only	.252	.369	.427
A and B	.275	.448	.406
A then B	.267	.448	.429
B then A	.248	.437	.437
Free recall all	.271	.391	.387

Note. Each point is based on 480 observations. See text for explanation of abbreviations.
[a] These figures represent intrusions, since *S*s were instructed not to recall the items in question.
[b] False alarm probability was .085.

does not. In the only conditions, *Ss* recalled less of the excluded items.

A 6 × 3 analysis of variance on the final recall data indicated a significant item effect, F (2, 1062) = 44.77, $p < .001$, but neither a significant effect of recall instruction, F (5, 1062) = 1.99, $p > .05$, nor a significant Item Type × Recall Instruction interaction, F (10, 1062) = 1.56, $p > .05$. The lack of interaction between item type and recall instruction indicates that the probability of recalling A, B, and F items remains invariant over recall instruction. The lack of an instruction effect suggests that the instruction effect obtained in immediate recall was short term and did not carry over into final recall. The significant item effect indicates that explicit F items were recalled less frequently than A or B items. When *Ss*, then, are asked to recall all items from the experiment, they still do not recall many explicit F items, although explicit F-item recall does increase slightly from immediate to final recall. This increase is entirely consistent with past studies using the final recall procedure (Woodward & Bjork, 1971). The B items from the only-A condition and A items from the only-B condition were recalled finally about as well as they were immediately.

The results of a 6 × 3 analysis of variance on the final recognition data were similar in nature to the analysis on the final recall data. A significant item effect was obtained, F (2, 1061) = 60.97, $p < .001$, but there was neither a significant effect of recall instructions, F (5, 1062) = .73, $p > .05$, nor a significant Item Type × Recall Instructions interaction, F (10, 1062) = .73, $p > .05$. Once again there were large differences between explicit and implicit F items, this time in their recognizability. Implicit F items were more likely to be recognized, just as they were more likely to be recalled. Final recall data, as well as final recognition data, are noteworthy, not in the small differences that occur for a given item type as a function of the recall instruction, but for the uniformity for a given item type across the various recall instructions. The F items clearly differ from A or B items in terms of their recallability and recognizability, but they do not differ as a function of the recall instruction. The A and B items do not differ as a function of recall instruction either, or from each other.

The data are not suggestive of an only effect. Epstein's (1969) only effect is defined as superior recall of the only condition compared with the appropriate both condition. Recall of A items in the only-A condition was .292, and in the A then B condition, .271. This difference was not significant, t (59) = .91, $p > .05$. Recall of B items in the only-B condition was not significantly greater than in the B then A condition, t (59) = 1.50, $p > .05$. Clearly, however, the items to be excluded at output are recalled, or actually intruded, far less frequently than items that are to be recalled. Thus, A-item recall in the only-B condition and B-item recall in the only-A condition is far less likely than in any other condition. The Item Type × Recall Instruction interaction stems largely from this low probability of recall of the items to be implicitly forgotten.

Finally, it should be noted that the data reported for the A then B condition and the B then A condition do not take into account order of recall. Although *Ss* were asked to recall (in accordance with the instruction) A items first followed by B items, or vice versa, recall of all items was scored. Taking order into account, and not accepting as correct A items intruded into B-item recall in the A then B condition, or B items intruded into A-item recall in the B then A condition, and the reverse, the probability of recalling A and B items was .183 and .214, respectively, in the A then B condition, and .210 and .194 in the B then A condition. There is some indication then that *Ss* had problems differentiating between A and B items.

Discussion

The fact that these data did not yield an only effect in retrospect is not surprising and is consistent with Epstein's research (1969, 1970). Epstein found that the only effect appears only when the two groups of items

are functionally separate. The interspersing of implicit items in this study through the use of the individual cuing technique resulted in a loss of the functional autonomy of each group of items and, subsequently, no only effect. Because no only effect was obtained, one could question the appropriateness of the term *implicit forget instruction.* In other words, is the presence of an only effect a necessary or prerequisite condition for the implicit forget instruction label? The present authors believe not. What is crucial are the operations required in producing the implicit forget instruction. In this regard, our operations were the same as those of Epstein's (1969). The instruction was given after input and before output, and in addition, *S*s did not know that they would ever be asked to recall or even recognize former list items. The recall-only-A instruction, as well as the recall-only-B instruction, although not successful in producing an only effect, were undeniably successful in reducing output of the excluded items.

The immediate recall data indicate that *S*s had very little difficulty separating implicit from explicit F items, but that making a similar discrimination within the implicit dimension (between A and B items) was considerably more difficult, although not impossible. Furthermore, final recall data indicate that the effect of the explicit instruction was long term, while the effect of the implicit instruction was short term. That is, recall of explicit F words was exceedingly low, both immediately and finally, while a low probability of recall of implicit F items immediately (i.e., a low recall of B items in the only-A condition and a low recall of A items in the only-B condition) did not reflect a similar trend in final recall.

The data strongly support the notion that explicit F items are different from implicit F items on indices of recall as well as recognition. Explicit F items are recalled rarely, immediately, or finally, and do not depend upon the recall instruction. Implicit F items are recalled with much higher probability than explicit F items, immediately and finally, and are also more likely to be recognized as old items. In addition, even when *S*s are asked immediately to recall explicitly labeled F items, they are less successful than when asked to immediately recall other types of items.

Epstein (1970) suggests that directed forgetting may be attributable to search and retrieval processes. Such an explanation may be appropriate for his pardigm which involves implicit postlist cuing and the only effect. However, the present authors would argue that the only effect is not representative of most directed forgetting experiments, and that implicit F items are not really forgotten. Directed forgetting, measured most reliably by either a final recall test or a special immediate recall test such as that which occurred with List 3, results with explicit within-list cuing, and its explanation involves rehearsal and other processing mechanisms at input, not search or retrieval processes at output.

The main difference, and a crucial one between explicit and implicit forget instructions, is the time of the instruction. In this experiment, explicit forget instructions followed the items immediately. The implicit forget instruction was delayed until the time of output and was far less effective in terms of leading to "forgetting." When the instruction is explicit, *S*s can stop further processing of the item. If the item is not processed, or processed minimally, it is not likely to be recalled or intruded even though it may be recognized. Items later followed by implicit forget instructions are processed by *S*s in the same way no doubt as items that they will attempt to recall. The *S*s, in an attempt to conform to the task requirements, exclude the implicit F items from recall, or attempt to, but this exclusion in no way affects later recall or recognition.

In conclusion, the experiment and the results reported in this paper point to clear differences both in recall and recognition between items that *S*s are explicitly told to forget as opposed to items that are implicitly to be forgotten. Put another way, there are vast paradigm differences among studies that fall under the label of intentional or directed forgetting and investigators should be sensitive to such differences.

EFFECTS OF IMAGERY INSTRUCTIONS, IMAGERY RATINGS, AND NUMBER OF DICTIONARY MEANINGS UPON RECOGNITION AND RECALL

M. J. PETERSON [1] AND S. H. McGEE

Indiana University

Three experiments investigated the effects of two "imagery-encouraging" variables, instructional set and imagery ratings, and of the number of dictionary meanings upon recognition and recall. Interactive imagery instructions produced superior recognition of stimulus words, response words, and pairs compared to rote-repetition instructions. Response recall also was higher following imagery instructions than following repetition instructions. High imagery ratings aided stimulus recognition and response recall, but not response recognition or pair recognition. Thus, the two imagery-encouraging variables had different effects upon recognition and recall and cannot be considered as two techniques for initiating the same underlying process. The effects of the number of dictionary meanings were independent of the effects of the two imagery-encouraging variables, although the meanings interacted with the imagery ratings of the pairs.

In recent years, two distinctly different techniques have been used to study "imagery" when the basic experimental materials were pairs of English nouns. One technique used nouns with scaled ratings of imagery (imagery ratings), and the other technique instructed *Ss* to imagine the referents of the nouns interacting in some way in their imaginary scene (imagery instructions). An interesting aspect of these two variables, which may or may not elicit imagery, is that they appear to have similar effects upon recall, despite the marked differences in experimental manipulations (e.g., Paivio & Yuille, 1969). The similarity of effects could be interpreted as the manifestation of a single underlying process that was induced by both variables, or as the reflections of independent but similar processes. Presumably, such identical or highly similar processes would influence various measures of retention, such as recognition and recall.

Suppose the variables trigger a single underlying process: both variables should then have similar effects on recognition and recall. Experiment I explored this possibility. As noted above, both variables apparently facilitate recall of the nouns compared to control conditions, but the effects upon recognition are less clear. Bower (1970), using only concrete nouns, reported no differences in recognition as a function of instructional set. However, his use of the concrete nouns may have produced a ceiling effect that precluded his finding a difference. The relevant recall literature suggested that words with low imagery ratings should be recognized less often than words with high imagery ratings when imagery ratings are varied, and these effects were verified by Peterson and Murray (1973). Their studies also showed better stimulus recognition following imagery instructions than following repetition instructions.

While the Peterson–Murray (1973) results indicated that both variables had similar effects upon recognition and recall, their experiments tested *stimulus* recognition (as did Bower's 1970 experiment). Experiment III of the present paper examined recognition of the response terms and of the pairs themselves as functions of imagery ratings and the instructional set.

Another purpose of the present studies was to probe the relationships between the two imagery-encouraging variables and a semantic characteristic of the words. We know that the imagery-encouraging variables are not reducible to the meaningful-

[1] Requests for reprints should be sent to M. J. Peterson, Department of Psychology, Indiana University, Bloomington, Indiana 47401.

ness or the familiarity of the words (see Paivio, 1971, for a review), or to lexical complexity (Kintsch, 1972). However, the imagery-encouraging variables may be related to a more cognitive index such as the conceptual complexity of the words. On an intuitive basis, words with high imagery ratings appear to differ in conceptual complexity from words with low imagery ratings, and the instructional set might produce similar differences. The possibility of relating the imagery variables to a single semantic index has theoretical appeal, of course. Consequently, Experiments II and III compared a measure of conceptual complexity, the number of dictionary meanings, with the two types of imagery-encouraging variables.

To summarize, the primary purposes of the series of studies were to investigate: (*a*) the effects of two imagery-encouraging variables upon the recognition of individual words and words in pairs and upon the recall of the word pairs, and (*b*) the symmetry of effects produced by the two imagery-encouraging variables and by the number of dictionary meanings.

Experiment I

Experiment I was designed to test recognition of the stimulus terms and recall of the pairs when the stimulus terms were shown alone, to provide an opportunity for imagining the referents of even low-imagery nouns, and when the pairs were then presented together. There were three phases. Phase 1 showed the stimulus items alone under instructions to imagine the referents of the words or to silently repeat the words. Phase 2 presented the stimulus items paired with the response words. Half of the *S*s given imagery instructions for Phase 1 were told to imagine the referents of the words interacting in their visual scene, and the other half were told to repeat the pairs silently. Similarly, *S*s who received repetition instructions before Phase 1 were split into imagery and repetition instruction groups for Phase 2. In Phase 3, all *S*s were tested for stimulus recognition and for response recall.

If imagery instructions and imagery ratings have essentially the same effect upon stimulus recognition [illegible] response recall, then both recogniti[illegible]nd recall should be higher with imager[illegible]structions and high imagery ratings th[illegible]ith rote-repetition instructions and [illegible] imagery ratings. No interaction woul[illegible]ear. On the other hand, if the va[illegible]s reflect independent operations, the[illegible]ht interact. For example, when *S*s re[illegible] imagery instructions, they may attem[illegible] imagine the referents (or some referen[illegible]gardless of the imagery ratings of the w[illegible]. When *S*s receive rote-repetition inst[illegible]ions, the words with high imagery ra[illegible] might induce the strategy of imaginin[illegible]e referents, while words with low ima[illegible] ratings would not. In this case, an [illegible]raction would be found such that the h[illegible]imagery items shown under imagery i[illegible]uctions would be recognized and recalle[illegible]ost accurately, and the low-imagery i[illegible] shown under rote-repetition instruction[illegible]uld be recognized and recalled least ac[illegible]ely.

Method

Design and materials. Four groups o[illegible] studied 36 nouns during Phase 1. Two of the[illegible]s were given instructions to visualize the obj[illegible]denoted by the words in a vivid way in their [illegible]l scene (imagery instructions). The two other [illegible]ps were told to repeat the words silently (ro[illegible]petition instructions). The groups then studied [illegible] pairs of nouns during Phase 2. One of the groups given imagery (I) instructions during Phase 1 and one of the groups given rote-repetition (R) i[illegible]uctions during Phase 1 received imagery instructions for Phase 2. These groups were identified as I–I and R–I, respectively. The two remaining groups received rote-repetition instructions just before Phase 2 began. These groups were designated as I–R and R–R.

The nouns shown in Phase 1 were the stimuli of the Phase 2 pairs. Thirty-six additional nouns were used as the Phase 2 response terms. Eighteen of the pairs were composed of concrete nouns, and the other 18 pairs contained abstract nouns. The concrete nouns had imagery ratings exceeding 6.00 and the abstract nouns had imagery ratings of less than 4.50, according to the Paivio, Yuille, and Madigan (1968) norms. The words were chosen to be approximately equal in rated meaningfulness. The high-*I* words were paired randomly to yield 18 pairs, and the low-*I* pairs were made up in the same way. Eighteen additional high-*I* words and 18 more low-*I* words were used as distractors in the stimulus recognition test. These words met the criteria stated above.

The words were typed on mats for slide presentation. The mats were ordered randomly for Phases

1 and 2 and for the stimulus-recognition and response-recall tests. All *Ss* received the same ordering of mats for each phase.

Procedure. The *Ss* were told that there were three phases in the experiment and that they should remember the items of each phase. They received the appropriate instructions and were shown the slides of Phase 1 at a 5-sec. rate. Following Phase 1, *Ss* were read their assigned instructions for Phase 2, and the Phase 2 slides were shown at an 8-sec. rate. After a 60-sec. break, instructions were given for the recognition-recall tests. The *Ss* were told to write down the stimulus word as it was shown on the screen. They then indicated their certainty that the word had been shown during Phases 1 or 2 by hecking a 5-point scale: Certainly Old, Probably ld, Don't Know, Probably New, and Certainly ew. The next task was to recall the word paired ith the word written on the sheet, if *Ss* thought hey had seen the stimulus word previously. Each lide was shown for 15 sec. during the recognition-ecall task.

Subjects. Students in introductory psychology courses at Indiana University participated as one method of fulfilling a course requirement. Sixty-four *Ss* were randomly assigned to 16 replications of the block of four groups.

Results

Stimulus recognition. The mean numbers of correct stimulus recognitions (hits), the mean numbers of incorrectly labeled new stimuli (false alarms), and A' estimates[2] (Pollack & Norman, 1964) are given in Table 1. The hit and false-alarm rates were calculated from judgments of Certainly Old and Probably Old given to true old stimuli and to the distractors, respectively. The mean number of hits for the groups receiving imagery instructions before Phase 1 reliably exceeded the mean number of hits for the groups with rote-repetition instructions for Phase 1, $F\ (1, 60) = 214.28$, but neither the instructions given for Phase 2, $F < 1$, nor the imagery ratings, $F\ (1, 60) = 1.02$, $p > .05$, produced significant differences in the hit rates.

The false alarms varied as a function of the instructions given for both phases. The false-alarm rates were higher following rote-repetition instructions given before Phase 1, $F\ (1, 60) = 55.86$, $p < .01$, and before Phase 2, $F\ (1, 60) = 16.93$. The imagery ratings did not have a reliable effect upon the false-alarm rates.

The more frequent labeling of a new stimulus as old following rote-repetition instructions suggested that *Ss* in these groups were using a more lax criterion for judgment than *Ss* in the imagery-instruction groups. To explore detection sensitivity further, A' estimates were obtained for each condition, and these estimates were subjected to an analysis of variance.

The mean A' estimate for groups receiving imagery instructions before Phase 1 was significantly greater than the mean A' for groups with rote-repetition instructions before Phase 1, $F\ (1, 60) = 34.00$, $p < .01$. The instructions that preceded Phase 2 did not show significantly different estimates of A', $F\ (1, 60) = 2.00$, $p > .05$, nor was

[2] The authors wish to thank Donald E. Robinson for supplying the tables of A'.

the interaction between the Phase 1 and Phase 2 instructions reliable ($F < 1$).

The other method of inducing imagery, the imagery ratings, also showed significant effects upon stimulus recognition when the bias toward labeling new stimuli as old was taken into account. The A' estimate was reliably higher for stimuli with high imagery ratings than for stimuli with low imagery ratings, $F\ (1, 60) = 20.62, p < .01$. Further, the imagery ratings interacted with the Phase 1 instructions, $F\ (1, 60) = 12.00, p < .01$. The mean A' scores for the conditions contributing to this interaction were high-*I* words, imagery instructions (.98), low-*I* words, imagery instructions (.97), high-*I* words, repetition instructions (.95), and low-*I* words, repetition instructions (.91). Tukey tests indicated that the means for high- and low-*I* words under imagery instructions did not differ reliably: all other comparisons were significant at the .01 level. These results indicated that when *S*s received imagery instructions, recognition performance was uniformly high, regardless of the imagery ratings of the pairs. The imagery ratings of the pairs became an important determinant of recognition performance only under rote-repetition instructions. No other interactions were reliable.

Response recall. Table 1 contains the mean numbers of correctly recalled responses and the proportions of correctly recalled responses conditionalized upon correct stimulus recognition. Analyses showed the same effects for both response measures, hence, only the second measure will be discussed. Reliably more responses were recalled following correct stimulus recognition under imagery instructions than under rote-repetition instructions for both Phase 1 and Phase 2: for Phase 1, $F\ (1, 60) = 40.00, p < .01$; for Phase 2, $F\ (1, 60) = 152.24, p < .01$; and when the pairs had high imagery ratings, rather than low imagery ratings, $F\ (1, 60) = 14.70, p < .01$. No interactions were reliable.

Discussion

As expected, both imagery-encouraging variables were associated with increased response recall, and the two variables did not interact. These results imply that t[illegible] variables reflect the same or highly s[illegible]processes, but the stimulus recognition d[illegible]ided contradictory evidence. Phase 1 i[illegible]y instructions facilitated stimulus recogni[illegible]re than rote-repetition instructions, but [illegible]gery ratings produced differences only wh[illegible]mbined with rote-repetition instructions. [illegible]nce, these two variables have different effe[illegible]pon stimulus recognition and must be a[illegible]ed to induce distinct underlying process[illegible]

Phase 2 instructions had [illegible] differential effects upon stimulus recogni[illegible]. The most plausible explanation for the [illegible]e of Phase 2 instructions to influence sti[illegible] recognition was that *S*s who received ima[illegible]nstructions before Phase 1 were likely t[illegible]inue to use an imagery strategy during Ph[illegible], regardless of the instructions that imme[illegible]ly preceded Phase 2. The carry-over fr[illegible]ne instructional set to the other may be [illegible]ated from consideration by comparing [illegible]ition performance on high-*I* and lo[illegible] words for Groups I-I and R-R. This co[illegible]son showed the same effects as those desc[illegible] above for stimulus recognition (see Tab[illegible]).

Experiment I may have und[illegible]imated recall, particularly for the groups [illegible]ving rote-repetition instructions. It is [illegible]ible that when *S*s were uncertain of their [illegible]gnition of the stimulus words or were unable to recognize the stimulus words, they did not try to remember the responses, thus suppressing recall. Experiments II and III were designed to avoid these potentially confounding effects.

Experiment II

Experiment II asked if the imagery-encouraging variables could be subsumed by the number of dictionary meanings of the words of the pair. Such a prediction would oppose the contemporary theories (e.g., Atwood, 1971; Bower, 1972; Paivio, 1971), which assume visual imagery and verbal attributes to be distinct but interacting processes. If these processes do interact extensively, then questions about the likelihood of enhanced encoding or whatever occurs when the imagery-encouraging variables are manipulated might better focus upon the conjoint relationship between measures of the verbal–linguistic characteristics of the words and of imagery ratings.

It is possible that the more meanings a word has, the greater are the chances that

so… of these characteristics will be imaginable. When an easily imagined noun has … eanings, or when *S*s attempt to imag… the referents of a noun with many …ings, these meanings may "enrich" … image or they may produce multiple images. Other easily imagined words with fewer meanings (or less meaningful words whose referents are to be imagined) would be expected to yield fewer images or images with less enrichment. On the other hand, the possession of many meanings might interfere with the encoding and acquisition of words which are more difficult to imagine.

Thus, Experiment II manipulated the number of dictionary meanings, instructional set, and the imagery ratings of the pairs of words. The ratings of the *pairs* were assumed to provide a better index of the saliency of an image combining the referents of the two words than an average of the imagery ratings of the individual words of the pair. The imagery ratings of the individual words were held relatively constant, while the rating of the pair varied. For example, JUDGE–TABLE had a high imagery rating as a pair and JUDGE–WHEAT had a low rating as a pair, although the imagery ratings of the individual words were approximately the same.

Method

Preliminary scaling and design. Eighty nouns with imagery ratings of 6.00 or higher and with meaningfulness ratings of 5.50 or higher were drawn from the Paivio et al. (1968) norms. Seventy-two randomly selected "stimulus" nouns were then paired with each of the eight remaining "response" nouns. The imagery ratings of these pairs were obtained by administering booklets containing the pairs to 30 students in introductory psychology courses at Indiana University. Six different booklets were used so that a particular stimulus noun would be paired with only one of its response words per booklet. The instructions for rating were similar to those used by Paivio et al., and *S*s rated the imagery of the pairs on a 7-point scale.

In addition, the numbers of different "meanings" or separate entries found in *Webster's Unabridged Dictionary* (1966) were tabulated. This variable was labeled "dictionary meaning" (*dm*). The numbers of dictionary meanings were calculated for pairs of words by adding the number of dictionary meanings for the two words of each pair. Finally, 12 pairs were selected for each of the four cells of the design that arose from the two levels of imagery ratings (high and low) and the two levels of dictionary meanings (high and low). The mean values are given in Table 2 for each cell. Table 2 also shows sample pairs. It should be noted that for the imagery variables, each stimulus noun was paired with two responses. This technique was used to control the imagery ratings of the stimuli and because Experiment III was to test recognition of the response words.

TABLE 2

MEAN IMAGERY RATINGS, MEAN NUMBER OF DICTIONARY MEANINGS, AND SAMPLE PAIRS OF MATERIALS: EXPERIMENT II

Condition	Imagery ratings[a]	Dictionary meanings	Sample pair
High *I*–high *dm*	5.76	13.62	JUDGE–TABLE
High *I*–low *dm*	5.74	6.92	DOCTOR–PUPIL
Low *I*–high *dm*	2.70	13.04	DOCTOR–EARTH
Low *I*–low *dm*	3.20	6.96	JUDGE–WHEAT

Note. Abbreviations: *I* = rated imagery, *dm* = number of different dictionary meanings.
[a] Maximum score for high imagery was 7.00.

Two lists were prepared, using the first pairing for a stimulus in one list and the other pairing in the second list. Each list contained six high-*I*, high-*dm* pairs; six high-*I*, low-*dm* pairs; six low-*I*, high-*dm* pairs; and six low-*I*, low-*dm* pairs.

Subjects. Sixty-four new *S*s from the same pool were assigned randomly to 16 replications of the block of two lists and two types of instructions.

Procedure. The *S*s were given either imagery or rote-repetition instructions. They were then shown slides with the noun pairs at the rate of 8-sec. per slide. After about a 2-min. interval, the stimuli were presented alone, and *S*s were instructed to write the appropriate response on their answer sheets. The procedure of Experiment II was comparable to Phase 2 of Experiment I, followed by a test for response recall. Experiment II had no Phase 1 counterpart, nor was any test for stimulus recognition introduced.

Results

The major results are shown in Table 3. The *S*s given imagery instructions recalled significantly more responses than *S*s given rote-repetition instructions, F (1, 60) = 34.17, $p < .01$, and more responses were

TABLE 3

MEAN NUMBER OF CORRECTLY RECALLED RESPONSES: EXPERIMENT II

Dictionary meanings	Imagery instructions		Repetition instructions	
	High *I*	Low *I*	High *I*	Low *I*
High	4.81	4.03	3.22	1.97
Low	4.50	4.38	2.84	2.59

Note. Abbreviation: *I* = rated imagery.

recalled from the high-I pairs than from the low-I pairs, $F(1, 60) = 20.47$, $p < .01$. The latter result indicates that response recall reflects the imagery ratings of the pairs, not simply the ratings of the individual words of the pairs. No other main effect was reliable.

The failure to demonstrate a significant main effect for the number of dictionary meanings indicated that this variable did not explain the effects of the two imagery-encouraging variables upon response recall. However, the number of dictionary meanings did interact with the imagery ratings of the pairs, $F(1, 60) = 12.42$, $p < .01$. The high-I pairs were recalled more often when they had more dictionary meanings than when they had fewer dictionary meanings, but the opposite was true for low-I pairs, as shown in Table 3. The number of dictionary meanings did not interact with the instructional set.

Discussion

The results of Experiment II supported theories which posit independent visual and verbal components or processes and argued against the possibility that the imagery-encouraging variables might be reduced to a measure of conceptual complexity such as the number of dictionary meanings. The interaction between the imagery ratings of the pairs and the number of dictionary meanings may have been produced by increases in the number of meanings which "enriched" the image or produced multiple images, while the extra meanings hindered the processing of words which were difficult to imagine.

Experiment II also showed that the imagery ratings of the pairs of words predicted recall more satisfactorily than the imagery ratings of the individual words, providing additional support for the notion that the association of the words is important. Experiment III investigated recognition of response terms and of the pairs under the same conditions as Experiment II.

Experiment III

Experiment III presented pairs of words with high and low numbers of dictionary meanings and with high and low ratings of imagery. During the exposure trials, one group received imagery instructions and the other group, repetition instructions. Half of each group was given a response recognition test and half, a pair recognition test. If the imagery-encouraging variables affect the encoding of the words, subsequent recognition of the individual words and of the pairs should be better for pairs shown under imagery instructions or for pairs with high imagery ratings compared with pairs shown under rote-repetition instructions or for pairs with low imagery ratings. These predictions have been tested for the *stimulus* items (Bower, 1970; Peterson & Murray, 1973; Experiment I of the present series). Experiment III examined the effects upon recognition of the response terms and of the pairs.

The number of dictionary meanings was included because other investigators have reported that recognition was inversely related to the frequency of occurrence of words (Shepard, 1967) and to the meaningfulness of dissyllables (McNulty, 1965), while recall showed a positive relationship. The finding that dictionary meanings mirrored these results while imagery-encouraging variables did not would be additional evidence that the imagery-encouraging variables differ from the various measures of verbal–linguistic characteristics.

Method

Materials and design. The materials were those used in Experiment II. Half of the *Ss* saw List 1 during the acquisition stage and the other half saw List 2. All *Ss* were then transferred to a recognition list that contained all of the pairs or responses from Lists 1 and 2. Thus, on the recognition test, half of the items would be old and half would be new, for all *Ss*.

One group was told to imagine the referents of the words, and a second group was told to repeat the words silently. These two groups were subdivided for the recognition test. Half of each group received the response recognition test and half, the pair recognition test.

Subjects. One hundred and ninety-two new students from the same pool were assigned to 24 replications of the block of eight cells produced by the two lists and the four instruction groups.

Procedure. After hearing the appropriate instructions, the pairs of the acquisition list were presented at an 8-sec. rate. The *Ss* were reminded to use imagery or rote repetition during the recognition test to help them make their decisions. The *Ss* rated their confidence of their judgments by

TABLE 4

PERFORMANCE ON RESPONSE AND PAIR RECOGNITION TESTS: EXPERIMENT III

Performance measure	Imagery instructions				Repetition instructions

Note. Abbreviations: I = rated imagery, dm = number of different dictionary meanings.

circling numbers on the same 5-point scale used in Experiment I. No measure of response recall was obtained in Experiment III.

Results and Discussion

The mean numbers of hits, false alarms, and the A' estimates are given in Table 4 for the four groups. The recognition of the response words was significantly better following imagery instructions than following repetition instructions, F (1, 46) = 13.64, $p < .01$, and for words with *few* rather than many dictionary meanings, F (1, 46) = 34.16, $p < .01$. Imagery ratings did not have a differential effect upon response recognition ($F < 1$). No interactions were significant.

The finding that words with few dictionary meanings were recognized with greater accuracy than words with many dictionary meanings, while the opposite was true for recall, corresponded to similar results reported by Schwartz and Rouse (1961) and Shepard (1967) for the frequency of occurrence of words and by McNulty (1965) for the meaningfulness of dissyllables.

In general, detection of old from new pairs was superior to the detection of old from new responses. Imagery instructions also facilitated the recognition of the pairs, F (1, 46) = 5.95, $p < .05$, but neither the imagery ratings, F (1, 46) = 1.00, $p > .05$, nor the dictionary meanings, $F < 1$, were effective in enhancing the detectability of the pairs. These results make it clear that the response recall found in Experiment II for these pairs could not be explained by simple recognition of either the response term alone or of the pair as a unit.

General Discussion

The results of the three experiments indicated that theoretical explanations of imagery must accord separate treatments to the two imagery-encouraging variables, instructional set and imagery ratings, because the two variables had different effects upon recognition. Their effects upon recall were highly similar and did not interact.

Imagery instructions aided recognition of the stimulus words, the response words, and the pairs to a greater extent than control (rote-repetition) instructions. Imagery ratings were directly related to recognition of the stimulus words experienced under rote-repetition instructions but not to recognition of the stimulus words shown under imagery instructions or to recognition of the responses or the pairs, irrespective of the instructional set. Clearly, the instructional variable has a wider scope of influence than the imagery ratings, and the two techniques for encouraging imagery induce processes which have differential effects upon recognition.

Despite their disparate effects upon recognition, the imagery-encouraging variables showed a highly similar influence on recall. Significantly more responses were correctly recalled following imagery instructions than following repetition instructions and for pairs with high rather than low imagery ratings.

Why should the two imagery-encouraging variables have different but interacting effects upon recognition but not upon recall? One

explanation is that one of these variables, imagery instructions, influences both encoding and retrieval, thus affecting recognition and recall, while the other variable, imagery ratings, exerts its primary effect upon retrieval. This explanation would have to be modified to permit imagery ratings to affect encoding when no imagery instructions were in effect (see Paivio, 1971, for a review).

A varient hypothesis is that imagery instructions induce a process that facilitates both recognition and recall. Imagery ratings, of secondary importance, are effective only to the extent that they induce the same process. This hypothesis predicts that recall performance should mimic recognition performance, in contradiction to the present results. A slightly different version of this hypothesis is that recall of the pairs is facilitated by both variables, through enhanced recognition of the cue term, and that imagery instructions are dominant over imagery ratings. Further, imagery instructions simply have additional effects, such as the enhancement of the responses and of the pairs, that are irrelevant to recall. This possibility seems most reasonable.

The process or processes that underlie the imagery-encouraging variables may or may not involve visual components. It is quite plausible that the imagery instructions, for example, trigger active, but not necessarily visual, rehearsal mechanisms on the part of *S*, whereas the rote-repetition instructions elicit a far more passive process. So long as the process produces sufficient encoding, recall will be possible. The more active rehearsal might well yield differential confidence ratings of recognition performance, but recall would not differentiate between rehearsal and more passive repetition if the items were encoded at some minimal level.

Neither imagery-encouraging variable was explainable by a measure of conceptual complexity such as the number of dictionary meanings. Increases in the number of dictionary meanings facilitated recall but hindered recognition of the responses, whereas the imagery instructions, in particular, were positively related to both recall and recognition of the responses. These results also refuted the earlier proposal that high-imagery words with many meanings might yield more encodings or an enriched encoding. Instead, the encoding accorded high-imagery words with many meanings presumably is less distinctive than the encoding of high-imagery words with a limited number of dictionar[illegible]ings. To explain the superior recall [illegible]e words despite the less accurate recogni[illegible] is necessary to assume that retrieval [illegible]gies are more effective with the high-[illegible], high-meaning words.

Thus, we are faced with [illegible]triguing dilemma of acknowledging [illegible]lapping, sometimes contradictory effects [illegible] recognition and recall of two variables [illegible]legedly induce imagery processes witho[illegible]ng able to assess precisely why these [illegible]bles are effective and without being able [illegible]ie these variables to other characteristic[illegible] verbal materials known to affect recog[illegible]on and recall.

[illegible]ARALLEL PROCESSING IN A WORD–NONWORD CLASSIFICATION TASK[1]

NEIL NOVIK[2]

University of Connecticut

Undergraduate *S*s were required to indicate whether each stimulus in a series of CCCs, CVCs, WORDs (CVC type) and meaningful CCCs (e.g., JFK, LSD) was a word or a nonword. Reaction time (RT) was the dependent measure. The serial model of word–nonword classification, which states that phonological evaluation precedes memory search, would predict no differences in RT between the meaningless CCCs and the meaningful CCCs, since the two items are equally unlawful. The parallel model, which assumes that phonological evaluation and memory search occur simultaneously, would predict that RTs to meaningful CCCs would be greater than those to meaningless CCCs, because for the former type of item, there is confusion in finding meaning in an unlawful nonword. The results supported the parallel model in that RTs to meaningful CCCs were consistently greater than those to meaningless CCCs. In a second experiment, RTs to frequent CCCs equalled RTs to nonfrequent CCCs, suggesting that the word nonword decision was not based on a frequency determination.

A considerable amount of attention has recently been paid to what Norman (1969, pp. 162–163) has termed the "mantiness problem." A person is able to recognize in a very short amount of time that "mantiness" is not a word in his vocabulary. The problem, of course, is how this accurate decision is arrived at so quickly. It has therefore been the goal of several recent studies to discover the processes underlying this ability.

When confronted with "mantiness" it is highly unlikely that the person engages in a scan of all the words he has stored in memory (this process would take too much time), but it is generally agreed that recognition of a word or rejection of a phonologically lawful nonword requires some search for meaning. In addition, several authors (Norman, 1969; Rubenstein, Lewis, & Rubenstein, 1971; Stanners, Forbach, & Headley, 1971) suggest that rejection of a phonologically unlawful item such as "mgsptzy" may be accomplished by means of some preprocessing of the item which would determine its phonological lawfulness.

The present paper deals with the question of how this preprocessing and the memory search may be related. The two basic alternatives are that the operations are sequential or that they act in parallel. In the sequential model, the person first decides whether the item could be a word, according to phonological rules. If a stimulus is rejected, no search through memory for meaning is needed. If, on the other hand, the item is accepted as being phonologically lawful, the person must search for meaning. A *word* response would be emitted if meaning was found, while a *nonword* response would follow the failure to find such meaning. This type of model has been described by Rubenstein et al. (1971) and Stanners et al. (1971). Its support comes mainly from studies in which *S* is required to respond to a visually presented stimulus simply on the basis of whether the item was a word or a nonword. The model predicts that reaction times (RTs) for rejecting phonologically unlawful units (e.g., consonant–consonant–consonants—CCCs) would be faster than for accepting words, since no search for meaning is required in the former case. Furthermore, RTs to

[1] This research was supported in part by National Institutes of Health Training Grant 00084. Part of this paper was presented at the meeting of the Eastern Psychological Association, Washington, D. C., May 3–5, 1973. The author wishes to express his gratitude to Ron Lecours for his assistance in the collection of data and to his advisory committee for their helpful suggestions.

[2] Requests for reprints should be sent to Neil Novik, Department of Psychology, University of Connecticut, Storrs, Connecticut 06268.

phonologically lawful nonwords (e.g., consonant–vowel–consonants—CVCs) should be slower than those to words, since an exhaustive search is needed when the item is not a word.

These predictions have been supported in several recent studies. Lawful nonwords have been shown to have longer RTs than both real words (Rubenstein, Garfield, & Millikan, 1970; Snodgrass & Jarvella, 1972) and unlawful nonwords (Rubenstein et al., 1971). The strongest support for the sequential model comes from the study by Stanners et al. (1971), in which *S*s responded *word* or *nonword* to a series of visually presented CCCs, words (CVC type) and CVCs (nonwords). As the sequential model predicts, CCCs were responded to the fastest, words were intermediate, and CVCs were the slowest (approximate RTs were 600, 715, and 840 msec., respectively). The authors also found that the frequency in the English language of the initial and terminal consonants of the stimuli affected the RTs for words and CVCs but not for CCCs. These results suggested that phonological evaluation precedes the search for meaning and that the former operation is unaffected by at least one variable (consonant frequency) affecting the latter operation.

The parallel model assumes that phonological information and the search for meaning are processed simultaneously. Although, at present, there is no direct support for such a model, several lines of evidence have demonstrated that familiarity can have a very early effect in the processing of visual information. At least two studies have shown that the recognition of individual letters is improved when those letters are embedded in words (Reicher, 1969; Wheeler, 1970). Words have also been shown to have an advantage over nonwords in physical matching (Eichelman, 1970) and visual scanning (Krueger, 1970; Novik & Katz, 1971).

These studies are important in showing that higher order information such as meaning may have very early effects in visual information processing. Although not directly supporting the parallel model described earlier, these data [illegible] st that it might be possible for the [illegible] ing of a given item to be processed ea[illegible] recognition, even simultaneously w[illegible] onological information.

The present study seeks to [illegible] le direct support for that type of p[illegible] model. Specifically, it was hypothes[illegible] hat two kinds of information, one co[illegible] g phonological lawfulness and the [illegible] her concerning the meaning of the i[illegible] may be processed simultaneously. Th[illegible] riment is based on the procedure used [illegible] anners et al. (1971). The *S*s were pr[illegible] l with a series of three-letter items [illegible] ad to indicate whether each item wa[illegible] rd or a nonword. The dependent [illegible] e was RT. As in the Stanners et al [illegible] er, *S*s were presented with CCCs, [illegible] and CVC words. In contrast to Stan[illegible] et al., *S*s in the present study also sa[illegible] group of CCCs which presumably co[illegible] ed a good deal of meaning (e.g., J[illegible] LSD, etc.). The main comparison in th[illegible] esent study was between the RTs to t[illegible] meaningful CCCs and those to the non[illegible] ningful CCCs. If a determination o[illegible] honological lawfulness were made prio[illegible] o the search for meaning, and *S* was able to reject an item on the basis of that determination, then the RTs to JFK and JRK should not differ. This is true because the items are presumably equally unlawful and because meaning does not affect the phonological decision in the sequential model. If, however, the two operations occurred in parallel, then the finding of meaning for JFK would conflict with the decision of phonological unlawfulness, causing a delay in the nonword response. In summary, the sequential model would be supported by the finding of no differences in the RTs to the two types of CCCs, while such a difference would tend to support the parallel model.

Experiment I

Method

Subjects. Twenty right-handed female undergraduate students enrolled in introductory psychology at the University of Connecticut served as *S*s in the experiment. Each *S* received 1 hr. of experimental credit toward the course requirement.

Apparatus. The main piece of apparatus was a Kodak Carousel slide projector with a Pronto Press tachistoscopic shutter. The equipment used in programming the slide presentations consisted of two Lafayette 100-sec. timers, a Lafayette triple pulse timer, and a Hunter interval timer.

There were three telegraph keys placed on a table in front of *S*. The center key was used to initiate a trial, while the two outside keys were used for making responses. A Hunter digital clock measured in milliseconds the interval between the presentation of the stimulus and the response.

The slides were projected onto a rear-projection screen placed 5 ft. from *S*. The screen measured 14 × 14 in., but all except a center portion of the screen, measuring 5 × 3 in., was blocked out by cardboard taped to the back. The projected image of the stimulus was 3 × 1 in. and was projected in the center of the screen.

[illegible] The stimuli consisted of WORDs (CVC type), CCCs, and CVCs (nonwords), typed in uppercase letters and copied onto transparency film by a 3M Thermofax copier. No stimulus contained more than one of the same letters.

There were two 60-trial practice blocks. In each block there were 30 WORDs, 15 CCCs, and 15 CVCs. The CCCs and CVCs were constructed by randomly selecting 15 of the WORDs and inserting a random consonant or vowel in the center position (the only restriction being, of course, that for the CVCs, another WORD did not result). For example, if CAN was the WORD, the CCC and CVC could have been CHN and CEN, respectively. Thus, in each practice session, 15 of the WORDs had two corresponding nonwords, while the other 15 WORDs were filler items.

For the test trials, 15 meaningful CCCs (e.g., JFK, LSD) were chosen. The selection of these items was based on the results of questionnaires in which pilot *Ss* were asked to indicate the meaning of 20 such meaningful CCCs. The five items responded to most incorrectly were eliminated. From each meaningful CCC (CCC+) another CCC and a CVC were constructed in the same manner as described for the practice stimuli. In addition, 45 WORDs were chosen for the test trials independently of the nonwords, since several of the CCC+s could not be transformed into words (e.g., JFK, NBC, LBJ). Thus, there were 90 test trials: 15 CCC+s, 15 CCCs, 15 CVCs, and 45 WORDs. Within each practice block and the test block the stimuli were randomly mixed. Each *S* received the same order of stimuli.

Procedure. The *S* was instructed that pressing the center key would initiate the trial, and that 2 sec. after she pressed the key, the stimulus would be presented. The *Ss* were told to respond to that stimulus as quickly and as accurately as possible on the basis of whether it was a word or a nonword. The key on the right was designated for a *word* response, while the left key was to be used for a *nonword* response. The *S* used her right hand for a *word* response and her left hand for a *nonword* response. There were no requirements as to which hand was to be used to press the center key, but *S* was instructed that both hands should be ready to respond when the slide was presented. No *S* reported any difficulty in getting ready for each presentation.

During the first practice block, speed and accuracy were emphasized by *E* approximately every 15 trials. There was a 5-min. rest period between the two practice blocks. There was also a 10-min. interval between the second practice block and the test trials, during which time *Ss* were told that for the test trials, they would receive 4¢ for every RT under 900 msec., and that 25¢ would be taken away for every error. There was a slight delay midway through the test trials, long enough for *E* to change slide trays.

For each trial, a maximum of 4 sec. was allowed for a response. The failure criterion for the test trials was 10 errors. Two *Ss* made more than 10 errors and were replaced.

TABLE 1

Mean Reaction Times (RTs) (in msec.), Standard Deviations, and Percent Errors for the Test Trials in Experiment I

Stimulus type	Number of stimuli	Mean RT	*SD*	% error
CCC+	15	695	66	1.6
CCC	15	672	59	1.6
WORD	45	677	47	3.9
CVC	15	785	78	11.6

Note. Abbreviations: C = consonant, V = vowel, + = meaningful.

Results

Median RTs of correct responses for the test trials were obtained for each *S* under each condition. Table 1 presents the RT data as well as the error data for the test trials. A one-way repeated measures analysis of variance was performed on the RTs to the three nonword conditions. The RTs to the WORDs were eliminated from the analysis because all of the WORDs were filler items, i.e., they were chosen independently of the nonwords. The analysis revealed a highly significant treatment effect, $F(2, 38) = 82.67$, $p < .001$. Comparisons between conditions were made by a series of Duncan's multiple range tests. As in several of the studies previously cited, the RTs to the lawful nonwords (CVCs) were longer than those to the unlawful nonwords (CCCs and CCC + s) ($p < .01$). More

importantly, however, the RTs to the CCC + s were significantly longer than those to the CCCs ($p < .05$). The latter effect was also found in individual trends, with 18 of the 20 *S*s having a greater RT to the CCC + s than to the CCCs. The CCC+ vs. CCC difference was also found with individual pairs of stimuli. Median RTs across *S*s for each CCC+ and CCC were obtained, and of the 15 pairs of stimuli, the RTs to 12 CCC + s were greater than those to their corresponding CCCs, while 3 pairs showed the reverse trend. Both of these proportions are significant ($p < .025$) according to sign tests.

In order to compare the RT data for WORDs to the data for the other conditions, a series of related *t* tests were performed on the individual medians. The RTs to WORDs were found to be significantly shorter than those to CVCs, $t(19) = 8.70$, $p < .001$, but no other differences were found.

A series of sign tests showed that there were significantly more errors made with the CVCs than with the other stimuli ($p < .001$), while no other differences in percent errors were found. Since the RTs of incorrect responses might be indicative of strategies in processing (Stanners et al., 1971), median RTs for the incorrect responses were obtained for the CVCs and WORDs. The medians were based on a total across all *S*s of 35 incorrect responses in both conditions. For the CVC errors, the median was 711 msec., which was considerably lower than the mean RT for CVC correct responses. The median for WORD errors, on the other hand, was 756 msec., which was greater than the mean RT for correct WORD responses. For both the CCC and CCC+ conditions, there were too few errors for a median to be meaningful.

Discussion

The most important finding of the experiment was that the RTs to the meaningful, but unlawful, items (CCC + s) were greater than those to the unlawful meaningless items (CCCs), a difference that would not be predicted by the sequential model described above. According to that model, there is a two-stage process in word–n[illegible]l classification. During the first stag[illegible]honological structure of the item is eval[illegible] and if the item is found to be phonolog[illegible] unlawful, a nonword response may be e[illegible]ed. If the item is found to be lawful, *S* s[illegible] his memory in order to determine if the i[illegible] is indeed a word.

In the present experiment, th[illegible]C + s and the CCCs were presumably e[illegible] unlawful, and therefore, according to suc[illegible]odel, both types of items should have been [illegible]ted in the first stage, yielding equal RT[illegible]e finding of a consistent difference in R[illegible]tween the CCC+ and CCC conditions brin[illegible]e sequential model into serious doubt. [illegible] present data suggest that a phonologic[illegible]aluation does not necessarily precede t[illegible] memory scan, and in fact, the two ope[illegible]ons may operate in parallel. It is hypo[illegible]zed that the RTs to the CCC + s are del[illegible] because there is a conflict of information[illegible] phonological evaluation leading to a n[illegible]ord response is opposed to the finding [illegible]eaning which might normally lead to a wo[illegible]esponse.

It is important to note that for [illegible] parallel model, no substantial changes need [illegible]e made regarding the nature of the operat[illegible]s themselves. It has usually been assume[illegible]hat the phonological evaluation involves s[illegible]ne rule process which analyzes and evalua[illegible] phonological lawfulness (Stanners et a[illegible], 1971). Rubenstein et al. (1971) suggest that part of this process also involves some ph[illegible]etic recoding of the visual stimulus. The [illegible]rch for meaning, on the other hand, has been described as a serial self-terminating scan through a subset of memory representations in search of some form of semantic marker (Stanners et al., 1971).

The postulation of a self-terminating scan for meaning was supported in several respects by the present data. First, the finding that RTs to CVCs were consistently longer than those to WORDs suggests that when the item was not a real word, *S* had to continue his search until he exhausted the set of representations he was searching. When meaning was found, however, the search was terminated, yielding faster RTs to WORDs. Secondly, a self-terminating scan leads to two related predictions concerning the RTs of incorrect responses. An error with a CVC would mean that a semantic marker was incorrectly detected, terminating the search. The RTs for CVC errors, therefore, should be shorter than those for correct CVC responses. This rela-

tionship should be opposite with WORDs, since an error indicated that *S* failed to find the marker, making the scan exhaustive. The data support these predictions: the CVC error RTs were 74 msec. less than the CVC correct responses, while the WORD errors were 79 msec. longer than the WORD correct responses. Similar results and conclusions were also reported by Stanners et al. (1971).

The parallel model not only has the advantage of being able to account for the CCC+ vs. CCC difference, but it is also not inconsistent with other aspects of the present data and previous data used to support the sequential model. As already mentioned, the finding that CVC RTs were longer than those to the other kinds of stimuli is easily predicted by the parallel model. Similar results were reported by Stanners et al. (1971), Rubenstein et al. (1970), and Snodgrass and Jarvella (1972), and this is probably the most consistent finding in this type of experiment.

The sequential model, as originally stated, clearly predicts that RTs to WORDs should be longer than those to CCCs, since with the latter stimuli, no memory search is required. This prediction was supported by Stanners et al. who found that RTs to CCCs were more than 115 msec. faster than those to WORDs. In the present study, however, RTs to WORDs essentially equalled those to CCCs. While this failure to replicate the previous findings may have been due to the fact that WORDs were responded to with the right hand, while nonwords were responded to with the left hand, it should be pointed out that at least two other studies have also reported that WORD RTs were as fast or faster than RTs to unlawful nonwords. Rubenstein et al. (1971) obtained RTs of 842 and 876 msec. for their words and unlawful nonwords, respectively, while Snodgrass and Jarvella (1972) reported RTs of 578 and 621 msec. for these types of stimuli, respectively. In both studies, the authors explain their data by asserting that when an item is phonologically unlawful, [illegible]preprocessing and the detection of that un-[illegible]lness, leading to a nonword response, [illegible]nger than the processing of lawful [illegible]

[illegible]ilarly, the parallel model can account for RTs of WORDs being slower or faster than those to CCCs by asserting that one of the operations takes longer than the other. It is also possible that the two operations may be differentially sensitive to such experimental manipulations as instructions or reward contingencies emphasizing either speed or accuracy. Therefore, it is clear that the relationship between the RTs to WORDs and CCCs is not critical for distinguishing between the parallel and sequential models, since both models can account for both kinds of data.

Experiment II

Experiment II was designed to control for the possibility that the memory search was sensitive not to meaning, but simply to the frequency of occurrence in the English language. Frequent CCCs were compared to infrequent CCCs much in the same way that CCC + s were compared to CCCs in Experiment I. If the memory search were sensitive to frequency, then, according to the present argument, RTs to the frequent CCCs should have been longer than those to the infrequent CCCs.

Method

Subjects. Twenty female undergraduate students enrolled in introductory psychology at the University of Connecticut served as *Ss* in the experiment. All of the *Ss* were experimentally naive. Each *S* received 1 hr. of experimental credit toward the course requirement.

Apparatus. The apparatus was the same as used in Experiment I.

Stimuli. The stimuli in the practice sessions were the same as in Experiment I. For the test trials, the 15 most frequent CCCs were selected on the basis of the total score in the norms reported by Underwood and Schulz (1960). The range of the frequency scores was 50 to 534, and the mean score was 153. From each of the frequent CCCs (CCCfs) another CCC was constructed by replacing the middle consonant with another consonant so that the resulting CCC had a frequency of 0 in the Underwood and Schulz norms. In addition, CVCs were constructed from each CCCf by inserting a random vowel in the center position (with the restriction that a word did not result). There were also 45 WORDs used in the test session, which were the same WORDs as used in the test session of Experiment I. Thus, there were again 90 test trials: 15 CCCfs, 15 CCCs, 15 CVCs, and 45 WORDS.

Procedure. All procedures were identical to those of Experiment I.

Results

All scoring and analyzing procedures were the same as in Experiment I. The results for the test trials appear in Table 2.

TABLE 2

Mean Reaction Times (RTs), Standard Deviations, and Percent Errors for the Test Trials in Experiment II

Stimulus type	Number of stimuli	Mean RT	*SD*	% error
CCCf	15	678	47	2.0
CCC	15	677	46	.7
WORD	45	685	49	1.4
CVC	15	792	75	7.6

Note. Abbreviations: C = consonant, V = vowel, f = frequent.

The analysis of variance revealed a significant treatment effect for the three nonword conditions, F (2, 38) = 49.11, $p <$ .001. A series of Duncan multiple range tests revealed that RTs to the CVCs were again greater than those to the other stimuli ($p < .01$), but there was no significant difference between CCCfs and CCCs, ruling out the frequency hypothesis. The lack of a CCCf vs. CCC difference in the overall means was paralleled by individual trends, and intrastimulus pair differences.

All other aspects of the results, including the RTs to WORDs, closely replicated the results of Experiment I.

Discussion

The hypothesis that *S*s decide that an item is a word or a nonword on the basis of a simple frequency determination was not supported by the present data. Although it might be argued that the CCCfs in the present study were not frequent enough to cause a delay in RT, it should be pointed out that they are more frequent than the CCC + s used in Experiment I, which did cause such a delay. Therefore, it seems likely that it was the meaning of the CCC + s, rather than their frequency, which caused the effect. As Rubenstein et al. (1970) suggest, the role of frequency might be to limit the subset of memory representations to be searched, but frequency itself is probably not the deciding factor.

Conclusion

The sequential model and the parallel model described above are based on many of the same arguments and assumptions, and can account for much of the same data. In Experiment I, however, the CCC vs. CCC+ comparison separates the predictions of the t[illegible]dels, and the data clearly support the [illegible] model. The results of Experiment II su[illegible]hat the memory search was not a sim[illegible]requency determination. The parallel mo[illegible]imilar in principle to other previous mod[illegible]ch as the one described by Ingalls (1972). [illegible] study, as in Experiment I, *S*s could ha[illegible]sponded on the basis of the prelimina[illegible]rations alone, if the organization of the o[illegible]ns was sequential. His data, however, s[illegible]ed that the higher order operations were [illegible]tilized to complete the task, without re[illegible] to the information gained by the prelimi[illegible]operations. Similarly, the most reasona[illegible]onclusion to be drawn from the present [illegible]s that *S*s are able to analyze the meaning o[illegible]timulus without first evaluating its p[illegible]logical properties.

THE [illegible]MPORAL COURSE OF RECOVERY FROM INTERFERENCE AND DEGREE OF LEARNING IN THE BROWN–PETERSON PARADIGM [1]

DELOS D. WICKENS [2] AND M. M. GITTIS

The Ohio State University

In the Brown–Peterson paradigm, performance declines across successive trials with the same class of materials, but it improves as a function of the [illegible] value of an interposed intertrial interval. One interpretation of [illegible]fect is that the previous interfering items are forgotten with time. This interpretation was tested by repeating items prior to the increased intertrial [illegible] order to reduce their rate of forgetting. No evidence was obtained to indicate that this variable influenced the temporal course of recovery from [illegible]e interference, suggesting that this interpretation of the effect is inadequate.

[illegible] the Brown–Peterson paradigm (B[illegible]n, 1958; Peterson & Peterson, 1959), suc[illegible]ive trials with the same class of mat[illegible]ls are given at an intertrial interval in t[illegible] neighborhood of 30 sec., and with a con[illegible]nt retention interval for all trials, per[illegible]mance drops markedly and reaches asy[illegible]ptote in three or four trials (Keppel & [illegible]nderwood, 1962; Loess, 1967; Wickens, 19[illegible]). Two kinds of interpretations have be[illegible]n made of these data. One is that *S* be[illegible]omes bored or "inattentive" and hence performs less well. This interpretation seems most implausible, for the asymptote is reached within 2 min. after the experiment is begun, and if *S*'s attention were as fickle as this interpretation implies, one would have to regard as suspect the results of almost all laboratory research in psychology.

The most plausible interpretation of the decline is that lower performance on the later trials is engendered by the interference resulting from the prior inputs. Since an asymptote is reached, it must be assumed that the growth of interference is limited to some maximum achieved within about four trials. Obviously, this is a proactive interference interpretation. Such an interpretation does not state whether the deficit occurs in the encoding, storage, or retrieval stage, but simply that prior experience with the same class of items inhibits performance on subsequent items. The occasional occurrence of intrusions of prior items during the recall of later items offers some positive evidence of competition at the time of retrieval, although it does not negate an interference effect at the other stages.

The degree of decline in performance is a function of the intertrial interval (Cermak, 1969; Loess & Waugh, 1967); but what is more important for the present research is that if after n trials, an increase in intertrial interval occurs before trial $n+1$, performance will improve on trial $n+1$ (Peterson & Gentile, 1965).

Kincaid and Wickens (1970) found an orderly increment in trial $n+1$ as the critical intertrial interval was increased beyond the usual 30 sec. by 15–120 se[illegible] At this latter temporal value, performance was increased by about two thirds of the drop from Trial 1 to Trial 4. This general result was also obtained by Hopkins, Edwards, and Cook (1972).

A further interesting characteristic of this spacing effect is found in the research of Nield (1968). He used consonant trigrams (CCCs) as his target items and color naming as the rehearsal preventative task. During the lengthened intertrial interval, whose increment was 16, 48, or 80 sec. for different groups, his three sets of groups engaged in different types of

[1] The research was supported in part by National Science Foundation Grant GB-33680 to the first author.

activities. One set of groups simply rested, another set named a matrix of color patches, while a third set continued with the Brown–Peterson memory task, using three-digit numbers as the target items. This latter task was chosen because there seems to be little or no interference between CCC items and number trigram (NNN) items. Note also that the distractor task was color naming, not digit subtraction as in the original Peterson and Peterson (1959) experiment. The set of groups did not differ from each other either in the rate or magnitude of recovery from the inhibitory effect. Within the limits of the kinds of tasks employed—resting, color matrix reading, or the Brown–Peterson task with items of a different conceptual class, the passage of time alone seems to have been responsible for the recovery.

The phrase "within the limits of the kinds of tasks employed" should be emphasized, since there is evidence that the recovery effect is influenced by the nature of the interpolated activity between trial n and $n+1$ and the nature of the target activity. Evidence on this topic will be presented in the Discussion section.

Several possible ways of accounting for these results seem available. One is that they are due to a forgetting of the interfering material either because of mutual interference among these items—an "acid bath" (Posner & Konick, 1966) type of approach or to some time-related weakening factor or factors. Another interpretation is a list differentiation process made possible through the separation of the n and the $n+1$ trials by different intervening materials (Gorfein & Riley, 1974).

The present experiment was designed to test the forgetting-of-interference interpretation. It was assumed that if one could delay the forgetting of the interfering items, one would also depress the rate of recovery of performance across time. The method used to reduce forgetting of the interfering items was simply to give a dual presentation of the to-be-interfering items for one group and only a single presentation of the items for the other (control) group. This method is based simply on the time-honored belief that repetition increases the degree of learning and hence retards forgetting.

Method

Subjects. The *Ss* were 960 male undergraduate students at The Ohio State University who chose to participate in this experiment to fulfill a requirement for their introductory psychology course. The *Ss* were assigned to the 10 different groups in rotating order of their appearance at the laboratory, with 96 *Ss* in each group.

Material and apparatus. The target items of the experiment consisted of eight CCCs with association values between 25% and 33% (Witmer, 1935) and six three-digit NNNs. The NNNs were compiled from a table of random numbers such that no NNN had two identical digits or comprised a "meaningful" sequence (e.g., 321). The digit 7 was not used. Slides of the Stroop (1935) test were employed as the distractor or rehearsal preventative activity.[3] They consisted of 15 color names appearing in a 3 × 5 matrix. These were photographed from a sample given by Underwood (1966, p. 540). A plain 3 × 5 in. index card with a hand-printed sample of the Stroop test was shown to each *S* during the instructions. A metronome was used to produce clicks during the presentation of the Stroop slides. All slides were presented by a Kodak projector and timed by a 35-mm. timer.

Procedure. An asterisk presented for 2 sec. served as a ready signal for the 1.5-sec. presentation of the CCC or NNN which followed. Next was a 12-sec. presentation of a Stroop slide accompanied

[3] The Stroop test was chosen for the rehearsal preventative activity because we have, in The Ohio State University Laboratory, found it to be a very effective distractor task in the sense that *Ss* become quite involved and challenged by the task itself—more so than a number subtraction task. It seems to be highly effective for distracting *Ss* from rehearsing the memory task.

by 15 beats of the metronome, and finally there appeared a [illegible] presentation of a question mark. Each trial, therefore, took 21.5 sec., and each trial was exactly the same except for the target item presented and the specific Stroop slide given.

The design of the experiment contained two sets of groups, the experimental set and the control set. The experimental set experienced repetition; the control set did not. Table 1 presents the basic outline of the procedure. In that table the letter "C" stands for the consonant trigram, while the letter "N" represents a digit trigram. The subscripts designate particular items with the zero referring [illegible] practice items (C$_0$ and N$_0$) [illegible] experiment to accustom [illegible]

[illegible] Experimental Group 2, which is typical. It began with two practice trigrams followed by three trials each on a different CCC. For the next three trials these same trigrams were repeated in their original sequence. Then, with no break in tempo, Ss received two NNNs, and finally they were tested on the critical trigram C$_4$. Its control has a similar program except that no repetition is given. It will be noted that trigrams C$_1$, C$_2$, and C$_3$ occurred just before the shift to NNNs as they also did in the experimental group. The other groups differ in the number of NNNs inserted between C$_3$ and the critical item C$_4$. Since the intertrial interval was 21.5 sec., the time value between C$_3$ and C$_4$ can be determined by the number of interpolated N trials. The use of NNNs during the recovery period was based upon the Nield (1968) finding of no apparent difference between type of activity interpolated and the beneficial value of the spacing effect. In addition, dealing with subsequent memory load activities tended to prevent Ss from thinking about any prior items. And finally, the present experiment is not concerned with the precise form of the recovery function but with the comparison of different groups' recovery.

Results

The effect of repetition. Figure 1 shows the percent correct recall based on items correct per trigram for the experimental and control groups across the first six trials. An analysis of variance of these data showed the performance of the experimental group to be significantly superior to that of the control group on the repetition series of trigrams, F (1, 958) = 48.22, $p < .01$. The effect of the trial block (Trials 1–3 vs. Trials 4–6) was also highly significant, F (1, 958) = 3,002.12, $p < .01$, as was the interaction of the two main effects, F (1, 958) = 16,548, $p < .01$. These results are essentially a replication of the work of Cermak (1969).

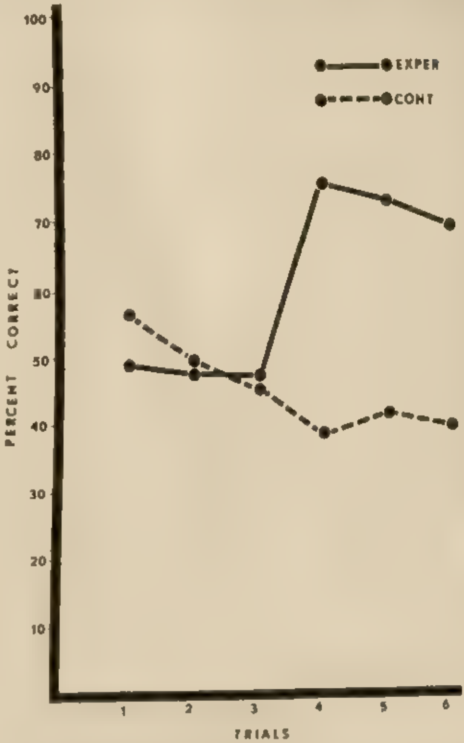

Figure 1. Performance of the experimental and control groups on the six items prior to the introduction of the increased intertrial interval.

It should be remarked that the usual decline in performance across the early trials does not occur at a significant level. Presumably this is because PI had already built up as a result of the practice trials, on which performance was not recorded. However there seems to be a slight downward trend across the first three or four trials for the control groups, showing the usual nadir of performance at about Trial 4.

The effect of temporal spacing on performance. The percent correct recall on the final trial as a function of the number of NNN slides interposed between the last presentation of a CCC and the critical trigram is shown in Figure 2. An analysis of variance of these data suggests that repetition had no effect, F (1, 950) = .285. There was no significant interaction between the effects of time and repetition, F (4, 950) = 1.928. The main effect of

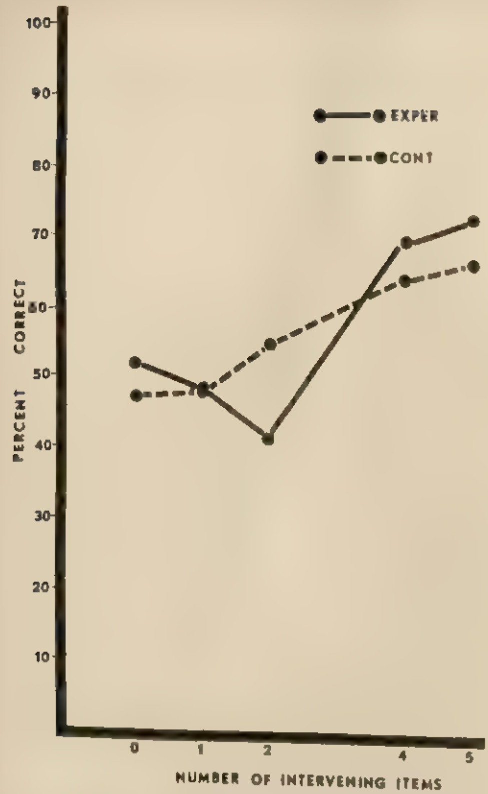

FIGURE 2. Performance on the new (critical) item as a function of the length of the added spacing interval. The duration of any intervening item presentation and test is 21.5 sec.

time, however, was highly significant, $F\ (4, 950) = 13.752$, $p < .01$.

Discussion

In beginning this discussion, it should be emphasized that the purpose of the experiment is not concerned with the retention of a previously presented target item, but rather with the measure of the effects of the strength of prior target items upon the recall of a different target item which is presented following a lengthening of the usual interval. Much data (Keppel & Underwood, 1962; Loess, 1967; Wickens, 1970) point to the fact that performance declines across the first three or four trials with the same class of materials. Presumably it does so because the input of the prior items interferes in some way with the performance on later items. With an increase in intertrial interval after trials with a constant interval, performance improves. The interference-from-prior [illegible] interpretation of the loss across tri[illegible]ld suggest that such gains would be du[illegible] forgetting of the prior items, and h[illegible]ecrement in interference and increment i[illegible]rmance.

This interpretation, there[illegible] would tend to account for the improvemen[illegible] performance which is associated with an [illegible]ed span of time between trial n and $n +$ [illegible] increased forgetting of the interferin[illegible]rial. The present experiment was desi[illegible] increase the retention of the interfe[illegible] items by repeating them in the earlier t[illegible]. Such an interpretation would predict [illegible]at better learned (and hence better reme[illegible]ered) items would persist longer in time [illegible] therefore would depress the temporal re[illegible]ery curve. The analysis of variance gave no [illegible]dence of a difference between the experime[illegible] and control groups, although the tim[illegible]fect was significant for both groups. De[illegible] the lack of main effect or interaction, the [illegible]o groups with two and five NNNs were c[illegible]pared by a t test, and they fell short of th[illegible] 05 level. Considering that there are 96 *Ss* in [illegible]ch group, the failure to find significance b[illegible]ween the experiments and controls is quite c[illegible]nvincing.

Assuming that the repetition did s[illegible]rengthen the first three triads, and Figure [illegible] indicates that it did, one should expect them t[illegible]e better retained across the interpolated ac[illegible]ity and, by producing greater interference, to suppress the recovery curve. Obviously this did not occur, and so no support for the forgetting of the interfering material is found

Research on the present topic by Hasher, Goggin, and Riley (1973) and also by Goggin and Riley (1974) led the authors to a list differentiation interpretation of the effect. In their research, they worked with word triads as their target items, and after presenting three triads all drawn from the same category, they (*a*) shifted to a new category for three trials; (*b*) continued with triads of the same category for three trials; or (*c*) shifted to a rest condition in which *Ss* viewed pictures. On the seventh trial they reverted to a triad from the original category. Enhancement of performance on the seventh trial was found only for the rest groups, despite the fact that the group shifted to a new category on Trial 4 showed release from PI (Wickens, 1970).

The interpretation they made of these results was that the interposed highly different activity of "rest" permitted or generated a differentiation between the specific materials of the first three trials and the material of the

seven[illegible] even though all four items came from [illegible] ame category. By so doing, the interf[illegible] of the previous three items was reduc[illegible] during seventh-item recall. Words in gene[illegible] even though of a different category, are [illegible] able to produce the necessary psycholog[illegible] contrast for differentiation.

[illegible] position that the differentiation was due [illegible] ply to the change in the nature of the task [illegible] n be contradicted for several empirical reasons. It will be noted in the Nield (1968) experiment described above that the group that continued to perform the Brown–Peterson task, but on a new class of materials—NNNs [illegible] ther than CCCs—demonstrated no differ[illegible] from the groups which either color named [illegible]

[illegible] cond experiment, Nield (1968) ch[illegible] the task and did or did not change the na[illegible] of the materials. Half of his groups be[illegible] their Brown–Peterson trials with CCCs as [illegible] target items and half with NNNs. Aft[illegible] three trials, they were shifted to a new task which consisted of simply reading a ma[illegible]x of numbers or of consonants. It had bee[illegible] clearly impressed upon *S*s that this shift wo[illegible]d occur and that they were not to be tested on the recall of the matrix material. Obviously, for half of each group the matrix was the same material as the target items, and for half it was different. On the subsequent Brown–Peterson trial, *S*s were tested with the class of materials of the original three triads. If the materials were the same type throughout the Brown–Peterson, matrix, Brown–Peterson sequence, no enhancement of performance on the final trial was formed. If the Brown–Peterson material and matrix material differed, however, performance on the final trial was markedly facilitated. Clearly, simply changing the task from a memorial one to a simple processing one does not achieve the psychological contrast effect which is necessary for list differentiation. It is apparent that, in our present state of knowledge, it is difficult to predict what manipulation will produce differentiation (if that is the basis for the improvement); although we seem to know that the employment of the same general class of material throughout, even though in a different manner, will prevent it.

An example of the difficulty in predicting when differentiation will make itself felt is found in the results of the present experiment. Underwood (1969) has presented a considerable body of evidence to the effect that frequency is a significant attribute of memory, and *S*s are highly capable of responding to differences in frequency of presentation independent of response strength itself. Our experimental group received two presentations of the three pre-interpolated-task triads, and the post-interpolated triad received only one. The ratio of 2:1 should have established a differentiation between the first set of triads and the test triad. This frequency differential would not have been available to the control group. Hence, one should predict that the experimental group would excel the control group, but it did not do so.

In conclusion it would appear that the forgetting-of-interfering-materials concept has no support from the data of this experiment; and that a differentiation interpretation, even though it is not without problems, may be somewhat more promising.

MAINTENANCE OF INTERFERENCE IN SHORT-TERM MEMORY[1]

JUDITH GOGGIN[2]
University of Texas at El Paso

DONALD A. RILEY
University of California, Berkeley

The nature of facilitation and interference effects was examined within the Brown–Peterson paradigm. Subjects were first given a block of three tests on items from a single taxonomic category. Three variables dictated the sequence of events thereafter: (a) the similarity relationship between a subsequent block of items and Block 1 items, i.e., same category–same items, same category–different items, or different category; (b) the time interval between Block 1 [illegible]uent block of interest, i.e., immediate vs. delayed presentation; [illegible]hin the delayed presentation conditions, whether the interval was [illegible] memory task or with rest. Recall was best when items were [illegible] with different items from the same category, and intermediate [illegible] the category changed. A rest delay improved recall in all conditions [illegible] both to no delay and to a delay filled with work. A differentiation [illegible]othesis was used to account for these results.

Recently Hasher, Goggin, and Riley (1973) demonstrated that both facilitative and inhibitory effects occurring within the Brown–Peterson paradigm (Brown, 1958; Peterson & Peterson, 1959) persist over intervals that would normally be considered outside the range of short-term memory (STM). In that experiment, *S*s were first tested with three triads of words from one taxonomic category, then three triads from another category, and finally three more triads from the first taxonomic category. The time intervening between the first and the third sets was approximately 90 sec. When the third set of triads was identical to the first set, facilitation over an appropriate control was demonstrated, thus showing a memorial effect for specific items. When, on the other hand, the third set of triads was from the same category as the first but was comprised of different words, inhibition equal to a control tested on the same category throughout was demonstrated. Controls made it clear that the inhibition was category specific.

Previous research (e.g., Cermak, 1969; Hebb, 1961) has shown the facilitative effects of repetition over rather long intervals in an STM paradigm, but studies investigating the persistence of inhibition have shown considerable loss of inhibitory effects. That is, for comparable time intervals, facilitation persists, but inhibition is lost. Some studies (e.g., Hopkins, Edwards, & Cook, 1972; Kincaid & Wickens, 1970) have found a moderate amount of recovery (approximately 62% and 48%, respectively) from the build-up of proactive interference (PI) after a 90-sec. interval, and Cermak (1970) found almost complete recovery following a 66-sec. rest interval. In the Hasher et al. (1973) study, on the other hand, such recovery was not found.

We speculated that the critical difference between our study and previous ones lay in the nature of the interpolated material and its effects on *S*'s ability to differentiate clearly between original learning and later learning. Only in Hasher et al. (1973) were the interpolated material and task identical in nature to those of original and final learning. The *S*s were required to recall items different only in that they came from a different taxonomic category. The other experiments used different kinds of activities in the intertest interval, such as symbol cancellation, Stroop color naming, and rest, but in no case were *S*s engaged in a memory task of the same nature. To determine whether or not the differences between these two classes of experiments are related to the nature of the intervening activity, it is necessary to include within the same design conditions that have a memory task as interpolated activity and conditions that

6	C_1	C_{1d}	C_{1d}
7	C_1	rest	C_3
8	C_1	C_2	C_3

Note. Abbreviations: C = taxonomic category, s = repetition of the same items, d = use of different items from the same category.

have some other sort of nonmemorial filler task. This was the purpose of the present experiment.

Method

Design. Outlined in Table 1 are the eight experimental conditions, each one of which was divided into three temporally equivalent blocks of learning or rest activity. A block of learning activity consisted of three Brown–Peterson tests; all to-be-remembered items in any one block belonged to the same taxonomic category (C). Numerical subscripts represent category membership. Thus, Condition 8 received a different category in each of the three blocks (C_1, C_2, C_3), while all items belonged to the same category in Condition 6 (C_1, C_1, C_1). When there was category repetition across blocks, letter subscripts designate the degree of item similarity. Repetition of the same items is represented by the letter "s"; the use of different items from the same category is represented by the letter "d." This distinction can be illustrated by an examination of Conditions 1 and 4. If the words on the first test of Block 1 had been, for example, MUSKRAT, WOLF, ELK, these same words would again appear on the first test of Block 3 in Condition 1, while GOAT, MULE, CAMEL might appear in the corresponding position in Condition 4.

All conditions were treated alike in the first block, receiving three STM tests on items from a single category. Dictating the sequence of events thereafter were three main variables: (*a*) the similarity relationship between a subsequent block of items and Block 1 items, i.e., same category–same items (Same), same category–different items (Different), or different category (Release); (*b*) the time interval between Block 1 and a subsequent block of interest, i.e., immediate or delayed presentation; and (*c*) within the delayed presentation conditions, whether the interval was a work interval filled with a memory task or a rest interval in which *S*s looked at scenic slides. Consider, for example, the same category–same item relation. Both [illegible] ons 1 and 3 received C_{1s}, but C_{1s} was t[illegible] ter a delay in Condition 1, whereas it was [illegible] mmediately in Condition 3. Comparison o[illegible] mance on C_{1s} can also be made between [illegible] ns 1 and 2, which were identical except th[illegible] lay was a rest interval in the former and wa[illegible] ith tests on a new category in the latter. Pa[illegible] mparisons on same category–different items [illegible] ible in Conditions 4, 5, and 6. C_{1d} was tes[illegible] r no delay in Condition 6, after a rest dela[illegible] dition 4, and after a work delay in Condi[illegible] Finally, performance on a new category c[illegible] ssessed after no delay (Conditions 2 and 5 [illegible] rest delay (Condition 7), and after a wor[illegible] (Condition 8).

Materials. Foods, body parts, and animals were the three taxonomic categories from which stimuli were chosen. The categories were used equally often within each condition and occurred equally often in each of the three blocks of trials. Each category was composed of 36 words, divided arbitrarily into 12 triads. Assignment of the 36 triads to conditions and test positions within conditions could not be equalized, but was reasonably well balanced. The 3 words in each triad were arranged diagonally across a slide.

Procedure. Subjects were first given practice trials to familiarize them with the task. Practice trials were identical to regular test trials except that symbols, instead of words, were the to-be-remembered items. Each *S* then received three 90-sec. blocks of learning or rest activity. A block of learning activity consisted of three Brown–Peterson tests, each of which lasted 30 sec. The sequence of events during this 30-sec. period was as follows: (*a*) a ready signal for 2.5 sec.; (*b*) a word triad presented for 1.5 sec., during which time *S* read the words aloud; (*c*) a 15-sec. presentation of a three-digit number from which *S* was instructed to count backward by threes as fast as possible; and (*d*) a question mark displayed for 11 sec., which was *S*'s signal to recall the word triad, in order if possible. If another test was to follow, it began immediately.

During blocks of rest, *S*s were shown 12 scenic slides. These slides were presented for the same time intervals (i.e., 2.5, 1.5, 15, and 11 sec.) that would have been used had the block been filled with STM tests. The *S*s were instructed simply to relax and to view the pictures. If a block of learning activity followed a block of rest, *S*s were forewarned shortly prior to the appearance of the ready signal. Slides were presented by a Carousel projector, with slide duration regulated by a Gerbrands tape timer.

Subjects. A total of 384 *S*s was used in the experiment, with 48 in each condition. The *S*s were students at the University of Texas at El Paso who participated in the study to receive bonus points in introductory psychology. The *S*s were randomly assigned to conditions in blocks of 8. Thirteen *S*s were discarded for failure to follow instructions or equipment malfunction.

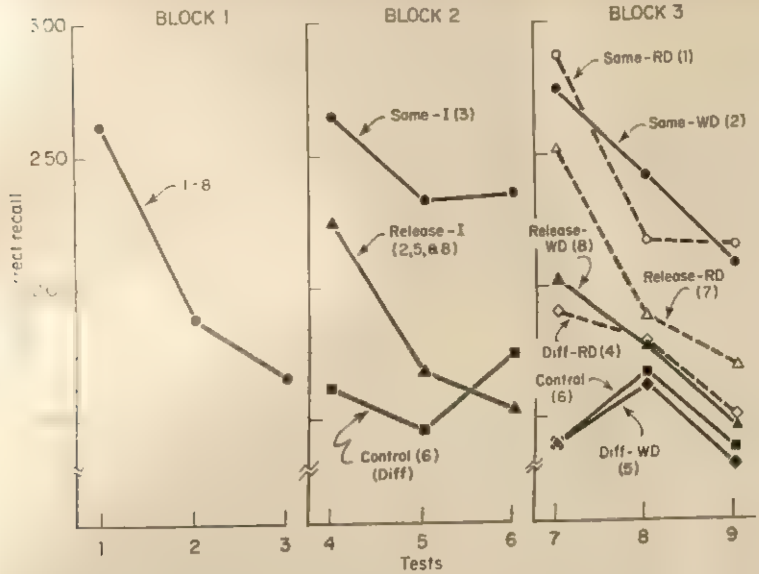

FIGURE 1. Mean correct recall as a function of condition and test. (Abbreviations: I = immediate presentation, RD = rest delay, WD = work delay, Diff = different.)

RESULTS

An item was considered correct if it was given, whether or not it was placed in correct serial position. Mean correct recall is presented in Figure 1. The figure is divided into three panels that correspond to the three blocks of trials. All conditions were treated alike in Block 1 and, consequently, are shown as a single curve. Those conditions treated alike in both Blocks 1 and 2 were similarly collapsed in Block 2 for simplicity of exposition. None of these conditions so treated differed significantly from each other.

Replication of basic phenomena. High recall on Test 1, followed by a drop in retention with succeeding tests on similar stimuli, is characteristic of the Brown–Peterson paradigm. The rapid drop in recall, which has been attributed to increasing PI across tests, is evident in Panel 1. This main effect of tests was significant, F (2, 752) = 140.93, $p < .001$; no other effects were.

Effects of block similarity. In the second and third blocks of work activity, there were three types of items defined by their similarity relationship to the Block 1 items: Items were drawn from the same category (Different–Control), were drawn from a new category (Release), or were repetitions of items that had appeared in Block 1 (Same). The effect of the similarity variable was examined on Test 4, across Block 2, and across Block 3.

On Test 4, the variations in item similarity had a strong and reliable effect on the level of recall, F (2, 141) = 16.52, $p < .01$. After PI has built up within a category, a change to a new category produces release from interference as evidenced by a marked improvement in recall (cf. Wickens, 1970). Replication of this phenomenon can be seen by comparing Release and Control conditions; a planned comparison showed that this difference was significant, F (1, 141) = 12.18, $p < .01$. Test 4 analyses also showed that repetition facilitated recall since Same *Ss* performed better than Release *Ss*, F (1, 141) = 4.88, $p < .05$.

Performance across the three tests of Block 2 is displayed in Panel 2. The general trend of recall by the Release condition was similar to that found in Block 1. On the first test with the new category, recall was high; on succeeding tests with similar

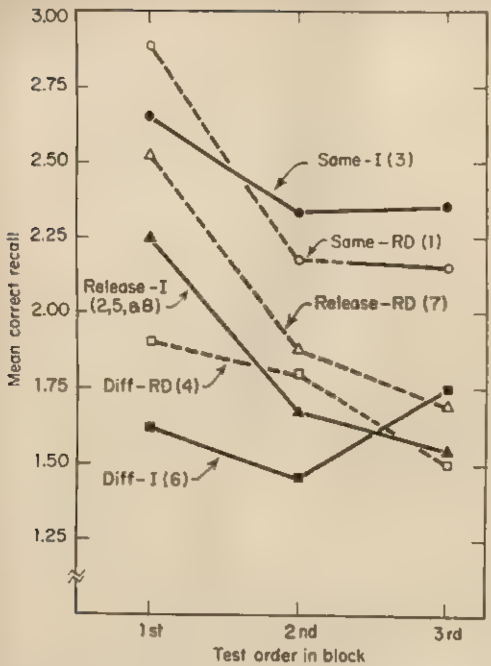

FIGURE 2. Mean correct recall as a function of condition and intertest interval. (Abbreviations: I = immediate presentation, RD = rest delay, Diff = different.)

materials, recall decreased, presumably because of cumulating interference. Thus, Control and Release *S*s, whose recall was quite discrepant on Test 4, were performing at similar levels on Tests 5 and 6. Performance in the Same condition showed the benefit of item repetition, with recall being maintained at a high level throughout the three tests. Analysis of Block 2 showed that both conditions, F (2, 141) = 25.75, $p < .001$, and tests, F (2, 282) = 6.60, $p < .01$, produced reliable differences. In addition, the interaction between conditions and tests was significant, F (4, 282) = 2.78, $p < .05$.

The effects of item similarity are somewhat more difficult to see in Block 3 because there were two groups for each similarity condition. The two groups are distinguished on the basis of whether Block 2 consisted of a rest interval or a work interval. Nevertheless, the general picture presented in Panel 3 is similar to that in Panel 2. The differences among similarity conditions occurred again and were significant, F (2, 282) = 54.96, $p < .001$. Overall, Same *S*s showed the benefit of item repetition; Different *S*s showed the depressing effect of cumulative PI; and Release *S*s showed the facilitation that accompanies a category change. Recall decreased over tests in the block, F (2, 564) = 25.88, $p < .001$. This main effect, however, must be interpreted in conjunction with the reliable Conditions × Tests interaction, F (4, 564) = 3.[illegible], $p < .05$. Recall decreased more rapidly over tests in the Same and Release conditions than in the Different condition, apparently reflecting some lower limit on recall in the last condition.

In summary, variations in item similarity between blocks of tests produced strong and consistent differences in recall. These differences were similar to those found by Hasher et al. (1973). After PI had built up within a taxonomic category, recall was depressed if there was continued testing on that category, or even if there was later return to that category after an interval of time. If there was a change in encoding category (Release), on the other hand, recall improved on the first test with the new items and then decreased as more items were presented in that category. Finally, repetition of items (Same) produced an improvement in recall in comparison to the release conditions, indicating that specific items were retained in this paradigm.

Effects of intertest interval. It has been pointed out that triads used in Blocks 2 and 3 were related to Block 1 triads in three ways, i.e., items were repeated, came from a new category, or were different items from the same category. One question of interest was whether performance on these later tests would be affected by the time interval separating them from Block 1 tests. This can be determined by comparing the level of recall for Same, Release, and Different conditions tested immediately with that after rest delay. Figure 2 shows this comparison.

Recall was better after a rest interval than after no delay on the first test of the block, F (1, 282) = 7.42, $p < .01$. Although the individual similarity conditions

did [illegible] …tistically reliable effect, the [illegible] of the effect in each of the three [illegible] plus the absence of any relia… [illegible] (F = .02) makes it clear that a [illegible] facilitated recall in each condition. …erior recall after a delay has been [illegible] by others under similar conditions [illegible]. Different *S*s (Cermak, 1970; Kinca… & Wickens, 1970) and, in one case, for bo… Different and Release *S*s (Hopkins et al., 1972).

Delay did not have a reliable effect when the block was considered in its entirety. The interaction between delay and tests was, however, reliable, $F(2, 564) = 3.06$, $p < .05$. As Figure 2 shows, the facilitation by delay was maintained across tests in the Release condition, but not in the other two.

Effects of interval filler. The main purpose of the present experiment was to determine whether the nature of the material interpolated between the original learning task (Block 1) and the final learning task (Block 3) would affect the level of recall in the third block of tests. These data are displayed in Panel 3 of Figure 1.

Condition 6 was not included in the overall analyses of interval filler, but it was compared to Condition 5 in a separate analysis. These groups did not differ statistically in Block 3 ($F < 1$), and their overall performance was strikingly similar. Thus, *S*s returning to an old category with new items after an intervening different category (Condition 5) performed the same as *S*s maintained throughout on the old category (Condition 6), i.e., inhibition did not dissipate with time even though release from this inhibition had occurred in Block 2. Similar results were found in Hasher et al. (1973).

Overall analyses of filler activity were conducted both on the first test of the block and on the block as a whole. On Test 7, recall was higher when Block 2 was filled with rest than when filled with work, $F(1, 282) = 14.68$, $p < .01$. Preplanned comparisons showed a significant effect of filler activity for both Different and Release *S*s, Fs $(1, 282) = 8.70$, ps $< .01$, but for Same *S*s, this effect, while in the same direction, was not significant ($F < 1$). The interaction between condition and filler activity was not reliable.

Examination of Panel 3 shows that these effects persisted throughout Block 3. Recall was higher when a rest interval occurred between the first and third blocks than when the interval was filled with tests on a different category, $F(1, 282) = 7.82$, $p < .01$.

Despite this pattern of results, the interaction between condition and filler did not reach significance, making conclusions about the differential effect of filler on similarity conditions ambiguous. Again, preplanned comparisons showed that recall after a rest interval was higher than after a work interval for Different and Release conditions, Fs $(1, 282) = 19.46$ and 18.52, ps $< .01$, respectively, but a difference in the Same condition was not found ($F < 1$).

Error analyses. A breakdown of the incorrect responses is shown in Table 2. The measure of errors/block was used because conditions differed in the number of blocks of learning activity. The most

intrusions were made in Condition 6, in which all items were different but belonged to the same category; the fewest intrusions occurred in Condition 8, in which a different category of items was learned in each block. This would be expected if number of intrusions reflected the amount of interference.

Most of the errors came from within the list; most of these, and in some cases all, were intrusions from an appropriate category. Thus, *S*s appeared to be able to monitor their recall and to restrict their output to the correct taxonomic category. By far the largest percentage of intralist errors, 72%, originated from the immediately preceding test trial. Frequency of intrusions from earlier test trials was not high, although in three groups some errors were Block 1 intrusions into Block 3 recall. These percentages were 14%, 15%, and 6% for Conditions 4, 5, and 6, respectively. It appears that even after 90 sec. of rest or other learning activity, Block 1 items are available to occur as intrusions if they are of the appropriate category. Frequency of this kind of error in the other conditions was almost nonexistent.

Discussion

The present study was addressed to three issues arising from differences in the results obtained by Hasher et al. (1973) and previous investigators. First, of the various studies that have examined the persistence of proactive interference in the Brown–Peterson paradigm over time, only Hasher et al. found no reduction in interference. That study, however, did not have an appropriate nonwork condition. Consequently, one cannot be sure that loss of inhibition would have been found under conditions comparable to other experiments. This study provides such a comparison. Second, the present study allows a direct comparison between a retention interval filled with rest as opposed to further rehearsal of words from a different category and further rehearsal of words from the same category. This comparison is necessary in order to make a direct connection between the presence or absence of persisting inhibition and the nature of the filler activity. Third, this experiment, by extending the question of the effects of the interpolated activity to release and repetition of original learning conditions, allows a test of the PI decay hypothesis.

Consider first the effects of time. In the Results section, these effects were analyzed both on the first trial and on all three trials of the relevant blocks. While the latter measure may be of interest, it is only the first-trial data that give an unambiguous measure of the effect of previous experimental operations. Consequently, our emphasis here will be on this measure. Figure 2 showed that our Different–Delayed condition was reliably superior to the Different–Immediate condition. Thus, we replicated the results of previous experimenters showing that PI dissipates with time. This facilitative effect of delay occurred, and to the same degree, in the Release and Same conditions.

The findings of Hasher et al. were reproduced in this study in that there was no such dissipation of PI in the Different condition if the interval was filled with tests on items from another category. Filling the interval also depressed recall in the Release condition; while this effect appeared in the Same condition, it was less reliable. It is of interest to observe that the facilitative effects on recall of time and those associated with a change in category are additive. That is, the superiority of recall following a rest interval as opposed to a work interval was as great in the Release condition as it was in the Different condition. The absence of an interaction between category change and intertest interval can also be seen in Hopkins et al. (1972).

It has been suggested (e.g., Kincaid & Wickens, 1970) that PI decreases as a function of intertest interval because there is a time-dependent decay of the encoding characteristics responsible for PI. Several aspects of the present data argue against such an interpretation. Presumably, a change in the type of items increases recall because there is a release from the interference that has accrued for the original encoding category (Wickens, 1970). If this is the case, a rest interval should be of no particular benefit when it is followed by a category change. That is, since the items following a change in category are not encoded in the same way as the original items, decay of the encoding characteristics of the original items associated with a long intertest interval should be irrelevant. A rest interval in the present study, however, facilitated recall just as much when there was a category change (Release) as when there was no category change (Different).

There is another feature of these data that weighs against a time-dependent decay interpretation of the effects of delay. One set of *S*s (Sample [illegible]) received a later repetition of the original block of items; in this case, recall also improved as a function of interblock interval. It seems somewhat unreasonable to suppose that retention of items on their second presentation was facilitated because there was more forgetting of the items from their first present[illegible]

[illegible] en established by this [illegible] of other investigators: (*a*) PI is reduced [illegible] ing a rest interval; and (*b*) PI is not reduced when the interval is filled with tests on a different taxonomic category. There is a third fact, however, that must be added in order to complete the picture. Several experiments (Cermak, 1969; Nield, 1968; Wickens & Gittis, 1974) have demonstrated that after PI has built up in a Brown–Peterson design with consonant trigrams as stimulus materials, filling the intertest interval with tests on number triads does *not* retard the reduction of PI. That is, with CCC stimuli, there is no apparent difference in performance on the next retention test whether the interval is unfilled or whether it is filled with tests on NNNs.

One explanation of these three facts must be ruled out. The task used as an interblock interval filler cannot be responsible for the dissipation or the maintenance of PI in the studies under consideration. Although Nield's (1968) results, for example, showed dissipation of PI over a filled interval and the present study did not, both procedures were ones in which *S* engaged in a Brown–Peterson learning task during the interval.

An alternative hypothesis, more consistent with the present data, is that the amount of PI depends on the differentiation that has occurred during the intertest interval. Two types of differentiation can be distinguished, the first being dependent on time, the second, on item similarity. An unfilled interval allows facilitation of recall, not because of a weakening of Block 1 items, but because the time gap allows them to be distinctively identified as coming from a different part of the experiment. The pool of items from which *S*s must retrieve the correct items during Block 3 will tend to be restricted to those encountered recently. Proactive inhibition is thus reduced because the Block 3 items have a new, unique encoding cue to distinguish them from Block 1 items. If, on the other hand, the interblock interval contains more of the same memory task with similar material, temporal differentiation cues are eliminated. Even though Block 3 is separated from Block 1 by the same nominal time whether the interval is filled with work or rest, the functional time is different.

Why should materials that are sufficiently different from Block 1 items to allow release from PI (i.e., items from a different taxonomic category) produce such an effect? Perhaps as *S* tries to recall Block 2 items, he must repeatedly examine and reject erroneous intrusions from Block 1. This activity may in turn bridge the temporal gap between Blocks 1 and 3. When, however, letters are the to-be-remembered items and numbers are learned during the interval (e.g., Wickens & Gittis, 1974), the items are sufficiently different in kind that letters do not intrude while *S* is trying to recall numbers. In these conditions, Block 1 items do not intrude and need not be rejected during Block 2, temporal differentiation between Blocks 1 and 3 occurs, and loss of PI in Block 3 is observed. The greater release of PI from Block 1 to Block 2 with letters and numbers (Wickens & Gittis, 1974) than with different taxonomic categories as in the present study is consistent with this interpretation.

INT[illegible]TION OF POSITIVE AND NEGATIVE LABELS WITH CA[illegible]RY COMPOSITION IN ATTRIBUTE IDENTIFICATION CONCEPT PERFORMANCE [1]

THOMAS C. TOPPINO AND PEDER J. JOHNSON [2]

University of New Mexico

The effect of response label (example or nonexample) was separated from the effect of ca[illegible] composition (the stimuli contained in a conceptual category) [illegible]s of complementary concepts and requiring *S* to solve two [illegible] with only examples or only nonexamples. It was pre[illegible] positive label (example) would facilitate performance in cate-[illegible] conditions characterized by a high relative frequency of [illegible] stimulus values, while the negative label (nonexample) would facili-[illegible]rformance in category composition conditions characterized by a low [illegible]e frequency of relevant stimulus values. Results on the initial problem confirmed the experimental prediction. By the second problem, the effects of response label had disappeared, leaving only a category composition effect. The experimental hypotheses were discussed in relation to an earlier hypothesis based on preexperimental experience.

A long-standing generalization in the concept literature is that instances from the positive category (examples) lead to more rapid solution than instances from the negative category (nonexamples). This generalization gained considerable support from early attribute identification (AI) concept experiments (rule known, relevant stimulus values unknown) where *S* was required to solve a given concept by using instances from only the positive or only the negative category (Freibergs & Tulving, 1961; Hovland & Weiss, 1953). However, recent studies (Davidson, 1969; Toppino & Johnson, 1973) have shown that the earlier experiments confounded two potential sources of solution difficulty: *category composition* (the stimulus types composing the category, i.e., TT, TF, FT, and/or FF)[3], and *response label* (whether the category is called positive or negative). In short, the positive and negative categories for any given concept differ in two respects: They contain different members of the stimulus population, and they are assigned different valenced labels. Thus, differences in performance associated with positive and negative instances of a given concept could be due to either or both of these factors.

The independent effects of category composition and response label can be experimentally isolated by using a pair of complementary concepts for which the positive category of each concept has the same composition as the negative category of its complement (Davidson, 1969). When the effects of category composition and response label are disentangled in this manner, results indicate that a positive label does not necessarily facilitate performance, and that solution difficulty depends primarily upon category composition factors (Davidson, 1969; Toppino & Johnson, 1973). However, response label is not completely without effect. In each experiment, there was at least one condition in which positive superiority was obtained independently of category composition. These findings suggest a weak form of the early positive superiority generalization, viz., while response label does not always influence performance, when it does, solution is easier

[3] Any stimulus population can be partitioned into four stimulus types (TT, TF, FT, and FF) depending upon the joint presence (T) and/or absence (F) of two relevant values (Haygood & Bourne, 1965).

with a positive label. The purpose of the present experiment was to investigate the possibility that, under certain category composition conditions, a negative response label may result in superior AI performance.

Toppino and Johnson (1973, Experiment I) employed two pairs of complementary concepts (inclusive disjunction/joint denial and biconditional/exclusive disjunction) resulting in a positive and a negative label condition within each of four category composition conditions [(TT, TF, FT), (FF), (TT, FF), and (TF, FT)]. The results indicated that a positive label yielded a clear advantage only when category composition had a high relative frequency of relevant values [i.e., (TT, TF, FT)].[4] Furthermore, the advantage of a positive label relative to a negative label, appeared to decrease as the relative frequency of relevant values decreased across category composition conditions [i.e., (TT, TF, FT) > (TF, FT) > (TT, FF)].

The above findings suggest that a positive label somehow facilitates or encourages the use of relative frequency cues. Since the label "example" seems to connote presence of something, a positive label may encourage *S* to use an *affirmational strategy* whereby stimulus values that are present in the training instances become the basis of *S*'s pool of hypotheses. Such a strategy would facilitate performance to the extent that the relevant values occur with a high relative frequency. However, a negative label may have the opposite function. Since the label "nonexample" seems to connote the absence of something, a negative label may encourage *S* to use a *negational strategy* whereby stimulus values that are present in the training instances are excluded from *S*'s pool of hypotheses. This would predict that a negative label should lead to superior performance in the (FF) category composition conditions where the relevant values are never presented.

While Toppino and Johnson (1973, Experiment I) found virtually no difference between the positive and negative (FF) conditions, this finding may be attributable to their use of distributed grid stimuli. These stimuli were generated on a 12-cell grid (four columns and three rows) by illuminating 1 cell (value) in each of the four columns (dimensions). Thus, the nonpresented stimulus values were always present and visible but simply unilluminated. This characteristic of grid stimuli may have reduced the difficulty of solution in Toppino and Johnson's (1973, Experiment I) positive (FF) condition because, if *S* attended to the unlit cells of the grid, the (FF) problem could be solved as a conjunctive (only the relevant values were never illuminated) by using an *affirmational strategy*. However, an affirmational strategy would have been totally inappropriate if conventional geometric stimuli had been employed because, with geometric stimuli, nonpresented values would be truly absent.

The present experiment employed inclusive disjunctive concepts and their complementary joint denial concepts in order to generate two conditions of category composition [(TT, TF, FT) and (FF)] crossed with two conditions of response label ("example" and "nonexample"). In addition, conventional geometric stimuli were employed instead of distributed grid stimuli. It was predicted that the use of these stimuli would substantially increase the difficulty of solution in the positive (FF) condition. The result should be an interaction between category composition and response label such that the positive label would yield superior performance in the (TT, TF, FT) conditions, while the negative label would yield superior performance in the (FF) conditions. Finally, each *S* was presented two successive problems to solve in order to investigate the stability of the interaction between category composition and response label.

[4] For a stimulus population defined on four three-valued dimensions, there are 9 TT instances, 18 TF instances, 18 FT instances and 36 FF instances. Thus, the (TT, TF, FT) category contains 45 stimuli and each relevant value appears on 27 stimuli. Therefore, the relative frequency of relevant values for the (TT, TF, FT) condition is .60. By similar computations, it can be shown that the relative frequency of relevant values is .50 for the (TF, FT) condition, .20 for (TT, FF) condition, and .00 for the (FF) condition.

Method

Su[illegible] design. Subjects were 50 introductory psych[illegible] [illegible]dents who earned extra class credit for exp[illegible]mental participation. Two *S*s were dismissed [illegible] to equipment malfunction. The remaining *S*[illegible] were randomly assigned by blocks of 4 to the four [illegible]xperimental conditions, generated by requiring *S* [illegible] use only examples or only nonexamples to solve either an inclusive disjunctive problem or a joint d[illegible]nial problem. In addition, each *S* was required to solve two succ[illegible] problems in his particular experiment[illegible]

[illegible]s. The stimulus population co[illegible] valued dimensions resulting [illegible] All *S*s were told that the [illegible] would vary along the dimensions o[illegible] [illegible]quare, or circle), arrow orientatio[illegible] ([illegible] up, sideward, or down), dot position (a[illegible] top, middle, or bottom), and border (dotted, da[illegible] or solid).

[illegible]timuli were mounted on 35-mm. slides and wer[illegible] projected onto a translucent screen by mea[illegible] of a Kodak Carousel 750 projector. Two resp[illegible] push buttons labeled "example" and "nonexa[illegible]" were located on a box situated in front of *S* [illegible]nd directly below the screen.

T[illegible]ee pairs of relevant values (solid border and dot in the middle, triangle and arrow pointing up, c[illegible] and dot at the bottom) were selected at random from among the 54 possible pairs. Each selected pair was relevant for one of the three problems which were prepared for each condition. Two of the three problems were presented to each *S* and the problems were assigned so that, in every condition, each of the three problems was presented to one third of the *S*s as the first problem and to another one third of the *S*s as the second problem. Sequencing restrictions used in the construction of these problems is described in detail in Experiment I of Toppino and Johnson (1973).

Procedure. The procedures of the present experiment were exactly the same as those detailed in Toppino and Johnson's Experiment I (1973). Briefly, *S* was given extensive rule training on his particular rule, followed by a test of rule acquisition to insure that he had achieved a maximally high level of rule learning prior to AI training. When *S* had correctly classified eight consecutive stimuli in the rule acquisition test, the nature of the AI task was thoroughly explained. A study–test procedure was employed, in which blocks of five training trials containing all positive or all negative stimuli were alternated with blocks of four test trials (without feedback) containing both positive and negative instances. Criterion was 12 consecutive correct responses accumulated over three or four test blocks.

Results

Analyses of trials and error data yielded virtually identical results. Therefore, only trials data are reported.

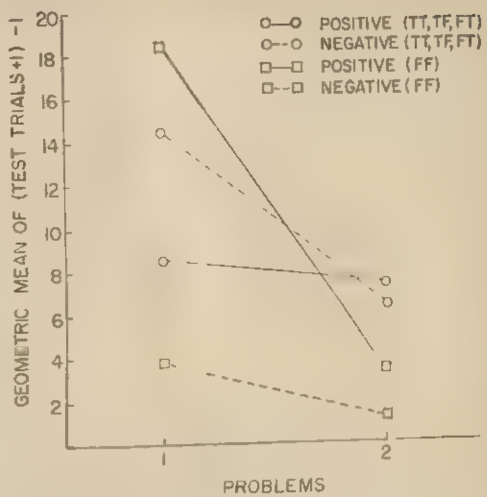

FIGURE 1. Mean test trials to criterion in terms of the antilogs of the means of $\log_e(x+1)$ minus one.

Test trials to criterion on the AI task were transformed into $x' = \log_e(x+1)$ in order to approximate homogeneity of variance and symmetry of distributions. The data are presented in Figure 1 in terms of the geometric means of (test trials to criterion $+1) - 1$ [i.e., antilogs of the means of $\log_e(x+1) - 1$].

Inspection of the data in Figure 1 suggests that the predicted two-way interaction between category composition and response label was obtained on Problem 1 but not on Problem 2, implying a three-way interaction. An overall analysis of variance (category composition, response label, pairs of relevant values, and problems) indicated that the overall two-way interaction between category composition and response label was marginally significant, F (1, 24) = 3.45, $p < .10$, and that the three-way interaction with problems approached significance, F (1, 24) = 2.81, $p \approx .11$. However, a more precise test of the experimental predictions was afforded by a separate analysis of variance for each problem.

On the initial problem, the predicted interaction was significant, F (1, 36) = 5.30, $p < .05$. The positive label yielded superior performance in the (TT, TF, FT) condition, while the negative label yielded superior performance in the (FF) condi-

tion. Neither category composition nor response label yielded a reliable main effect, both Fs $(1, 36) < 1.19$, $p > .20$.

Performance on the second problem indicated that practice eliminated the Response Label × Category Composition interaction, $F(1, 36) = .82$, $p > .20$, leaving only a main effect of category composition. The (FF) condition was solved more easily than the (TT, TF, FT) condition, $F(1, 36) = 7.77$, $p < .01$.

Discussion

The most important aspect of the present results was the interaction which occurred between response label and category composition on Problem 1. The nature of this interaction indicated that a positive label facilitates processing of (TT, TF, FT) instances, while a negative label facilitates processing of (FF) instances.

The hypothesis that predicted the obtained interaction represents an extension of an earlier hypothesis proposed by Bruner, Goodnow, and Austin (1956). According to these authors, preexperimental experience with conjunctive and affirmational concepts leads *S* to base solution attempts on stimulus elements which are common to positive instances (i.e., an affirmational strategy). The present hypothesis expands Bruner et al.'s notio[illegible] proposing that this same preexperimental [illegible]ould lead *S* to eliminate stimulus elemen[illegible]h appear in negative instances (i.e., a n[illegible]al strategy). Finally, if the effect of r[illegible]e label is based on preexperimental expe[illegible] it might be expected that the effect woul[illegible]ish with practice as observed in the pres[illegible]ults.

STRE[illegible] OF AUDITORY STIMULUS–RESPONSE COMPATIBILITY AS A FUNCTION OF TASK COMPLEXITY[1]

JAMES CALLAN, DIANE KLISZ, AND OSCAR A. PARSONS[2]

Center [illegible] Alcohol Related Studies, University of Oklahoma Health Sciences Center

Ear response side and ear-hand components of lateral stimulus-response (S–R) compatibility were examined as a function of information processing [illegible] experiments. Experiment I investigated the compatibility [illegible] (two stimuli–one response) and Donders' *b* (two stimuli–[illegible] choice reaction time (RT) paradigms. A second experiment [illegible] effects in a Donders' *a* (simple) RT paradigm. Neither ear-[illegible] response location correspondence were evident in the *a* RT, [illegible] significant in the *b* and *c*. Ear hand correspondence was not [illegible] affected by task complexity but ear-response side correspond-[illegible]ntly increased from *c* to *b* and became more symmetrical. The [illegible] significantly faster to right ear stimulation in the *a* task but signi-[illegible]ly faster to left ear stimulation in tasks *b* and *c*. The results are discussed [illegible] terms of stage theory of information processing and in terms of their relevance for examination of functional asymmetry.

A [illegible] series of experiments has demonstra[illegible] the existence of a potent stereotypic response pattern (Simon, Hinrichs, & Craft, 1970). In a typical experimental paradigm *S*s respond to stimuli, which are presented to either the right or left side, by manual deflection of response keys located to the right and left of the body midline. The consistent finding has been that *S*s respond more rapidly when the (apparent) side of stimulus presentation and side of response execution correspond. Simon, Hinrichs, and Craft (1970) have identified ear-hand correspondence and ear-response location correspondence as two significant factors in this lateral stimulus-response (S–R) compatibility effect. In a choice (two stimuli–two response) reaction time (RT) task in which the content of a monaural tone (high or low) determined the responding hand, response side (as opposed to hand used) was identified as the most significant factor. Locus of the tone stimulus (right ear or left ear) was irrelevant in this task. When locus of a tone stimulus, which contained no information content (i.e., only one tone presented instead of two tones) determined the responding hand, both ear–response side and ear–hand correspondence effects contributed to the lateral S–R compatibility effect.

Simon and his colleagues have demonstrated this lateral S–R compatibility with both auditory and visual stimuli. They have manipulated the strength of the response pattern by (*a*) decreasing the directional information of the stimulus (Simon, Craft, & Small, 1971), (*b*) causing a conflict between the directional information in the stimulus content and in the stimulus location (Simon & Rudell, 1967), (*c*) introducing higher intensity stimulation (Simon, Craft, & Small, 1970), and (*d*) adding irrelevant directional stimuli in the same or different modalities (Craft & Simon, 1970; Simon & Craft, 1970; Simon, Craft, & Small, 1970; Simon & Small, 1969).

As an explanation for this phenomenon, Simon, Hinrichs, and Craft (1970) have postulated that it is the reflection of an "innate tendency [in humans] to respond toward the source of stimulation [p. 101]." However, the fact that this effect has been observed only in choice RT studies raises questions as to the generality of the above explanation. For example, is the compatibility effect also present in experimentally comparable, simple RT para-

digms? Further, what stage or stages of information processing are involved in the compatibility effect? Is the effect primarily due to stimulus choice or response choice or both?

Information processing theory offers a conceptual framework within which the lateral S–R compatibility effect can be explored. According to this approach, a choice RT paradigm contains four information processing stages (Smith, 1968); (*a*) stimulus preprocessing, (*b*) stimulus categorization, (*c*) response selection, and (*d*) response initiation. Donders' (1969) three RT paradigms provide a systematic approach which enables inferences to be made concerning stages of information processing. Briefly, Donders' *a* is a simple RT paradigm (one stimulus, one response), Donders' *b* is a choice RT paradigm (two stimuli, two responses), and Donders' *c* is a go–no-go choice RT paradigm (two stimuli, one response). Donders' *b* compared with *c* allows the role of response choice to be examined while Donders' *c* compared with *a* enables the role of stimulus categorization to be investigated. In this article, two experiments are reported which examine both the ear–response side and ear–hand components of the lateral S–R compatibility effect as a function of information processing complexity within the framework of Donders' three RT paradigms. The results are pertinent to the following specific questions (which are addressed to both components of the compatibility effect): (*a*) Can the lateral S–R compatibility effect be replicated (Donders' *b*)? (*b*) Is the lateral S–R compatibility effect differentially affected by limiting response choice in a go–no-go paradigm (Donders' *c*)? (*c*) Is the effect present when both stimulus choice and response choice are eliminated as in a simple RT experiment (Donders' *a*)?

Experiment I

The purpose of Experiment I was to answer the first two questions posed above. Both choice (Donders' *b*) and go–no-go (Donders' *c*) RT paradigms were given to the same *S*s and the comp[illegible]ty effects were compared.

Method

Subjects. The *S*s were 16 femal[illegible] [illegible]6 male paid volunteers. All *S*s were right-hand[illegible] [illegible]d reported having normal hearing. The *S*s ra[illegible] in age from 18 to 31 yr. with a mean of 23

Apparatus. The *S*s were seated [illegible] [illegible]mfortable chair with arm rests on either side. A [illegible]onse panel was located directly in front of *S*'[illegible] [illegible]air. Two response keys were located on th[illegible] panel so that they could be reached without [illegible] the forearm from the arm rests. One res[illegible] key was located 15 cm. to the right, the other [illegible] 15 cm. to the left of *S*'s midline. The response [illegible]s were of the standard telegraph type, calibrate[illegible] [illegible] that the gap between contacts was maintained a[illegible] mm. and a pressure of 228 gm. was sufficient to m[illegible] contact. All responses were made by depressio[illegible] [illegible] the key with the index finger from a position i[illegible] which the finger rested lightly on the button to b[illegible] [illegible]epressed.

The stimuli were 200- and 500-Hz. tones generated by two Hewlett Packard Model [illegible]0 oscillators. The tones were presented throu[illegible] [illegible]atched pair of TDH 39 earphones which wer[illegible] [illegible]alibrated within 1 db. of each other. Output leve[illegible] the earphones was maintained at 90 db. (re .00[illegible] [illegible]b.) and was checked at regular intervals by a [illegible]librated sound level meter. The intensity rem[illegible]ed constant throughout the experiment. Tone [illegible]resentation and response time measurements w[illegible]re controlled by BRS 200 series digital pro[illegible]ramming equipment. Response times were recorde[illegible] in milliseconds on a Lehigh Valley 420-9 printout counter.

A green warning light located midway between the two response keys was presented 1 sec. prior to the onset of each tone, and there was a 4-sec. interval between tone onsets. Both the warning light and the tone remained on either until *S* made a response or until 1.5 sec. had elapsed from tone onset.

The *S* room was dimly lit by a small (6-w.) incandescent lamp located behind *S*. A 70-db. white noise background prevented disturbance from extraneous noises including the sound of the experimental equipment in an adjacent room.

Procedure. The *S*s were instructed to respond by depressing the key with their index finger. Each *S* performed under two RT conditions: a choice (Donders' *b*) and a go–no go (Donders' *c*). Half of the *S*s received the *b* RT condition first, and the others received the *c* RT condition first. Each *S* received eight practice trials before each condition.

In the *b* RT condition there were two blocks of trials. The *S*s responded on one block of trials with arms uncrossed, so that their left index finger was on the left key and their right index finger was on the right key. On the other block of trials *S*s responded with their arms crossed, so that their left index finger was on the right key and their right index finger was on the left key. Each block con-

Reaction time in milliseconds.

d of the same random sequence of 76 trials. ner a low pitched (200-Hz.) or a high pitched 0-Hz.) tone was presented monaurally on each al. Half of the *Ss* were told to respond with their right index finger when they heard the high-pitched tone and with their left index finger when they heard the low-pitched tone; the other half of the *Ss* were given the opposite hand–tone rule. Each *S* used the same hand–tone rule throughout the entire experiment. Within the b RT condition the crossed and uncrossed trial blocks were counterbalanced. In the crossed block, half of the *Ss* performed the task with the left arm over the right and the other half performed the task with the right arm over the left.

In the c RT condition there were four blocks of trials. Each block consisted of the same random sequence of tones that was used in the b RT condition. On each block of trials *S* was instructed to respond when he heard one tone, not to respond when he heard the other tone, and to place only one index finger on one response key. Every *S* performed one block of trials with each of the possible combinations of index finger and key positions: right-on-right, right-on-left, left-on-left, and left-on-right. The nonresponding arm was placed on the armrest alongside *S* out of the way of the responding hand. The order of presentation of the blocks of trials within the c RT condition was randomized.

Results

For each *S*, median RTs were calculated for each tone–ear combination. Means of the median RTs are presented in Table 1.

Planned comparison t tests were made on (a) order of presentation (b followed by c, c followed by b), (b) effect of hand–tone rule (high-right, low-left; low-right, high-left), and (c) effect of arm over in the crossed conditions (right-over-left, left-over-right). None of these tests were significant, and they were, therefore, eliminated from further analysis.

A five-way repeated measures analysis of variance (ANOVA) was conducted with condition, hand, ear, and side as repeated factors and sex as a between-*S* factor. The following main effects were significant: Sex, $F\ (1, 30) = 7.08$, $p < .05$, males responding faster than females (350 vs. 409 msec.); Condition, $F\ (1, 30) = 60.13$, $p < .001$, c responses were faster than b responses (338 vs. 421 msec.); Ear, $F\ (1, 30) = 18.81$, $p < .001$, left ear was faster than the right (374 vs. 386 msec.); and Side, $F\ (1, 30) = 4.78$, $p < .05$, left side was faster than the right (376 vs. 384 msec.).

The Ear × Side interaction $F\ (1, 30) = 109.71$, $p < .001$, successfully demonstrated the ear–response location correspondence effect and replicated the finding of Simon, Hinrichs, and Craft (1970) in that when stimulus and response sides corresponded, response times were significantly faster

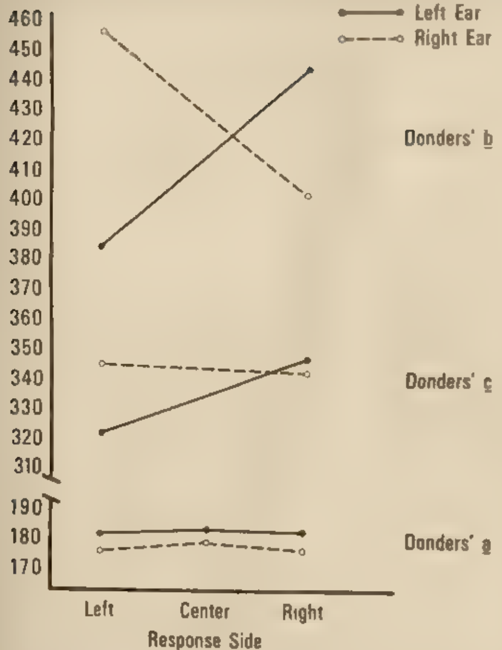

FIGURE 1. The Ear–Side correspondence effect in simple (Donder's *a*), two stimuli–one response (Donders' *c*), and two stimuli–two responses (Donders' *b*) RT conditions. (Right and left hands are collapsed.)

(Figure 1). The Condition × Ear × Side interaction, F (1, 30) = 67.43, $p < .001$, indicated that the ear–response location effect was significantly greater in the *b* than in the *c* condition (Figure 1). A second ANOVA was performed on the Ear × Side interaction within the *c* condition and the effect proved significant, F (1, 31) = 14.29, $p < .01$, although predominantly on the left side. Thus this correspondence effect, while stronger in the *b* RT, does appear in both conditions.

The Ear × Hand interaction was also significant, F (1, 30) = 18.53, $p < .01$, but the Condition × Ear × Hand was not (F = .04), indicating that the ear–hand correspondence effect, although present in both conditions, was not differentially affected by task complexity. The Ear × Hand interaction has another interesting feature; that is, the correpondence is entirely in the left hand. The means for right hand–right ear and right hand -left ear are both 377 msec. while the mean for the left hand–left ear was 370 msec. and for the left hand-right ear, 395 msec.

A comparison of Ear × Side and Ear × Hand correspondence effects are displayed in Table 2 for both *b* and *c* conditions. This table provides convenient comparison with the results of Simon, Hinrichs, and Craft (1970).

The only other significant effect was Sex × Condition × Ear, F (1, 30) = 10.84, $p < .01$; males had less difference between the right and left ear in the *c* condition than the females. This interaction may reflect differences in functional asymmetry between males and females as has been suggested by Kimura (1969). The failure of the Hand × Side interaction (F = .69) to achieve significance indicates that crossing the hands was not a significant factor. Simon, Hinrichs, and Craft (1970) found that uncrossed trials were significantly faster than crossed trials, but direct comparisons between their experiment and this cannot be made as the relative comfort of the arm positions is unknown.

EXPERIMENT II

The purpose of this experiment was to answer the third question, i.e., whether the lateral S–R compatibility effect would be found in a simple RT task (Donders' *a*)

TABLE 2

REACTION TIME AS A FUNCTION OF EAR–RESPONSE LOCATION CORRESPONDENCE AND EAR–HAND CORRESPONDENCE

in which bo[illegible] [illegible]timulus and response choice are elimi[illegible]ed. Simon (1967) examined ear prefer[illegible]e in a simple RT task with a centrally [illegible]ositioned response key and preferred [illegible] [illegible]nd responding. The possibility of an [illegible]teraction with response side was, there[illegible]re, not examined. In the present exp[illegible]ment, lateral and central response lo[illegible]ations are compared with right-ear, left-ear, and binaural stimul[illegible].

[illegible]

[illegible] male paid volunteers. All [illegible] as determined by self-report and [illegible] [illegible]rvation of writing habits. All *Ss* repo[illegible] normal hearing. Ages of the *Ss* range[illegible] 17 and 37 yr. of age with a mean of 26.

Ap[illegible]. The apparatus was basically the same [illegible] described in Experiment I with the addit[illegible] a third response key located on the *S*'s midli[illegible]dway between the two lateral response keys. [illegible]muli were 200-Hz. tones of the same intensity as in Experiment I. A green warning light locat[illegible] 15 cm. above the central response key preceded the stimulus tone by a randomly varying interval, either .5, 1.0, or 1.5 sec. The interstimulus interval was 5 sec. between tone onsets.

Procedure. Eight blocks of trials were presented. Six consisted of single-hand responses with each hand performing in turn on each response key. Two blocks of trials consisted of two-hand responding (crossed and uncrossed) in conjunction with another experiment. During two-hand responding trials, the *S*'s task was to respond with both index fingers simultaneously while *E* recorded RT in milliseconds to the first key depressed. Half of the *Ss* received the two-hand block followed by the single-hand block, and the other half of the *Ss* received the trial blocks in the reverse order. The order of single-hand trial block presentation was randomized across all *Ss*.

The *Ss* were given 21 practice trials randomly presented so that there were 7 each in the right ear, the left ear, and binaurally. Practice responses were on a randomly chosen single-hand response key. Each trial block consisted of 63 randomly presented stimuli, 21 each to the right, left, and both ears. In between trial blocks, *S* was told that he had performed very well and then told which hand–response key condition would follow. The *Ss* were exhorted at the beginning of the experiment and between each trial block to respond as rapidly as possible. Further, they were told that the tone would appear sometimes in the right ear, sometimes in the left, and sometimes in both. Regardless of where the tone appeared, they were to respond as rapidly as possible with the assigned hand–key condition.

Results

Median RTs were calculated for each of the ear presentation locations (right, left, binaural) within each of the trial blocks. Planned comparison *t* tests of single-hand vs. two-hand response trial blocks revealed no significant differences. Further *t* tests of single-hand responding before vs. single-hand responding after two-handed response trials revealed no significant differences. The two-hand responses were omitted from further analyses. A three-way (Ear × Hand × Side) repeated measures ANOVA was then performed on the median scores of the single-hand response trial blocks. Table 3 presents the median scores. Of the seven possible main and interaction effects, only two were significant: Ear, $F(2, 58) = 16.22$, $p < .01$, and Hand × Side, $F(2, 58) = 3.94$, $p < .05$. The right-ear and binaural RTs did not differ, but both were significantly faster than the left-ear

Note. Reaction time in milliseconds.

responses: left-ear mean = 181 msec.; binaural mean = 176 msec.; right-ear mean = 177 msec. Figure 1 presents the means of right- and left-ear responses on the three response keys for comparison with the results of Experiment I.

The significant Hand × Side interaction reflected the fact that the right hand was faster when operating on the left-side response key; similarly, the left hand was faster on the right side. This effect was not present in Experiment I and may represent a chance finding.

Discussion

Lateral stimulus–response compatibility effects. Those results which are relevant to the specific experimental questions are as follows: (*a*) The lateral S-R compatibility effect described by Simon, Hinrichs, and Craft (1970) in the Donders' *b* paradigm is quite strong and reproducible. (*b*) The ear-response location component of the lateral S–R compatibility effect is present under the Donders' *c* RT condition but is significantly less than in the Donders' *b* condition. At the same time the symmetry of the effect increases from *c* to *b*. The ear–hand correspondence effect is consistently present in both *b* and *c* conditions but operates almost exclusively in the left hand. (*c*) There is no S-R compatibility effect in a simple RT situation, Donders' *a*.

The presence of the Ear × Side interaction in the Donders' *c* paradigm and its absence in the Donders' *a* paradigm suggests that the stimulus categorization stage, but not stimulus preprocessing or response initiation, is important with respect to the ear–response location correspondence effect. When the additional stage of response selection is added in the Donders' *b* paradigm, this correspondence effect significantly increases. Response choice appears to be an important determinant of the effect. The ear–hand correspondence is also present in both *b* and *c* paradigms, but not differentially so, and is absent in Donders' *a*. Stimulus categorization, therefore, appears to be the most important stage for the ear–hand correspondence effect. It is also important to note that both left-ear–hand and left-ear–response location correspondence effects are stronger than those for the right. Further, while ear–response location correspondence becomes more symmetrical as the task complexity increases from *c* to *b*, ear–hand correspondence is almost entirely a left-hand effect.

Ear effects. The significantly faster response to right-ear stimulation in the simple RT (Experiment II) is consistent with the finding of Simon (1967). However, it is interesting to note that in the choice RT conditions (Experiment I), responses to left-ear stimulation were faster than to right-ear stimulation, a reversal of the relationship in the simple task. This reversal may have been due in part to the additional stimulus processing required in the stimulus categorization stage. Kinsbourne (1970) has suggested that the strong right-ear bias in the simple RT may reflect an attentional preference for the left hemisphere as a consequence of *S*s concurrent verbal thinking processes, i.e., the hemisphere in use displays a lower attentional threshold. The results from these experiments suggest another explanation within the framework of Kinsbourne's attentional hypothesis. The more complex *b* and *c* choice tasks appeared to require more concentrated concurrent verbal activity as *S* had to remember the hand–tone rule, e.g., "high tone–right hand." The significant left-ear effect in these situations might have been due to the preoccupation of the left hemisphere with verbal rehearsal. In fact, some *S*s reported rehearsing the rule over and over to themselves during the task. Systematic control of this variable, however, was not attempted in this experiment.

A second explanation for the ear effects in the *b* and *c* conditions may be that the right hemisphere is more effective in tonal discrimination than the left hemisphere. The work of Kimura (1967) provides support for this hypothesis. This would explain the facilitation of left-ear stimulus processing in those conditions in which high and low pure tones must be discriminated before responding. Perhaps both left hemisphere interference and right hemisphere facilitation are operating to produce the results obtained in the choice RT conditions.

In conclusion, the data from these experiments suggest that information processing complexity, as exemplified in the additive model of Donders, must be taken into account when making inferences about the generality of the lateral S–R compatibility effect. These data further suggest that lateral asymmetries in RT performance are affected by the manipulation of information processing complexity.

ESTIMATION OF WORD FREQUENCY IN CONTINUOUS AND DISCRETE TASKS [1]

IAN BEGG [2]

McMaster University, Hamilton, Ontario, Canada

Long lists of concrete and abstract nouns which appeared varying numbers of times were presented to two groups of *S*s. One group judged how many times each word occurred during presentation (online), and again after the whole list had been presented (delayed). The second group only judged the words after the list had been presented (discrete). All *S*s subsequently recalled the words. Frequency estimates were above true frequency for relatively low frequencies, and below for relatively high frequencies in both the delayed and discrete judgments, but more so in the latter. Additionally, the interaction was more pronounced in abstract than concrete nouns. Recall was a positive function of concreteness, true frequency, and subjective frequency. The results were discussed in terms of multiple-trace and multiple-process views of how frequency is represented in memory.

This paper addresses the question of how *S*s estimate the number of times a word has occurred in a given situation. According to Howell (1973a), there are four major hypotheses concerning the representation of event frequency in memory. The first, the trace-strength hypothesis, maintains that each presentation of an event causes an increment in the strength of the memory trace corresponding to the event, and that frequency estimation is effected by reading out current strength values. The second, the multiple-trace hypothesis, maintains that each presentation of an event produces a new trace (Hintzman & Block, 1971), or a new "list marker" (Anderson & Bower, 1972), and that frequency estimation consists of counting the number of traces or list markers. What the two hypotheses have in common is that there is no unique frequency representation process. Rather, frequency estimation consists of inferring numerical judgments from a general memory representation. What differentiates the hypotheses is that the trace-strength hypothesis has no mechanism for separately retaining information about the individual contexts in which each presentation of an event occurs. Since *S*s can retrieve information about the duration (Hintzman, 1970) and modality (Hintzman, Block, & Summers, 1973) of specific occurrences of events, the multiple-trace hypothesis is more useful than the trace-strength hypothesis, which will not be discussed further here.

Two further hypotheses can be derived from the proposition that the situational frequency of occurrence of an item is specifically represented in memory, and is not simply inferred from the general memory representation. One such hypothesis, the numerical-inference hypothesis, is that *S*s simply count the number of times items have occurred, and give the current count as the frequency judgment. The second hypothesis, the frequency-attribute hypothesis, is that an item is remembered as a set of attributes, one of which increments with situational frequency; estimates of event frequency could thus be made by reading out the frequency attribute (Underwood, 1969a). Since the numerical-inference hypothesis can be subsumed by the frequency-attribute hypothesis, they will both be referred to as multiple-process hypotheses, since they posit that frequency information is specifically represented in memory, rather than as an incidental component of the general memory representation of an event.

It is difficult, if not impossible, to differentiate experimentally between a multiple-

trace and a multiple-process hypothesis. Since memory can be conceived of as being characterized by different levels of processing (Craik & Lockhart, 1972), words processed for memory could simply be processed to a deeper level than words processed for frequency, so that differences in memorability between words processed under the two conditions could either reflect different processes, as [illegible]ied by Underwood ([illegible]), or reflect the fact that words processed under frequency instructions were not processed as deeply as words processed under memory instructions. Howell ([illegible]) found that words processed under frequency instructions were not as well recalled as those processed under memory instructions, but that frequency judgments were not affected by the set under which the events were processed. Howell concluded that the memory difference reflected a different process, although it is also possible to interpret the results in terms of different levels of processing.

If either the multiple-trace or the multiple-process hypothesis is to provide a reasonable account of frequency estimation, there are certain basic facts that must be taken into account. First, if *S*s are presented with a list of words that appear varying numbers of times, and judge on every trial the number of times a particular word has occurred, average judgments correspond closely to actual frequency (Begg & Rowe, 1972, Experiments II & III). Either hypothesis could handle the finding easily. For the Anderson and Bower (1972) multiple-trace model, the mean number of list markers available for an item presented n times in a list is $n\ \alpha$, where α is the probability of establishing a list marker at the time of presentation. The mean number of list markers has an upper bound defined by true frequency (n) and a lower bound of zero. Frequency estimates are provided by a transformation of the number of list markers. The results reported by Begg and Rowe could be accounted for by making the transformation linear (i.e., $Fn = a + bn\alpha$), in which case $a = 0$, and $b\alpha = 1$. The multiple-process hypothesis could handle the result by assuming that the frequency attribute, on the average, increments by a unit amount for every unit presented and is, at least during acquisition, generally retrievable.

The second general finding to be accounted for is that if frequency judgments are not made until after the list has been presented, the judgments generally are higher than relatively low true frequencies, but below relatively high frequencies (e.g., Peterson & Beach, 1967). There are several points to note about the interaction between true and judged frequency. First, the interaction obtains when *S*s are previously instructed either that the task will require frequency judgments (e.g., Howell, 1973b; Underwood & Freund, 1970) or to remember the words (e.g., Hintzman, 1969; Howell, 1973b). Second, the interaction is sensitive to the frequencies used in the specific task, since it occurs with as few as 2 presentations representing the highest frequency level (Hintzman et al., 1973), or as many as 10 (Howell, 1973b). That is, the interaction is a function of relative, rather than absolute, frequency. Third, a retention interval makes the interaction more pronounced, both with respect to overestimation of low and underestimation of high relative frequencies (Underwood, Zimmerman, & Freund, 1971).

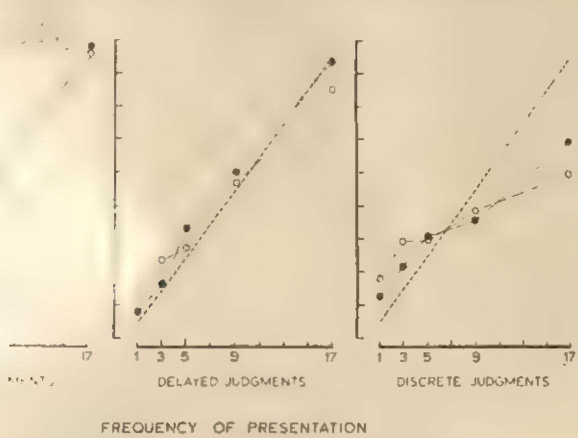
Since true and judged frequency interact when judgments are made after presentation of a list (discrete judgments), but not during presentation of the list (online judgments), the interaction could reflect one of two factors, or a combination of the two. Online and discrete judgments differ both with respect to the presence of a delay interval interposed between the last presentation of an item and the subsequent estimation in the latter case, and with respect to the presence of overt running judgments in the former. In the present experiment, *S*s who made online judgments were also asked to judge the words at the end of the task (delayed judgments). Comparisons between the two sets of judgments reflect retention effects, while comparisons between delayed and discrete judgments reflect the effects of the overt running judgments made in the former condition.

The facts that true and judged frequency interact, that the interaction is relative to the range of true frequencies used, and that a retention interval accentuates the interaction, must be accounted for by the hypotheses, either by changes in the memory representation over time, or by variables affected by the presence of overt judgments during acquisition. First, consider the effects of a retention interval on the representations from which frequency estimates are inferred. According to Anderson and Bower (1972), the effect of a retention interval is to reduce the availability of individual list markers, so that the best fit line relating true and judged frequency would become less steep over time. The problem is that the model has no explicit provision for raising the intercept of the line as a function of forgetting, and so does not account for (*a*) the overestimation of low-frequency words, (*b*) the fact that the interaction is relative to the range of experimental frequencies, or (*c*) the exaggeration of the degree of overestimation of low frequencies with longer delay intervals. However, the problem is not serious. If *S* compares his subjective mean number of list markers available across the full range to his subjective estimate of the mean number of occurrences of words, the difference between the two could simply be added to all estimates derived from the number of list markers available. That is, the effect of a retention interval is to move all judgments closer to the task-defined mean frequency. For Underwood's (1969a) multiple-process model, no specific statement is made about the effects of a retention interval on the frequency attribute. A reasonable result of deterioration of the frequency attribute, however, is that the attribute will become assimilated to the mean situational frequency of occurrence of the words. Thus, judgments would generally become closer to the task mean over increasing retention intervals. Consequently, both models of frequency estimation can account for a frequency interaction, which is a function of relative frequency, and which becomes more pronounced with time. The forms of both models as developed here would also predict that the overall average of responses would not differ as a function of retention interval, as found by Underwood et al. (1971).

Recall that, in addition to a retention interval, online and discrete judgments differ in that *S*s in the former case make running judgments during the presentation of the words. Whether such estimation requires closer attention, or provides retrieval practice, or whatever, both hypotheses, as interpreted above, would yield the prediction that the effects of such judgments would be effectively opposite to the effects of forgetting. That is, removing the running estimates should cause judgments to become closer to the task mean.

In the present experiment, concrete and abstract words were presented to *S*s who either judged the frequency of occurrence of each word as it occurred (online) and then again after the list had been presented (delayed), or only judged frequency after the presentation of the entire list (discrete). The expectation is that the online judgments will be relatively accurate, the delayed judgments will show an interaction between true and judged frequency, and that the interaction will be most pronounced in the discrete judgments. The effects of concreteness on frequency estimation are not very pronounced in online judgments (Begg & Rowe, 1972). Since Anderson and Bower (1972) conceive of tagging with list markers as essentially a paired-associate task, abstract words should show a more pronounced frequency interaction than concrete words with both delayed and discrete judgments, because (*a*) concrete words are known to be better stimuli than abstract words in paired-associate learning (e.g., Paivio, 1969), and (*b*) concrete words are better retained than abstract words over long periods of time, particularly if the recall task is associative (Begg & Robertson, 1973). A frequency attribute, if it is conceived of as a paired-associate of the word, would yield the same predictions as the Anderson and Bower model.

The *S*s in the present experiment were also asked to recall the words after they



1. Online, delayed, and discrete judgments of frequency, as a function of concreteness and the frequency of presentation.

had made their terminal judgments. Recall was expected to be a positive function of concreteness (e.g., Begg & Robertson, 1973), true frequency, and subjective frequency (e.g., Underwood et al., 1971).

Method

Subjects. Twenty volunteers from McMaster University were paid $2/hr for their participation. Half of the *Ss*, determined randomly, judged the frequency of each word as it occurred, and half made their first judgments after the entire list had been presented.

Materials and procedure. Fifty concrete and 50 abstract nouns were chosen from the Paivio, Yuille, and Madigan (1968) norms, with mean *I* ratings of 6.39 and 3.04. All words were A or AA in frequency of occurrence. Ten concrete and 10 abstract nouns were printed on 17 cards, 10 were printed on 9 cards, and another 10 were printed on each of 5, 3, and 1 card. The 700 cards thus produced were arranged in 28 sets of 25 cards, with successive occurrences of the words from each frequency level being placed in consecutive piles. The pile in which the initial presentation of an item occurred was as random as possible, given the constraint that there were enough adjacent piles for the later presentations of an item, and that an equal number of concrete and abstract nouns from any given frequency level started in the same pile. After the sorting, each pile was thoroughly shuffled, and the blocks were placed together to form one deck of 700 cards. On the average, then, 25 items separated successive presentations of a particular item.

The task was presented to each *S* in three stages. In the presentation stage, *S* went through the entire list of 700 cards at his own rate, reading each word aloud. The *Ss* in the continuous-presentation condition estimated the frequency of occurrence of each word in the list, while *Ss* in the discrete-presentation condition made no overt judgments, although they had been told that their task was to remember how many times each word occurred. In the second stage of the task, the judgment stage, all *Ss* were presented with lists containing the 100 words from the initial list. Six different random orders were used. The *Ss* were instructed to write down next to each word a number representing how many times they thought the word had occurred in the initial list. In the final stage of the task, the recall stage, all *Ss* were asked to write down as many of the words as they could remember, in any order. The whole task took about 75 min.

Results and Discussion

Frequency estimates. Since any departure from accuracy in judging the frequency of once-presented items would necessarily be above true frequency, median rather than mean judgments were analyzed. For *Ss* in the continuous-judgment task, two sets of medians were calculated, one for the online judgments made during presentation and one for the delayed judgments. Each set of medians had 10 members, 1 for the 10 concrete and 1 for the 10 abstract nouns at each of the five frequency levels. For the online judgments, only responses made to the last presentation of an item were scored. The medians for the delayed judgments and for the discrete judgments included all nouns in the final judgment list.

The mean medians, averaged across *S*s, are presented in Figure 1. For each of the three types of judgments, results are plotted separately for concrete and abstract nouns, and a perfect-accuracy line is included for reference purposes. There are several points to note in the figure. First, the online judgments made in the continuous task did not depart much from true frequency, as found by Begg and Rowe (1972), and there were no apparent effects of concreteness. However, when the same *S*s repeated their judgments in the delayed condition, the judgments showed an interaction between true and judged frequency, and the interaction was more pronounced for abstract than concrete nouns. The *S*s in the discrete task showed a more exaggerated interaction than *S*s in the delayed task, and the interaction was again most pronounced with abstract nouns. It is also perhaps of note that the means of the 10 medians in each judgment condition (7.1, 7.7, and 6.7 for the online, delayed, and discrete judgments, respectively) did not depart much from the true mean frequency of presentation, which was 7, suggesting that *S*s have some idea of how many presentations actually occurred, and adjust their responses accordingly.

The reliability of the results was determined by two analyses of variance. The first analysis compared the online and delayed judgments made in the continuous task, to assess the effects of a delay interval on the judgments. Thus, time of judgment (online or delayed), concreteness (abstract or concrete), and frequency of presentation were all repeated factors. Overall, judgments increased with frequency, F (4, 36) = 53.3, $p < .01$. More importantly, frequency and the time of judgment interacted, F (4, 36) = 7.44, $p < .01$, confirming the reliability of the tendency to overestimate low- and underestimate high-frequency nouns in the delayed judgments. Further, the three-way interaction, F (4, 36) = 2.65, $p < .05$, reflected the fact that the pattern found in the delayed condition was more pronounced with the abstract than concrete nouns. In fact, there is only a hint of the interaction in the delayed judgments of concrete nouns. The results can be seen in the two left-hand panels of Figure 1.

The second analysis compared the two sets of judgments made after all the words had been presented. Differences between the delayed judgments and the discrete judgments can be attributed to the running estimates made by the *S*s in the delayed task. The results were analyzed by 2 × 2 × 5 analysis of variance, with the type of task as an independent factor, and concreteness and frequency as repeated factors. As in the previous analysis, judgments increased with frequency, F (4, 72) = 67.3, $p < .01$. The task variable interacted with frequency, F (4, 72) = 6.18, $p < .01$, since the interaction between true and judged frequencies was more pronounced in the discrete than the delayed task. Finally, there was a significant Concreteness × Frequency interaction, F (4, 72) = 4.22, $p < .01$, since the interaction between true and judged frequencies was more pronounced with abstract than concrete nouns in both tasks, as seen in the two right-hand panels of Figure 1.

Overall, then, the interaction between judged and true frequency is absent in online judgments, is present in both delayed and discrete judgments, and is especially pronounced in the latter. Further, the interaction is more pronounced when abstract rather than concrete words are judged. The results conform quite well to the expectations of either a multiple-trace model that posits a comparison process between the number of list markers available and the number of presentations made, or to a frequency-attribute model that assumes the frequency attribute becomes assimilated into the task-defined mean frequency as it deteriorates.

If the individual judgments become assimilated to situational frequency, then it should be the case that the amount of variability around the mean decreases as the interaction between true and judged frequency becomes more pronounced. From online to delayed judgments, the mean standard deviation decreased from 6.39 to 5.89, F (1, 9) = 7.27, $p < .025$, for the

abstract nouns. The decrease was not found for [illegible] nouns, which did not show as pronounced an interaction as the abstract [illegible]. [illegible] the mean standard deviation in the delayed judgments was 6.[illegible] compared to [illegible] for the discrete judgments. A t test performed on $\log_{10}$ transformations of the standard deviations showed the [illegible] reliable, t (18) = 14.0[illegible] [illegible] general [illegible] the judged situa[illegible].

Recall data. The [illegible]er of words recalled by *S*s in [illegible] was analyzed by a 2 × 2 × [illegible] variance with task (cont[illegible]) as the independent factor, [illegible]teness and frequency as repeated [illegible]. Recall increased with frequency, F ([illegible], 72) = 10.3, $p < .01$, with respective mean recalls of 1.95, 2.40, 2.68, 3.28, and [illegible].88, each out of a possible 10. Concreteness was also positively related to recall, F ([illegible], 18) = 15.5, $p < .01$, with 16.8 and 11.5 concrete and abstract words recalled out of a possible 50. The Concreteness × Task interaction was not reliable ($F < 1$), although in absolute terms, the concreteness effect was larger in the discrete task (16.5 vs. 9.4) than in the continuous task (17.1 vs. 13.7).

In order to determine whether apparent frequency affected recall, the frequency judgments made to the words that were later recalled were compared to the judgments of words not recalled. Because of a number of empty cells, the data were averaged over low frequency (1, 3, and 5), high frequency (9 and 17), and concreteness. In the discrete task, the mean judgment of recalled words was higher than the judgment of forgotten words, both at low frequency, 6.23 vs. 5.12, F (1, 9) = 6.70, $p < .05$, and at high frequency, 11.07 vs. 8.92, F (1, 9) = 15.0, $p < .01$. The same was true in the continuous task, both at low frequency, 5.92 vs. 4.70, F (1, 9) = 7.22, $p < .05$, and at high frequency, 13.49 vs. 11.89, F (1, 9) = 5.83, $p < .05$. Thus, recalled words were consistently higher in judged frequency of occurrence than forgotten words.

As a second test of the hypothesis that subjective frequency is related to recall, recall was conditionalized on whether the final frequency judgments were above or below each *S*'s median judgment at each frequency level. For each *S*, the results were averaged over concreteness, and once-presented items were not considered, since for several *S*s there were no judgments below the median. The proportions of words recalled, given that the final frequency judgment was above or below the median, were analyzed by a 2 × 2 × 4 analysis of variance, with task (continuous or discrete) as an independent factor, and level of final judgment (above or below the median) and frequency (3, 5, 9, or 17) as repeated factors. Both subjective frequency, F (1, 18) = 13.5, $p < .05$, and actual frequency, F (3, 54) = 3.50, $p < .05$, were positively related to recall. Thus, items initially judged above the median were more likely to be recalled than items judged below the median, with respective proportions of .356 and .250, and recall increased over the four frequency levels included in the analysis, with proportions of .240, .280, .317, and .375. No other effects were reliable.

Thus recall is a positive function of both subjective and actual frequency of occurrence, whether subjective frequency is defined by average ratings of recalled words, or by recall or words partitioned according to the level of the frequency judgments. This extends the finding of Underwood et al. (1971).

The general conclusion of the paper is that any reasonable account of frequency estimation must include some process that allows judgments to become closer to the task mean, whether that process is an additive bias (multiple trace), or assimilation of a frequency attribute into that mean. In his review, Howell (1973a) did not consider the nature of the interaction between true and judged frequency, or the fact that the interaction is a function of relative, rather than absolute frequency. However, his conclusion that it is not possible to rule out the alternative hypotheses is entirely correct.

The present results also have implications for verbal discrimination learning, a task in which concrete items lead to better performance than abstract items even on the first trial (e.g., Rowe & Paivio, 1971). Ekstrand, Wallace, and Underwood (1966) offered an account of verbal discrimination in which situational frequency was viewed as the dominant attribute affecting performance. Such an account cannot easily explain imagery effects, since abstract words actually have higher subjective frequencies than concrete words for low frequencies if the judgments are delayed, and the judgments are not different if they are made at the time of presentation of the words. Thus, although situational frequency is a powerful explanatory construct with respect to verbal discrimination learning, additional constructs must be invoked to explain the effects of imagery in the task.

HYPOTHESIS BEHAVIOR AS A FUNCTION OF AMOUNT OF PRETRAINING[1]

RAYMOND M. WHITE, JR.[2]

Miami University

Two ex[illegible]iments were performed to determine the effects of conceptual pretrainin[illegible] the hypothesis behavior exhibited by human *S*s on simultaneous discrim[illegible]n problems that included blank trials. For Experiment I, 80 *S*s [illegible] 1, 2, 3, or 4 simultaneous discrimination problems prior to four blank t[illegible] problems. Experiment II was defined by the factorial combination of [illegible], 4, or 6 pretraining problems and two sets of instructions, 128 *S*s being [illegible]en routine instructions or directions to consider a single hypothesis at a time. With training, *S*s were more likely to maintain their previous hy[illegible]esis after positive outcomes and to alter their hypothesis after negative [illegible]s. The conclusion was that the uniprocess hypothesis models, such [illegible]ne proposed in 1966 by Levine, do not accurately describe the behavior [illegible]trained *S*s, and that a multiprocess model of conceptual learning is [illegible]ted.

Many, if not all, theories of concept identification (CI) ascribe a single process to the problem solver in his attempt to identify the relevant attributes of a conceptual problem (e.g., Levine, 1966; Restle, 1962). However, recently White (1972a, 1972b) has discussed the possibility that *S* retains a number of means for solving a problem: Which of the approaches will be adopted in attempting to solve a problem depends on a number of factors such as the type and amount of training *S* has received.

Support for White's (1972a, 1972b) multiprocess view of CI was indirect. The *S*s in his experiments were given one of two types of pretraining problems. The performance of *S*s who were given systematic training (i.e., a routine conceptual problem) was unaffected by the length of postfeedback intervals after correct responses—indicating the absence of problem-solving activity during that interval—but strong effects due to the duration of the postfeedback interval after errors were observed. These results were as predicted by an error-trial-only theory of CI (e.g., Bower & Trabasso, 1964). On the other hand, the performance of *S*s who received unsystematic training, consisting of a problem whereby *S* could reach the solution criterion by memorizing the placement of each stimulus pattern, was affected equally by the length of intervals after both correct and incorrect responses. The latter result is consistent with the predictions of an all-trials, response-independent theory of CI (e.g., Bourne & Restle, 1959). Furthermore, as the amount of pretraining was increased, the effects of the length of postfeedback intervals were more consistent with the predicted outcomes of the opposing theories: Systematic training provided performance orderings as predicted by error-trial-only CI models, and unsystematic training produced orderings as predicted by all-trials CI models.

Levine (1966, 1970) has provided a more direct way of assessing the processes underlying performance in a CI problem and a theory to account for behavior in such problems. Levine's method is to provide certain trials during which *S* is given feedback concerning the correctness of his response (hereafter termed outcome trials, OTs). Following an OT, typically, are a series of trials for which no feedback is given (hereafter termed blank trials, BTs).

By observing the responses *S* makes during the BTs, the hypothesis *S* is entertaining can be determined. For example, in a simultaneous discrimination problem, if *S* always selects the stimulus appearing on the left side of the display as containing the correct attribute, it is inferred that he is hypothesizing that "leftness" defines problem solution. Through such analyses, it can be determined on what occasions *S* changes hypotheses and the manner in which the hypotheses are changed.

Levine (1966, 1970) has reported several important findings using the BT procedure: (*a*) *S*s consistently use hypotheses; (*b*) *S*s rarely change hypotheses after having received a positive OT; and (*c*) *S*s nearly always change hypotheses after receiving a negative OT. All of these results are consistent with the data reported by White (1972a, 1972b). First, Levine's *S*s typically receive extensive pretraining. Indeed, Levine assumes the universe of hypotheses is known by *S* and that the assumption can be met by training and instruction. White's (1971) finding was that *S*s receiving extensive systematic pretraining and instruction are likely to behave as hypothesis testers. Second, the behavior of extensively and systematically trained *S*s was as predicted by an error-trial-only CI model; *S* retains his hypothesis after positive outcomes and returns it to a pool of hypotheses for further sampling after negative outcomes. However, the question of whether the pretraining and instruction induced *S*s to develop and test hypotheses and thereby behave as they did in the BT problems has not been answered. It was, therefore, the purpose of the experiments reported herein to explore the effects of varying amounts of systematic training on performance in BT problems. Would, for example, highly trained *S*s provide more response sequences during BTs that are identifiable with hypotheses than untrained *S*s?

Experiment I

Method

Subjects and design. A total of 80 *S*s were randomly assigned, except for equating the number of males and females, to one of fiv[illegible]perimental conditions. The five conditions w[illegible] defined in terms of the number of pretraining [illegible]ms which preceded the administration of four [illegible] problems. The *S*s received either 0, 1, 2, 3, o[illegible] pretraining problems.

Stimuli. The stimuli consisted o[illegible] letters *X* and *T*, which were paired on each [illegible]lus card. The letters also varied in size (small [illegible]rge), texture (clear or crosshatched), and po[illegible]n (left or right side of card). The stimuli we[illegible]pared as 8 × 11 in. dittos.

A randomized blocking procedur[illegible]ed for arranging the pretraining stimuli. [illegible] consisted of the random arrangement of t[illegible] timuli of the population. Each dimension wa[illegible]evant to problem solution equally often. A ra[illegible]n order of the problems was selected for each [illegible]

Four of the aforementioned stimuli [illegible]lected for use during the BT problems. The [illegible]n was conducted such that certain configur[illegible] of responses during the BTs could be ind[illegible] consistent with one of eight unidimensiona[illegible]eses. The remaining four stimuli were used [illegible] the OTs. The OT stimuli were randoml[illegible]d for each problem with the restriction that e[illegible] appear equally often.

Procedure. The *S*s were run individua[illegible] by one of three *E*s. After being seated across a t[illegible]le from *E*, *S* was given routine instructions rega[illegible]ng the pretraining problems. Each *S* was shown [illegible] stimulus population, instructed as to the me[illegible]ng of feedback signals, and told that either text[illegible] position, size, or form of figure would defin[illegible]oblem solution.

For the various pretraining condition[illegible], an attribute for the single problem condition, or a combination of attributes for a series of problems, was randomly sampled. No repetitions of relevant attributes was permitted. The criterion of problem solution for these problems was set at 10 consecutive correct responses. The *S* was given a total of 48 trials to solve each problem, the problem being terminated by *E* showing *S* the solution. A trial consisted of showing *S* the stimulus card for approximately 5 sec., a pointing response by *S*, indicating which of the two figures contained the relevant attribute, and a verbal "right" or "wrong" by *E*. A period of approximately 5 sec. transpired between trials. The *S*s were asked to state the solution upon meeting criterion.

Following successful completion of pretraining, all *S*s were instructed as to the procedure involving BTs. They were told that feedback would not be given consistently as it had during pretraining, and were asked to continue responding as they would if feedback were given on each trial. Following these instructions, a series of four 15-trial problems was administered. For each of these problems, Trial 1 was designated as a positive OT. Regardless of *S*'s response, it was called correct. Trials 6 and 11 were also OTs. Feedback for the latter OTs was arranged such that one trial was designated positive

and the other negative. Since there are 16 possible combinations of feedback for Trials 6 and 11 for four problems, each *S* was randomly assigned to one of the sequences with the restriction that a single *S* be assigned to each order.

Results

According to Levine's (1966) hypothesis theory, a large percentage of the response sequences during BTs should be consistent with a single hypothesis. For his problems, approximately 91% of the sequences were found to be consistent with single hypotheses. In the present experiment, the proportion of univariate hypotheses was computed for each *S*, the means for the 0-, 1-, 2-, 3-, and 4-problem conditions (Conditions 0–4) being .69, .85, .86, .86, and .89, respectively. An analysis of variance applied to these data revealed significant differences among these proportions, $F\ (4, 75) = 3.86$, $p < .01$.

One major assumption made by certain hypothesis-testing theories of CI (e.g., Restle, 1962) is that *S* retains the hypothesis which dictated his previous response if that response is called correct. Indeed, Levine (1966) reported that hypothesis retention after correct responses occurred in 92% of the cases studied. Comparable proportions from the present experiment for zero through four problems, respectively, were .66, .72, .76, .81, and .75. The differences among these proportions were not reliable, $F\ (4, 75) = 1.24$, $p > .05$.

A second assumption made by the aforementioned hypothesis-testing theory, and by Levine (1970), is that *S* returns his hypothesis or set of hypotheses to a pool for resampling if the response dictated by the set is called wrong. Therefore, the probability of resampling that hypothesis should be low if *S* resamples from the available pool of hypotheses randomly, and exceedingly low if *S* remembers hypotheses that have been infirmed. Levine (1966) reported that on 98% of the occasions after *S*'s response had been called wrong a hypothesis different from the one manifested prior to the OT was observed. Again, for the present experiment, comparable values for Conditions 0 through 4 were .73, .91, .88, .86, and .94, respectively. Analysis of variance showed the differences among these proportions to be significant, $F\ (4, 75) = 2.54$, $p < .05$. Inspection of the proportions shows the difference to lie between Condition 0 and the other four conditions.

Since the frequency of hypothesis changes is a function of the number of pretraining problems administered, it might also be expected that similar observations could be made over the BT problems themselves. For that reason, the proportion of hypothesis changes after correct responses was computed for each BT problem, the obtained values for one through four BT problems, respectively, being .29, .36, .21, and .26. The obtained proportion of hypothesis changes after errors for one through four BT problems, respectively, were .85, .81, .91, and .90. Inspection of these da a indicate small differences and the lack of a discernible trend. Apparently, three OTs is an insufficient inducement for strategic change.

A natural extension of the assumptions listed above is that the size of *S*'s hypothesis pool remains constant regardless of the point at which the pool is measured. For example, if the pool is determined to contain, say, four hypotheses after the first negative OT, it ought to contain a like number of hypotheses after, say, the third consecutive negative outcome. To assess the size of the hypothesis pool, Levine (1966) computed the obtained proportion of successes for a group of *S*s. Reasoning that the obtained proportion of correct hypotheses would ordinarily be computed by dividing the number of logically correct hypotheses, as determined by feedback, by the number of hypotheses in the pool, Levine was able to obtain an index of the size of the pool by dividing the obtained proportion of hypotheses into the number of logically correct hypotheses. Using an identical procedure, the size of the hypothesis pool after each OT was estimated for each experimental condition and is shown in Table 1. Several trends are apparent from these data: (*a*) the size of the hypothesis pool is reduced over OTs; (*b*) *S*'s efficiency in handling information

TABLE 1

ESTIMATED SIZE OF THE HYPOTHESIS POOL AFTER EACH OUTCOME TRIAL IN EXPERIMENT I

Trial sequence	Number of pretraining problems				
	0	1	2	3	4
+, BTs	7.31 (5.41–7.69)	4.57 (4.30–5.13)	5.56 (4.88–6.78)	4.74 (4.40–5.56)	4.65 ([illegible]30–5.41)
+, BTs, +, BTs	4.93 (3.45–7.69)	2.37 (2.15–2.94)	2.75 (2.35–3.57)	2.75 (2.35–3.57)	2.52 ([illegible]–3.28)
+, BTs, −, BTs	6.40 (4.08–10.53)	3.37 (2.70–4.76)	3.65 (2.86–5.26)	3.26 (2.60–4.55)	3.88 ([illegible]–4.44)
+, BTs, +, BTs, −, BTs	4.00 (2.38–7.69)	2.91 (2.00–4.76)	2.20 (1.64–3.45)	1.65 (1.32–2.27)	[illegible]20 ([illegible]–3.45)
+, BTs, −, BTs, +, BTs	3.10 (2.00–5.56)	1.60 (1.70–2.22)	1.55 (1.27–2.13)	1.29 (1.14–1.67)	2.00 ([illegible]–2.94)

Note. Ninety-five percent confidence intervals appear in parentheses. Abbreviations: BTs = blank trials, + = positive outcome trial, − = negative outcome trial.

improves as a function of amount of training; and (*c*) the information from positive OTs is used more efficiently in reducing potentially valid hypotheses than that from negative OTs.

EXPERIMENT II

Experiment I showed reasonably strong training effects. In general, as *S* received more pretraining, he was more likely to alter his hypothesis after having received a negative OT and to maintain his hypothesis after positive OTs. Furthermore, *S* used both outcomes more efficiently with more pretraining in the sense that the size of the pool of hypotheses being entertained was smaller after, say, a single positive outcome for *S*s who had received three pretraining problems than for those who had received none. However, two aspects of the data were not entirely consistent with these aforementioned general trends and Levine's (1966) data. With four pretraining problems, *S*s were more likely to alter their hypotheses after positive OTs than *S*s with three pretraining problems. With respect to Levine's data, the probability of hypothesis change after positive OTs was considerably higher than for Experiment I. One viable explanation for the discrepancy is that different procedures were used. Levine, for example, began some of the BT problems with negative OTs, while all of the BT problems in Experiment I were begun with a positive OT.

Experiment II was designed to assess the reliability of the results of Experiment I and to determine what, if any, effects were produced by the variant procedures of Experiment I and Levine's (1966) experiment. The procedures of Experiment II were, therefore, as nearly identical to Levine's as was possible. In addition, a hypothesis arising out of Experiment I was tested by the manipulation of instructions. One interpretation of the high rate of hypothesis alteration after positive OTs is that *S* entertains several hypotheses simultaneously, and any one of these active hypotheses may be used as a basis for responding after a positive OT. To assess the accuracy of this interpretation, special instructions were included for some of the groups of Experiment II, asking them to consider a single hypothesis while attempting to solve the problem.

Method

Subjects and design. The *S*s were 128 male and female undergraduate students at Miami University who were assigned randomly, but in equal numbers with respect to sex, to one of eight experimental conditions. The conditions were defined by a factorial arrangement of two variables: number of

pretraining problems (0, 2, 4, or 6) and type of instructions (routine vs. restricting).

Materials and procedure. The materials and procedures were nearly identical to those of Experiment I save for the special instructions given to restrict *S*'s hypothesis pool and the designation of the various OTs as positive or negative.

The *Ss* in the special instruction condition were told to "consider only *one* characteristic as possibly relevant at any one time," and to "never, for example, consider the possibility that *X* and/or *large* are the relevant characteristics."

The dimensions made relevant to solution were balanced for frequency of occurrence and order to the extent that this was possible. For the two-problem condition, the 12 permutations of the four stimulus dimensions were assigned to the first 12 *Ss* assigned to that condition. The four dimensions were represented equally often in the problems assigned [illegible] other 4 *Ss* in the two-problem condition [illegible] the four-problem condition, four 4 × 4 Latin squares were selected to determine order of problem assignment. The Latin squares selected for the four-problem condition were also used in the six-problem condition. One of the permuted pairs or one of the remaining pairs of the two-problem condition was added to each row of each square to form the six-problem condition.

For the BT problems, eight sequences of positive (+) and negative (−) feedback were possible (e.g., + + +, + + −, etc.). Four 4 × 4 Latin squares were combined to determine the feedback sequences for each of the BT problems for the 16 *Ss* in each condition. The last OT of each BT was called positive to assure that *S* would not "leave" the univariate hypothesis realm.

Results

The mean proportion of hypothesis changes after negative OTs for each experimental condition are shown in Table 2. Analysis of variance applied to these data showed only a significant effect due to number of pretraining problems, F (1, 120) = 6.40, $p < .01$. The proportion of hypothesis changes was an increasing function of the number of pretraining problems.

Table 2 also displays the mean proportion of hypothesis changes after positive OTs. Analysis of variance showed the Type of Instructions × Number of Pretraining Problems interaction to be the only significant source of variation, F (3, 120) = 3.20, $p < .05$. Hypothesis changes were especially prevalent where *S* had not received instructions to limit his hypothesis pool to univariate hypotheses, especially in the case where two or fewer pretraining problems had been administered.

The mean proportions of multivariate hypotheses for each experimental condition are shown in Table 3. Any response sequence that could not be identified as consistent with a known univariate response sequence was assumed to be the product of a multivariate hypothesis. Analysis of variance applied to these data revealed significant effects due to type of instructions, F (1, 120) = 10.84, $p < .01$, with the groups being instructed to restrict their hypothesis pool to univariate hypotheses showing a smaller proportion of multivariate hypotheses than the noninstructed group. Additionally, moderately reliable effects were observed in the Instruction × Pretraining Problem interaction, F (3, 120) = 2.53, $p < .10$. As the number of pretraining problems increased, the proportion of multivariate hypotheses was reduced for the routine instruction condition. The proportion of multivariate

4	6.06 (5.26–7.40)	3.57 (2.99–4.55)	3.03 (2.22–4.35)
6	5.80 (5.06–7.14)	3.45 (2.90–4.35)	2.44 (1.89–3.33)

Note. Ninety-five percent confidence intervals appear in parentheses.

hypotheses was nearly constant for the special instruction condition.

As in Experiment I, no systematic effects were observed as a function of BT problem.

An estimate of the size of the hypothesis pool after negative outcomes on OT_1, OT_2, and OT_3 as a function of the number of pretraining problems is shown in Table 4 for the routine and restricted instructional conditions, respectively. The estimates were arrived at by computing the proportion of correct hypotheses after each negative OT for each condition and dividing the appropriate proportion into the number of logically correct hypotheses (i.e., four after OT_1, two after OT_2, and one after OT_3) for the trial involved. In general, these data show the size of the hypothesis pool to be a decreasing function of the trial involved, that the size of the pool is reduced more substantially from trial to trial as *S* has more experience with the type of problem at hand, and that the size of the pool is smaller in the case where *S*s were specially instructed to restrict their hypotheses to a univariate realm.

TABLE 5

ESTIMATED SIZE OF HYPOTHESIS POOL AS A FUNCTION OF NUMBER OF PREVIOUS POSITIVE OUTCOME TRIALS (OTs) AFTER NEGATIVE OT_3

Number of problems	Number of preceding positive OTs		
	0	1	2
0–2	6.25 (3.13–12.50)	4.00 (2.63–6.67)	2.50 (1.92–5.00)
4–6	2.63 (1.82–4.35)	3.57 (2.50–5.56)	2.13 (1.59–3.23)

Note. Ninety-five percent confidence intervals appear in parentheses.

An estimate of the size of the hypothesis pool as a function of the number of preceding positive OTs is shown in Table 5. The estimates were obtained by computing the proportion of correct hypotheses after a negative outcome on OT_3 and dividing the obtained proportion into the number of logically correct hypotheses after OT_3 (i.e., one). Unfortunately, there were no discernible trends where the data were analyzed separately for each condition. Quite likely, too few data points (e.g., in most cases, as few as eight) were involved in the estimates. To improve the reliability of the estimates, the data for the one- and two-pretraining-problem conditions (collapsed over instructions) were combined and compared with the combined results of the four- and six-problem conditions. In general, Table 5 shows a systematic reduction in the size of the hypothesis pool as a function of the number of preceding positive OTs for the zero–two problem combination, but no reduction in size of the pool for the four–six problem combination.

DISCUSSION

Hypothesis theory. Levine (1966, 1970) reported that *S*s attempting to solve simultaneous discrimination problems for which solution is defined by a single cue employ univariate hypotheses, usually alter their hypotheses after negative OTs, and rarely alter their hypotheses after positive OTs. An additional assumption is that *S* samples a subset of the total pool of potentially correct hypotheses. Both experiments appear to justify the first three assumptions, but only under certain conditions. The *S*s who receive relatively extensive pretraining on a problem identical to the test problem nearly always alter their hypotheses after negative outcomes, rarely alter them after positive outcomes, and restrict their hypotheses to the univariate realm. The *S* who receives very little pretraining either entertains multivariate hypotheses, or no hypotheses at

all, and is [illegible] to alter his hypothesis after both negative and positive outcomes.

The subset-sampling assumption appears to be correct in view of the present data. The probability that S would alter his hypothesis after a positive OT was much higher when instructions did not require him to restrict the size of his working hypothesis set to one. Moreover, the effect of such an instructional set is uniform over varying numbers of pretraining problems.

Finally, Levine (1966) reported that Ss used the information after positive OTs to adjust their hypothesis pools more than after negative OTs, but that Ss regularly reduced the working set of hypotheses after all outcomes. The results of the present set of experiments generally confirm Levine's observations, with one potentially important exception. In Experiment II, it may be worth noting that the size of the working hypothesis set is unrelated to the number of preceding positive OTs where Ss had received four or six pretraining problems. Unfortunately, the reliability of this finding is in question, since the results of Experiment I indicate that Ss do reduce the size of their working hypothesis set over positive OTs regardless of whether 0, 1, 2, 3, or 4 pretraining problems are given. Perhaps six or more pretraining problems would produce this effect with greater reliability. On an intuitive level, it seems plausible to assume that S would eventually adopt a strategy which produces a single hypothesis to be tested and retained, if positive OTs ensue, since S is not required to hold in memory a fairly large set of hypotheses, some of which have been confirmed and others that have not been tested. In any case, it is not clear at this point whether S adopts a strategy which places less emphasis on memory as he solves more problems of a particular class.

Multiprocess theory. The main assumption of the multiprocess point of view is that S is capable of several, perhaps many, approaches to a problem. Furthermore, it is assumed that, among other factors, the amount of experience S has had with the problem at hand determines the approach he will use in solving the problem. The results of both experiments appear to be entirely consistent with these general assumptions. In addition, the notion expressed by White (1972a, 1972b) that inexperienced problem solvers would adopt an associative learning strategy, while more sophisticated Ss would adopt a more efficient and elegant strategy of testing hypotheses, appears to have been confirmed by the present data.

More specific with respect to the associative-to-hypothesis learning progression are the data of untrained Ss who show a high rate of unidentifiable BT sequences, a potential indicator of nonhypothesis behavior on their part. However, with training the rate of such BT sequences was reduced, but still remained above 10%, indicating that Ss were not simply dropping multidimensional hypotheses from their working pool.

A corollary of the notion that S will adopt a hypothesis-testing strategy with training is that rarely will S alter his hypothesis after a positive OT. In fact, the rate of hypothesis change was reduced over training problems; in addition, the size of the hypothesis set remained relatively constant over a series of positive OTs for extensively trained Ss, a result which is consistent with the one-hypothesis-at-a-time model of Restle (1962).

A final major hypothesis predicted that the rate of hypothesis alteration after negative OTs would be an increasing function of number of pretraining problems, and that the probability of hypothesis change after positive and negative OTs would be equal. The first half of the hypothesis was confirmed by the data; hypothesis change occurred on 96% of the trials for the six-problem condition of Experiment II and was somewhat lower for all of the remaining conditions of both experiments. However, the second half of the hypothesis was not supported by the data in any condition. One interpretation of the fact that the rate of hypothesis change was considerably higher after negative OTs than positive OTs has been suggested by White (1972a). In the latter paper, it was hypothesized that within a sample of adult human problem solvers a variance of strategies would obtain. For example, from instruction and previous problem-solving experience, some Ss would decide that their task was to memorize the response that was to be given in the presence of each stimulus; no consideration would be given to the possibility that the various stimuli are related. Other Ss might conceptualize the task as requiring an active reorganization of the problem, and the formulation and testing of hypotheses. A proper mix of such problem solvers could conceivably have produced the data obtained in both experiments. If the data of a sizable number of Ss who are testing hypotheses, and who are altering their hypotheses after errors and maintaining con-

firmed hypotheses are combined with a group of *S*s who are adopting an associative strategy, and who are altering "hypotheses" after both positive and negative OTs, it would be expected that the rate of hypothesis alteration would not be equal after positive and negative OTs, and that some moderate rate of hypothesis change would occur after positive and negative OTs. While the notion of variant strategies among *S*s has not been directly determined by the present experiments or White's (1972a, 1972b) earlier experiments, the hypothesis appears more credible in light of these experiments.

Theoretical sketch. The data from the present and earlier experiments suggest that *S* has available several approaches to a CI problem. The most rudimentary approach simply involves the representation of stimuli in their entirety with a proper response. Given the known difficulty *S*s have with negative instances of concepts, it seems plausible to assume that *S* organizes the instances in such a way as to differentiate the negative and positive instances; however, the negative instances are ignored so far as solution to the problem is concerned. If *S* finds that simple representation of the stimuli and responses is overloading memory, it is likely that he will adopt a new strategy. If such an interpretation is correct, it would be expected, for example, that training effects would be far less substantial if the stimulus population was delimited to a few examples. Moreover, a nonassociative strategy would be more likely to occur if *S* knew the stimulus population to be large (e.g., selection paradigm).

Movement to the nonassociative or hypothesis-testing realm, then, depends on the knowledge *S* has of the problem at hand and the development of the hypothesis-testing skill itself. The data that are available seem to indicate that Levine's (1966) description of the hypothesis-testing *S* is correct at least in those cases where *S* knows it is clearly beneficial to him to consider several hypotheses simultaneously and to retain in memory those that have been infirmed. It could also be assumed that the hypotheses generated early in a series of problems are restricted to those suggested by positive examples. Later in training, negative examples may serve as a source for hypothesis generation and hypothesis testing. Finally, *S* may adopt the single-hypothesis selection mode if circumstances are appropriate. For example, in the present experiments, *S* learns that 16 trials are given for each problem, with four outcomes per problem. Since [illegible]iency is not being reinforced, movement to[ward] a less taxing strategy would be expected.

So far as training effects, [illegible] changes, and the development of the ability to test hypotheses are concerned, it seems the most powerful test of the overall hypothesis would be with young children (up to [illegible] yr.), who are known not to possess the ability to test hypotheses (e.g., Douglass & Bourne, 1971). Training effects would not be expected for these *S*s.

SEMANTIC ENCODING AND RECOGNITION MEMORY: A TEST OF ENCODING VARIABILITY THEORY[1]

EUGENE WINOGRAD[2] AND MARY FULCHER GEIS

Emory University

periment I compared recognition memory for two types of homographs. balanced homographs, there are two relatively equiprobable semantic odings; for polarized homographs, there is one dominant encoding. It was edicted, on the basis of encoding variability theory, that recognition would e superior for polarized homographs but the opposite outcome was obtained it two retention intervals and replicated. In Experiment II, successive word ssociation tests were administered at two intertest intervals. The semantically ored responses supported the assumption of greater variability of semantic codings for the balanced homographs. A retrieval strategy of semantic oding was proposed to account for the better recognition of balanced mographs.

The present research is an extension of encoding variability theory to the semantic encoding of ambiguous words. According to Martin (1968) and others, the subject makes a perceptual-encoding response to a presented stimulus. Although this encoded, functional stimulus may not be identical to the nominal stimulus, it constitutes the memorial representation of the nominal stimulus. The stimulus-as-coded (Bower, 1972), not the stimulus-as-presented, is stored in memory. Encoding variability theory further assumes that a given *S* may make different encodings of the same nominal stimulus on different occasions. Since Martin's research has been concerned with paired-associate learning and transfer situations in which trigrams were used as stimuli, he has viewed encoding as stimulus selection. The principles of encoding variability theory are, however, applicable to a wide variety of experimental contexts.

The experimental context with which we are concerned is recognition memory for familiar English words, and the type of encoding with which we are concerned is the memorial representation of the semantic features of a stimulus. One basis for the presumed encoding variability of familiar words is their semantic ambiguity. In a large number of instances, the same sequence of letters and phonemes may have two or more quite different meanings. Examples of such polysemous words, or homographs, are BANK, which may refer to a financial institution as well as to land adjoining a body of water, and CLUB, which may refer to an organization of people united by a common interest and to a wooden stick used as a weapon. The distinct meanings of a homograph may be considered different semantic senses of the words that allow for different semantic encodings of the same nominal stimulus across *S*s in a psychological experiment, or more importantly here, by the same *S*s on different occasions.

We believe that encoding variability theory has clear implications for recognition memory research. To recognize an old item correctly, it is assumed that *S* must make the same encoding of the item at the time of study and at the time of test. If the test encoding of an item differs from the study encoding of the item, *S* will not recognize the item, since he is accessing an encoding that does not have appropriate occurrence information, whatever that may be, associated with it. From this perspective, forgetting may be explained as failure of trace contact due to differences between

the stored encoding and the test encoding, rather than as loss of stored information.

Another aspect of the present argument which needs to be made explicit is an assumption of encoding specificity. According to this assumption, only a single functional encoding is made by the subject on a given occasion, with an occasion defined as the presentation of a verbal stimulus on either a study or a test trial. Light and Carter-Sobell (1970) and Winograd and Conn (1971) have presented evidence consistent with the specificity assumption as it applies to the semantic encoding of homographs.

The first experiment and its replication are concerned with recognition memory for two types of homographs. A *balanced* homograph is defined here as having two distinct semantic senses that are relatively equiprobable encodings. A *polarized* homograph is defined as one with two distinct semantic senses that are markedly different in their semantic encoding probabilities, with one sense being highly likely. In our opinon, encoding variability theory leads to the prediction that recognition memory for polarized homographs should be superior to recognition memory for balanced homographs. With high likelihood, *S* should make the same semantic encoding of a polarized homograph at study and at test, since its one dominant sense is a highly probable encoding. As argued above, trace contact and successful recognition depend upon such identity of study and test encodings. On the other hand, since two senses of a balanced homograph are equally probable semantic encodings, *S*'s encoding of a balanced homograph may vary from one occasion to the next. When different encodings are made at study and at test, the consequence is failure to recognize the item as old. Thus, successful recognition of old items should be more likely for polarized than for balanced homographs.

The longer the interval between study and test, i.e., the longer the interval between successive encodings of an item, the greater should be the likelihood that the encodings are independent. If this hypothesis of increased encoding variability over time is correct, the predi[illegible]riority of recognition memory for [illegible]ed homographs should be most ev[illegible]t a long retention interval.

Experiment [illegible]

Method

Design. The design of Experim[illegible] Ia and Ib was a 2 × 2 factorial in which type [illegible] homograph, balanced or polarized, was a wit[illegible]jects variable and retention interval was a [illegible]n-subjects variable. The length of the ret[illegible]tervals is the only difference between the [illegible]periments. In Experiment Ia, the retention [illegible]ls were 3 min. and 25 min.; in Experiment I[illegible] retention intervals were 3 min. and 48 hr.

Materials. The homographs and [illegible] semantic encoding probabilities were taken [illegible]e norms of Cramer (1970), Kausler and Kolla[illegible]970), and Perfetti, Lindsey, and Garson (1971[illegible] majority of the homographs were selected f[illegible] the last-named source. These norms had be[illegible]ined by requiring *S*s to give a single word ass[illegible]tion to a series of homographs. Judges classifi[illegible] associations according to the semantic se[illegible]at they represented. For example, associat[illegible] such as "money," "vault," and "check" to the homograph BANK were classified as representing the encoding of bank as a financial institution; associations such as "river," "hill," and "slope" were classified as representing the encoding of "land adjoining a body of water."

Fifty-six balanced and 56 polarized homographs[3] were used in Experiment I. The selection criterion for a balanced homograph was that fewer than 75% of the associations were classified by the judges under the primary semantic sense (S_1). In other words, the normative or cultural encoding probabilities of S_1 for the balanced homographs were less than .75. For the 56 balanced homographs, the mean probabilities of S_1 and S_2, the secondary semantic sense, were .54 and .31. The selection criterion for a polarized homograph was that at least 75% of the associations were classified by the judges under the primary semantic sense The mean probabilities of S_1 and S_2 for the polarized homographs were .83 and .11. The median word frequencies (Kučera & Francis, 1967) were 25 per million for the balanced homographs and 36 per million for the polarized homographs. The corresponding means were 99 and 107 per million.

Two lists, A and B, each containing 28 balanced and 28 polarized homographs, were constructed. One random order of each list was used for study. The list that was not presented for study supplied the distractor items on the two-alternative, forced-choice recognition test. Three different test forms were constructed by randomly pairing List A and List B homographs that were of the same type, i.e.,

[3] A list of the words used in Experiment I is available from the first author.

on the test, the choice was always between two balanced homographs or two polarized homographs. Since list effects were not significant, this variable is not mentioned again.

Procedure. Subjects were shown either the List A or List B slides at a 3-sec. rate. In both experiments, approximately half of the *S*s who were tested at each retention interval studied List A. Following presentation of the last word, *S*s worked for 3 min. on number progression problems. In Experiment Ia, half of the *S*s were administered the recognition test immediately after the filler task. Before the other *S*s were administered the recognition test, they received a 22-min. break during which they were asked to leave the room and not to discuss the experiment. In Experiment Ib, the filler task was followed by either immediate testing, as in Experiment Ia, or testing at 48 hr. The experiments were conducted in sessions with small groups of *S*s. Experiment Ia was completed before Experiment Ib was begun.

Subjects. Fifty *S*s participated in the first experiment and [illegible] *S*s participated in the second experiment. [illegible] were assigned randomly to lists, test forms, and retention intervals, until there were 25 *S*s at each interval in Experiment Ia and 24 *S*s at each interval in Experiment Ib. Subjects in Experiment Ia were summer session students at Emory University. [illegible] 41 were paid for participation and 11 were fulfilling an introductory psychology course requirement. Subjects in Experiment Ib served during the regular school year to meet an introductory psychology course requirement.

Results and Discussion

The results of the experiments are shown in Table 1. In Experiment Ia, the main effect of type of homograph was the only significant outcome, $F\ (1, 48) = 21.60$, $p < .001$.[4] The interesting aspect of the results is that recognition memory for balanced homographs was superior to recognition memory for polarized homographs. Since this result was contrary to predictions, and since no effect of retention interval was evident, the experiment was repeated with a retention interval that was sufficiently long to allow for a performance decrement.

In Experiment Ib, recognition memory for balanced homographs was again superior to that for polarized homographs, $F\ (1, 46) = 20.41$, $p < .001$. There was a significant decline in performance at the 48-hr. retention interval, $F\ (1, 46) = 18.55$, $p < .001$, but there was no statistical support for an interaction between type of homograph and retention interval.

TABLE 1

CORRECT RECOGNITION PROPORTIONS

Experiment	Type of homograph: Polarized	Balanced
Ia		
3 min.	.80	.86
25 min.	.83	.87
Ib		
3 min.	.81	.86
48 hr.	.65	.76

Imagery ratings of the homographs were collected to determine whether an uncontrolled difference in rated imagery might account for the difference in recognition memory between the two types of homographs. Thirty-seven undergraduates from the Emory University subject pool rated each homograph on a 7-point imagery scale, according to the procedure described by Paivio, Yuille, and Madigan (1968). The difference between the mean rating of the balanced homographs (4.94) and of the polarized homographs (4.90) was not significant.

The data of Experiments Ia and Ib evidence a relationship between semantic encoding probabilities and performance in a recognition memory task. Since the direction of the relationship was contrary to predictions, it is necessary to reconsider our argument. Although this reconsideration will be undertaken more fully after presentation of Experiment II, one hypothesis that led to the second experiment is mentioned here. It is conceivable that *S*s are more likely to encode both semantic senses when there are two encodings of similar strength, as is the case with balanced homographs, than when there is one culturally dominant encoding, as with polarized homographs. If two semantic representations are encoded, then either encoding at the time of test can result in trace contact and successful recognition. While such double encoding violates the strong form of

[4] All *F* values reported in this paper treat words as a fixed effect. If words are treated as a random factor and *min F′* is computed, following Clark (1973), all of the significant outcomes remain so.

the encoding specificity assumption outlined earlier, it is consistent with a weak form of encoding specificity, namely, that one or more semantic representations may be tagged on a given occasion. As Light and Carter-Sobell (1970) point out, this assumption is still distinguishable from an assumption of generic encoding, since it is not assumed that all senses sharing the same lexical form are encoded whenever that form is studied.

Mnemonic performance in Experiment I was predicted from encoding data obtained by other investigators. These encoding data were taken from word associations given on a single occasion, while our concern is with variability within *S*s on two occasions. Therefore, Experiment II was conducted to assess the stability of semantic encodings over the time periods used in the first experiment with the expectation that such data would illuminate the recognition memory performance of Experiment I.

Experiment II

Method

Design. Two coordinate procedures were employed. In one procedure, discrete word associations to the same homographs were obtained from the same *S*s on two occasions separated by either 5 min. or 48 hr. In the other procedure, the method of continued association was used to obtain from *S*s two different associations to the same homographs on one occasion. From the first procedure, data concerning the relative stability of semantic encodings over time were obtained. From the second procedure, the likelihood of *S* making two semantically distinct encodings on the same occasion, when instructed to produce two different responses, was determined.

Materials. More stringent selection criteria were used to choose 25 balanced and 25 polarized homographs from the norms cited in Experiment I. A homograph was considered balanced if the normative encoding probability of S_1 was less than .58 and the normative encoding probability of S_2 was at least .40. The mean published values of S_1 and S_2 for the balanced homographs were .49 and .41. A homograph was considered polarized if the normative encoding probability of S_1 was at least .78 and if the normative encoding probability of S_2 was at least .10. The mean published values of S_1 and S_2 for the polarized homographs were .81 and .14. The actual S_1 and S_2 values for the Emory population, as distinguished from the published values, are reported in the results section. Thirty nonhomographs were also selected, half of which were used in the booklets for the first [illegible] and the other half of which were used in th[illegible]klets for the second test at 5 min. or 48 hr. T[illegible]homographs were chosen from words whose di[illegible]ary (Random House Dictionary of the English [illegible]guage, 1968) meanings represented only one se[illegible] sense in the authors' judgment. The m[illegible] frequencies (Kučera & Francis, 1967) were 28 [illegible]illion for the balanced homographs, 30 per mill[illegible]or the polarized homographs, and 29 per [illegible]on for the nonhomographs.

In the booklets for the discr[illegible]iation procedure, a single word appeared on [illegible]page with a space for *S*'s response next to th[illegible]ls. In the booklets for the continued associ[illegible] procedure, the same word appeared twice on [illegible]ge with a space for *S*'s response next to each o[illegible]rence of the word. Each *S* received a 67-page bo[illegible]. A space for *S*'s name and instructions were [illegible]ed on the first 2 pages. The remaining 65 pa[illegible]onsisted of the 25 balanced homographs, the 25 [illegible]zed homographs, and 15 of the nonhomograph[illegible]ers. Four random orders of the words were used [illegible]struction of the booklets

Procedure. Small groups of *S*s were t[illegible]ed. Subjects in the discrete association proc[illegible] were instructed to write down the first word [illegible]t came to mind upon seeing a stimulus word. A[illegible] completing the first association test, all *S*s in [illegible]e discrete association procedure received a 5-[illegible] number progression task. In the 5-min. con[illegible], the *S*s then were readministered the associatio[illegible]st, while in the 48-hr. condition, the *S*s were d[illegible]ssed and retested 48 hr. later. For the second [illegible]sociation test, *S*s received a booklet consisting of t[illegible]50 homographs on which they had been teste[illegible]eviously and the 15 nonhomographs on which the[illegible] had not been tested previously. The words in the second test booklet were in a different random order from those in the first test booklet. The order of the words and the filler words were changed to reduce *S*'s tendency to respond exactly as before, i.e., to minimize possible intralist context effects. Subjects in the continued association procedure were dismissed upon completion of their one test booklet.

Subjects. The *S*s were 105 Emory undergraduate students who participated to fulfill an introductory psychology course requirement. Groups were randomly assigned to conditions and booklets. In the discrete association procedure there were 38 *S*s in the 5-min. condition and 30 *S*s in the 48-hr. condition. In the continued association procedure, 37 *S*s were tested.

Scoring. Two judges independently classified the associations according to the semantic senses that were represented. The semantic senses that were used in scoring were similar to those that were reported in the norms cited in Experiment I. There was 95% agreement between the two judges. A third judge resolved the scoring disagreements. The third judge and one of the first two judges were unaware of the purpose of the scoring and of the expected distributions of encoding probabilities.

Six percent of the associations were unscorable

in that [illegible]ges could not classify them under a reason[illegible]antic sense. These associations were exclud[illegible]he reported analyses. Three percent of the [illegible]g associations were scored as representative [illegible]hird semantic sense, i.e., 97% of the scorable [illegible]tions were classified under either S_1 or S[illegible]nd conditional probabilities for the tertiary [illegible]re not reported because of the small number [illegible]tions that were classified under S_3.

Results a[illegible]scussion

Stability [illegible]f group norms. The stability of the obtai[illegible]ed group norms as well as their comparabi[illegible]y with the norms of other investigat[illegible]s will be reported first. Based on the d[illegible] from the first test for the 68 *S*s in th[illegible]discrete association procedure, the ob[illegible] mean values of S_1 and S_2 for the 25 [illegible]rized homographs were .87 and .12. [illegible] th[illegible]5-min. retest (n = 38), the mean [illegible]f S_1 and S_2 were .88 and .12; at 48[illegible]30), they were .86 and .12. Thes[illegible] in good agreement with the [illegible]es of .81 and .14 that were obtai[illegible]n the published norms cited in E[illegible]nt I and also demonstrate the stabilit[illegible]ne group norms.

For 10 [illegible] the 25 balanced homographs, but for no[illegible] of the polarized homographs, there were discrepancies between the Em[illegible]y norms and the published norms as to which semantic sense was dominant, i.e., as to the definitions of S_1 and S_2. This outcom[illegible] not surprising, since the criterion for a balanced homograph was that its semantic encodings were relatively equiprobable. When S_1 and S_2 are redefined according to the obtained norms, the balanced homographs became more polarized than when they are based on the published values. At the first, 5-min., and 48-hr. tests, the mean S_1 and S_2 values were .63 and .34, .62 and .34, and .62 and .3[illegible] respectively. In subsequent analyses, the de[illegible]ns of S_1 and S_2 and their encoding probabilities are based on the Emory data.

Although the balanced and polarized homographs are different with respect to the probabilities of their primary associates when the associates are defined semantically, it should be noted that they are not different when the primary associate is scored in terms of words. In word association norms, the primary associate usually is defined as the single word that the subjects gave most frequently. For the present materials, collapsed across procedures and tests, the mean probabilities of the primary word associates were .26 for the polarized homographs and .24 for the balanced homographs.

TABLE 2

Encoding Patterns from Test to Retest

	Time	Polarized	Balanced
P(same)	5 min.	.88 (902)	.79 (886)
	48 hr.	.87 (710)	.77 (699)
$P(S_2 \vert S_1)$	5 min.	.06 (793)	.15 (552)
	48 hr.	.07 (616)	.17 (448)
$P(S_1 \vert S_2)$	5 min.	.44 (106)	.28 (310)
	48 hr.	.48 (86)	.28 (238)

Within-subject encoding stability. Data relating to the question of the stability of semantic encodings over time are presented in Table 2. The entries in Table 2 are for pooled observations over *S*s and words. The number of observations in each cell is given in parentheses. In the upper portion of the table, the probabilities of making the same semantic encoding at test and retest are shown. At each interval, the probability of the same semantic encoding is less for balanced homographs than for polarized homographs. The data were subjected to an analysis of variance by taking the proportions across words for each *S*. The effect of type of homograph was the only significant outcome, F (1, 58) = 52.38, $p < .001$. The assumption of greater variability of semantic encoding for balanced homographs, on which the first experiment was based, is supported. However, the assumption of increased variability over time is not supported.

The likelihoods of switching from S_1 to S_2, and vice versa, are shown in the middle and lower portions of Table 2. In the middle portion of the table, $P(S_2|S_1)$ is the probability of a switch to the secondary encoding at retest, conditionalized on the occurrence of the primary semantic encoding at the first test. Although the probabilities of switching from S_1 to S_2 are low, the greater likelihood of switching for the

balanced homographs is significant, $F(1, 58) = 44.61$, $p < .001$.

The bottom portion of Table 2 contains the probabilities of switching from S_2 to S_1, $P(S_1|S_2)$. These probabilities are substantially higher than those of the preceding analysis and are an indication that subjects are less likely to repeat an encoding if it is the normative secondary than if it is the normative primary. It is evident that the probability of an encoding switch from the normatively weaker to the normatively stronger encoding is greater for polarized homographs, $F(1, 52) = 10.39$, $p < .01$.

Independence of encodings. The question of whether responding at the second test was independent of responding at the first test was examined next. The observed joint probability of particular test–retest encoding patterns was compared to a predicted joint probability that was determined from independent estimates of S_1 and S_2 encoding probabilities. Since all values for 5 min. and 48 hr. were almost equal, these data were combined. For example, the observed joint probability of an S_1 encoding at both test and retest, $P(S_1 \text{ and } S_1)$, was .52 for balanced homographs. The predicted $P(S_1 \text{ and } S_1)$, if it is based on independent estimates of $P(S_1)$ on each occasion, is $P(S_1)P(S_1)$, or (.63) (.62), or .39. In every comparison, there was a lack of agreement between the predicted and observed values and the discrepancies were consistent. The observed probability of making the same encodings over time was greater than expected on the independence assumption, and the observed probability of two different encodings over time was smaller than expected. The differences are significant by chi-square. There is no evidence that semantic encoding on the second test is independent of the first test.

Scoring by word. So far, the data have been considered largely in terms of semantic types or senses. The probability of obtaining the identical word as the response to the same homograph at both tests is also of interest. For the polarized homographs, the probabilities of the same word at both tests were .54 at both 5 min. and 48 hr. For the balanced homographs, the corresponding values were .49 and .45. The effects of type of homograph, time, and their interaction were not significant. Semantic scoring apparently was not affected by differential bias to repeat particular words for either balanced or polarized homographs. This outcome was expected, since the strength of the primary *word* associate, as reported above, was the same for the two types of homographs.

The absence of a significant effect of test–retest interval on word repetition is consistent with the outcomes of semantic scoring. Our data are in close agreement with those of Fox (1970) with respect to within-subject change. Fox administered identical word association tests to the same *S*s with a test–retest interval of 59 days and scored the responses by exact words rather than by semantic senses. He reported that the probability of within-subject word change was .52. For our data, the overall probability of a word change was .48. Thus, across the two studies, the probability of *S* changing his associative response does not increase from 5 min. to 59 days. Both here and in Fox's work, there is evidence for considerable normative or within-group stability in conjunction with considerable within-subject instability. That is, while *S*s change their responses, the group norms remain constant.

Continued association. In the continued association procedure, the subjects were required to produce two successive but different associations to each homograph. The probabilities that the two associations represented the same semantic sense were .65 for the polarized homographs and .52 for the balanced homographs. The difference was significant, $F(1, 72) = 39.06$, $p < .001$. When the probability of a switch to the secondary encoding is conditionalized on the occurrence of the primary encoding as the first response, i.e., $P(S_2|S_1)$, the resulting values are .26 for the polarized homographs and .36 for the balanced homographs, $F(1, 72) = 19.27$, $p < .001$. For the opposite pattern, i.e., $P(S_1|S_2)$, the conditional probabilities are .75 and .54 for the polarized and balanced

homog...hs, respectively, F (1, 70) = 34.46, p < .001. The patterns are the same as those obtained for discrete associations (Table 2), but the likelihood of change ...ater in all cases for continued associ... This difference may be due to the ...traint of not being allowed to repeat the same word in the continued associat... procedure.

General Discussion

Experiment I was based on some assumptions about semantic encoding processes leading to the prediction that recognition memory for balanced homographs would be inferior to recognition memory for polarized homographs. However, the opposite state of affairs prevailed: recognition memory for balanced homographs was superior to that for polarized homographs. This finding was replicated, and the assumptions concerning the variability of semantic encoding of the two types of homographs ...ted by administering a word association test on two occasions. The word association findings were clear-cut: In agreement with the assumptions underlying the recognition memory experiments, semantic encoding was more variable for balanced than for polarized homographs.

Since the results of Experiment II support the assumptions on which the experimental tests of encoding variability theory were based, we must reconsider what is happening in recognition memory. Earlier, a model that incorporated the assumption of multiple encoding was mentioned as a possible fit for the recognition memory data. In a simple form of such a model, it is assumed that S may achieve, on some occasions, more than a single semantic encoding of a homograph. If multiple representations are encoded at study, recognition memory should be improved, since trace contact can result if any one of the previously stored encodings is made at test. The encoding data from the continued association procedure of Experiment II are evidence that, when more than one encoding is attempted, S is more likely to arrive at two semantically distinct encodings for balanced homographs than for polarized homographs. When Ss were required to provide two responses, the second response represented a different semantic sense significantly more often for the balanced homographs. Thus, the superior recognition of balanced homographs is consistent with an assumption of multiple encoding.

Rather than assume multiple semantic encoding at study, we consider it more likely that Ss in a word-memory experiment make a single encoding of an item at study but, when forced to choose between two seemingly unfamiliar items, attempt to recode the test items semantically at the time of test. (It is assumed that, if S makes a test encoding of an old word that differs from its study encoding, he is placed in the situation of having to choose between two unfamiliar items on a forced-choice recognition test.) Furthermore, Ss may be more likely to recode if they notice that the words in an experiment are homographs.

We do not know of any evidence to compel an assumption of recoding at test over the alternative assumption of multiple encoding (double tagging) at study. However, at present, we believe that it is both parsimonious and plausible to continue to assume encoding specificity at study, unless an alternative strategy is made more efficient by special conditions such as producing puns. This view preserves the original encoding variability argument on which this research was based, with the addition of an assumption concerning the likelihood of additional retrieval operations at test.

An alternative account of the superior recognition performance for the balanced homographs would be in terms of word frequency. Although the balanced and polarized homographs were equated on word frequency, it is obvious that they were equated only on frequency of the homograph form, rather than on frequency of particular meanings. For example, assume that the homographs BANK and CLUB are of equal frequency. If CLUB is balanced and BANK is polarized, then the primary encoding of CLUB necessarily will be lower in frequency than the primary encoding of BANK, since the primary sense of a balanced homograph must have a smaller slice of the frequency pie than the primary sense of a polarized homograph if the pies have been kept the same size. Thus, it is possible that the superior recognition of balanced homographs is a special case of the well-documented finding that recognition memory is better for low-frequency than for high-frequency words (Schulman, 1967; Shepard, 1967). Whether differences in frequency of the semantic types used here are sufficient to account for the difference found in recognition memory is an empirical question. The reader will note that the

selection of items matched in S_1 frequency but differing in S_1 and S_2 probabilities not only is a formidable task in itself, but necessarily must result in unequal frequencies of the homograph forms.

Finally we note some interesting features of the word association data of Experiment II. With regard to stability, a distinction must be made between scoring for repetition of the same word, the traditional word association measure, and scoring for repetition of the same category of semantic meaning. With respect to the exact associate, *S* is as likely to change his response as to repeat it. If our data are compared to Fox's (1970), this within-*S* instability is relatively constant from 5 min. to 59 days. If word associations are scored semantically, they are much more stable on the whole (see Table 2). But, even with semantic scoring, time between successive tests has very little effect, at least over a 48-hr. interval.

We seem to have assessed a relatively permanent characteristic of the semantic memory system. In distinguishing between semantic and episodic memory, Tulving (1972) points out that information in semantic memory is not temporally dated while information in episodic memory is. In these terms, the present research was an attempt to predict some simple phenomena of episodic memory, using a recognition memory task, on the basis of independently determined characteristics of semantic memory. Although our particular predictions were not confirmed, we have found a relationship between the two systems that must be accounted for.

Experiment I

Method

The *S*s consisted of 36 male albino rats from Carworth of New City, New York, which were 60–90 days old at the start of the experiment.

A traditional two-alley frustration apparatus was used throughout the experiment. All start and goal boxes were 30 cm. long, and the two alleys were 89 cm. in length. The apparatus was 15 cm. wide and 30 cm. in depth and was painted gray except for the black endbox (Goal Box 2). The floors of the start box, midbox (Goal Box 1), and endbox were spring loaded and permitted the recording of latency and running times in both segments. When *S* was placed in the initial start box, an electric circuit was opened which was later closed when *E* raised the start-box door. The first Standard electric clock, begun with the opening of the door, stopped when *S* left the start-box plate. Clock 2, which started with *S*'s departure from the start-box plate, stopped as *S* entered and depressed the midbox (Goal Box 1) plate. Clocks were read, reset, and readied for identical activation in the second alley. Times were recorded in hundredths of a second.

The *S*s were housed in pairs and allowed a 5-day habituation period with food and water ad lib. On Day 6, *S*s were placed on a 23-hr. deprivation schedule which continued throughout the experiment except for the time constraints encountered as the number of trials was increased during acquisition. On Days 8–10, *S*s were placed in pairs in the open apparatus and allowed 10 min. of exploratory activity. On Days 11–12, *S*s were allowed 10 min. of rewarded exploratory activity which consisted of free access to a cup of Noyes 45-mg. regular pellets in each goal box.

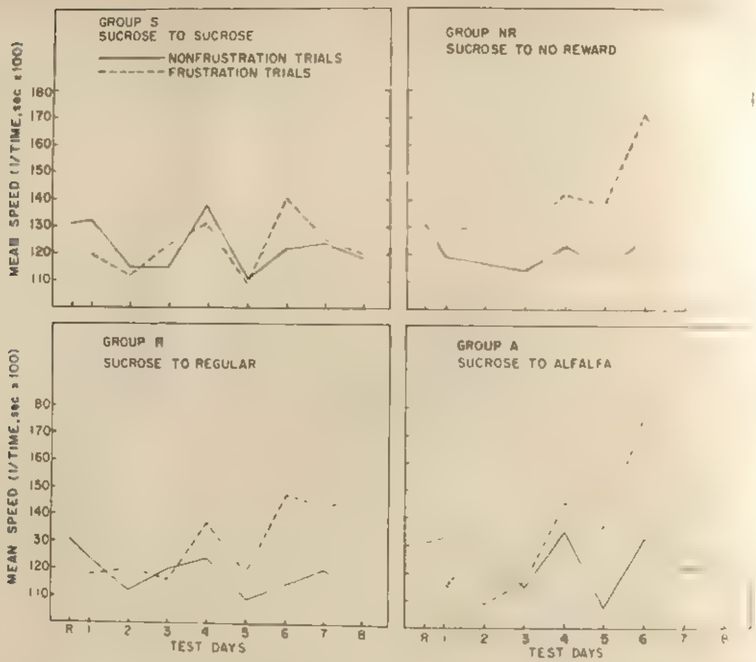

FIGURE 1. Alley 2 speed scores for frustration and nonfrustration test trials for the four basic groups over eight test days. (Abbreviation: R = mean score for the group at the end of acquisition training.)

Acquisition training was begun on Day 13 and continued through Day 35. All *Ss* were given a total of 66 trials which were rewarded in both the midbox and the endbox with four 45-mg. Noyes 93% sucrose pellets. The trials were initially given at the rate of 1 trial/day but were ultimately increased to 6 trials/day according to the following daily schedule: 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 1, 1, 1, 1, 1, 1, 6, 6, 6, 6, 6, 6, and 6. The *Ss* were given 3 sec. in the start box before the door was raised and were subsequently retained for 30 sec. in the midbox. The *Ss* were taken from the goal box after they finished eating their reward. All *Ss* were run in squads in a rotation which generated an intertrial interval of 10–15 min.

Following acquisition trials, the total running speed for Alley 2 was determined for the last six acquisition trials. All 36 *Ss* were rank ordered in terms of their terminal running speed and the four fastest *Ss* were then "blocked" and each member of the "block" was randomly assigned to a different treatment group. This procedure was continued until *Ss* had been distributed into nine such blocks. During the test trials, the four treatment groups each continued to receive two daily trials in which sucrose pellets, as in training, were available in both the midbox and the endbox. These daily test trials were ordered according to the following schedule of frustration (F) and nonfrustration (N) trials: FNFN, NFFN, FFNN, NFNF, FNNF, NNFF, FNFN, and NFFN. On the other two daily trials, the "frustration" trials, *Ss* received either sucrose reward, regular reward, alfalfa reward, or no reward in the midbox according to their respective group designation: S, R, A, or NR, respectively. When reward was given on designated frustration trials it always involved the same weight amount of food which had been employed during acquisition, i.e., four 45-mg. pellets. There was no change in endbox reward from that employed during acquisition. During this test phase, trials were run at the rate of 4/day and were continued for a total of eight days.

Results

The time scores (in seconds) for the second alley were reciprocally transformed (1/Time × 100) for each test trial. Subsequently, a mean speed score was computed for the frustration and nonfrustration conditions for each test day, and these mean speed scores served as the basic datum in a multifactored randomized block analysis of variance.

Figure 1 graphically depicts the experimental findings over the eight test days. It can be seen that in Group S there is no reliable difference between mean running speed on frustration and nonfrustration trials. This result was predicted since, in

this co[illegible] group, there is actually no differenti[illegible]atment for frustration and nonfrustra[illegible] trials. However, for the other groups [illegible]ere is a noticeable increase in runnin[illegible]peed as one moves from the nonfrustra[illegible]n to the frustration trials and this differe[illegible], i.e., frustration vs. nonfrustration, is [illegible]tatistically significant as indicated by b[illegible] a significant main effect for frustr[illegible]n condition, $F\ (1, 8) = 62.67$, $p <$ [illegible]05, and a significant Group × Frust[illegible]on Condition interaction, F (3, 324) [illegible]4, $p < .002$. There were two other [illegible]istically reliable differences: one differe[illegible]elated to an overall increased speed [illegible] test days, $F\ (7, 56) = 11.66$, $p <$ [illegible], and the other to a Days × Fru[illegible]ation Condition interaction, $F\ (7, 56) = 10.00$, $p < .000001$. These basic statis[illegible]al findin[illegible] revealed in Figure 1.

[illegible]omparisons with Duncan [illegible] indicated that only in [illegible] no reliable difference in m[illegible]peed for all shift trials between frustr[illegible]on ($\bar{X} = 122.89$) and nonfr[illegible] conditions ($\bar{X} = 121.97$). In the [illegible] groups the frustration tri[illegible]duced significantly faster [illegible] did the corresponding nonfrustration trials: Group R ($\bar{X} = 131.06$ vs. $\bar{X} = 117.00$), Group A ($\bar{X} = 138.39$ vs. $\bar{X} = 124.83$), and Group NR ($\bar{X} = 143.29$ vs. $\bar{X} = 117.49$).

[illegible]urther demonstration of the increased running speed produced by quality reduction in the midbox can be seen in the group comparisons on nonfrustration trials. The only significant comparisons were obtained between Group A and Group NR and between Group A and Group R. The slight elevation in running speed on nonfrustration trials in Group S animals was an anomalous result. In Groups S, R, and NR, the nonfrustration condition comparisons did not differ. A comparison of only the frustration condition across groups suggests something of the relative strength of a possible FE produced by quality reduction in the midbox and bears on the initial hypothesis that an FE would be inversely related to quality of reward obtaining on frustration trials. Groups R, A, and NR all differed significantly from the control situation, Group S, in frustration condition speeds. Beyond that, Group A did not differ from Group NR but did significantly exceed Group R and Group S in running speed. Group R *Ss* were also significantly faster than Group S animals on frustration trials.

Discussion

The results of this study suggest that it is possible to produce a primary FE by nonzero or incomplete reward reduction. In this particular case, the incomplete reward reduction was achieved, in Group A and Group R animals, while actually holding constant the weight of the food available on frustration and nonfrustration trials. The fact that *Ss* of Groups A and R had available on frustration trials a reward of equal weight and one that most probably contained more nutritional or satiety value than the nonfrustration sucrose reward would seem to militate against any attempt to invoke the original form of the "demotivation" or "response-depression" hypothesis (Seward, Pereboom, Butler, & Jones, 1957) as an explanation of the present results. On the other hand, it is true that the design of the present study does not effectively guard against the interpretation that the observed results are attributable to absolute effects stemming out of such things as subtle differences in eating times caused by different reward texture, etc. Another interpretation problem results from the fact that there was a Frustration Condition × Days Interaction. A perusal of Figure 1 shows that, with the exception of Group S, there is an increasing difference between frustration and nonfrustration trials over test days. It is possible that what is interpreted in the present study as an unlearned energizing effect of frustration is contaminated with an association component. For these reasons, it was decided that a second experiment should be attempted in which control conditions are established in a between-*Ss* design.

Experiment II

Method

The *Ss* were 44 male albino rats purchased from National Breeding Laboratories, Creve Couer, Missouri, which were 60–90 days old at the beginning of the experiment. The same two-alley frustration apparatus (Experiment I) was employed except that it was modified by painting the second alley black

and by placing ½-in. hardware cloth on the start box, first alley, and midbox. Both Alley 2 and the endbox (Goal Box 2) were black and were devoid of hardware cloth.

The Ss were housed in pairs and were allowed a 20-day habituation period in their cages with food and water ad lib. On Day 21, Ss were placed on a 23-hr. food deprivation schedule which continued throughout the experiment except for the time constraints encountered as the number of trials was increased during acquisition. On Days 22–26, Ss were placed, before their feeding period, in groups of six in the open apparatus devoid of all food cups and were allowed 5 min. of nonrewarded exploratory activity. On Days 27–29, the deprived Ss were placed in groups of two in an unpainted rectangular pine box (46 × 28 × 25 cm.) and were permitted to eat specific reward pellets from specific and differentiable food cups affixed on opposite ends of the box. The food cups were of different shape and the white one, which was later to occupy the midbox (Goal Box 1), was either empty or contained a large supply of 45-mg. pellets appropriate to the experimental group in which the two Ss had been randomly placed. The black cup, which was to occupy the endbox or Goal Box 2, always contained a large quantity of 45-mg. pellets appropriate to the experimental group in which the two Ss had been randomly placed. The black cup, which was to occupy the endbox or Goal Box 2, always contained a large quantity of 45-mg. 93% sucrose pellets since all Ss, regardless of their experimental group, were ultimately to receive such sucrose reward in the endbox. On Days 30–32, all 44 Ss were given, before their feeding period, a single goal placement in the black endbox of the two-alley frustration apparatus and were allowed to eat five 45-mg. Noyes pellets composed of 93% sucrose. The endbox door was down and the pellets were given in the black food cup appropriate to the endbox (Goal Box 2). On Day 33, all Ss received their first acquisition trial in the entire apparatus. The S was placed in the start box and the start-box latency and Alley 1 running times were recorded as in Experiment I. When S entered the midbox he received either no reward, 5 pellets of Noyes 45-mg. alfalfa pellets, or 93% sucrose. The difference in midbox reward constituted the only difference in the treatment of Ss during acquisition. After a 10-sec. delay in the midbox, E activated the midbox door and again latency and running times were recorded for the second portion of the apparatus. For 4 days, Days 33–36, each rat received only a single trial in the double-alley apparatus. This was followed by 6 days, Days 37–42, of 2 daily trials. On Day 43, the number of trials was increased to 3 and this schedule was continued through Day 63 when all Ss had received 79 trials in the double runway. On Day 64, the first frustration trial was given on the third daily trial, Trial 82, and these test days continued for a total of 12 days, Days 64–75.

At the start of the experiment all Ss were randomly assigned to one of four experimental groups ($n = 11$) which differed only in their midbox (Goal Box 1) reward experience. Group A-S Ss always received five 45-mg. alfalfa pellets in the midbox and five 45-mg. 93% sucrose pellets in the endbox. This reward experience was continuous over the entire experiment and did not change during the final 12-day test period. Group O-S Ss also received continuous training throughout. Group O-S animals differed from Group A-S Ss only in that on all trials they found no reward in the white food cup in the midbox. Group SS-A Ss all received 81 training trials in which both the midbox and the endbox always contained five 45-mg. 93% sucrose pellets. On Trial 82, the initial frustration trial, SS-A Ss received five 45-mg. alfalfa pellets instead of their customary 93% sucrose. Since the SS-A Ss had never before encountered alfalfa, and since pilot work indicated that the first encounter with alfalfa produces "shock" and long midbox latencies and Alley 2 running speeds, these Ss were given five alfalfa pellets to eat from a Gerber's baby jar lid in the neutral pine box approximately 1.5 hr. before their first test experience. This was done only once and was not repeated during the additional test days. The Ss of Group SS-O received five 45-mg. 93% sucrose pellets in both the midbox and endbox for the first 81 trials. Again, on Trial 82, these Ss received their initial frustration trial when they encountered an empty midbox. On the 12 test days, the initial daily trial for the two frustration groups, SS-A and SS-O, was always rewarded. The single daily frustration trial, when, occurred either on Trial 2 or Trial 3 and was randomly determined according to a schedule which had only the restraint that there be an equal number of frustration trials in each position (Trial 2 and Trial 3) over any 4-day test block. The actual schedule during test days was as follows: NNF, NFN, NFN, NNF, NFN, NFN, NNF, and NNF.

Results

To test that the four treatment groups were performing in a similar way at the end of acquisition, the Alley 2 time scores for the last six trials of acquisition (Trials 74–79) were reciprocally transformed and subjected to a split-plot analysis of variance. The group or treatment effect was not significant, $F\ (3, 40) = .31$, and the Group × Trials interaction was also insignificant, $F\ (15, 200) = .64$. Only the trials effect was significant, $F\ (5, 200) = 6.69$, and this was attributable to the fact that the initial daily trials (in this case Trial 74 and Trial 77) were depressed relative to the other trials within a given day.

Since all groups were essentially alike in Alley 2 speed at the end of acquisition, additional analyses centered around Alley 2 speed during the 12 test days in which

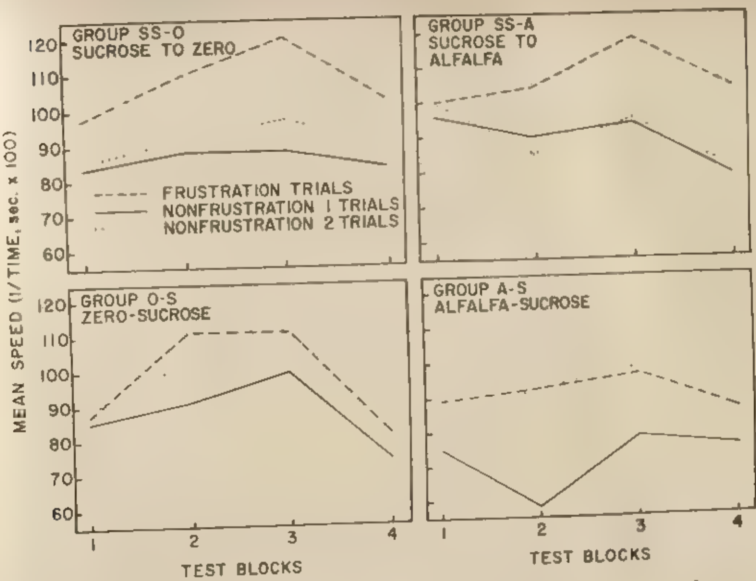

FIGURE 2. Alley 2 speed scores for Nonfrustration Trial 1, Nonfrustration Trial 2, and frustration trials for the four basic groups over four test blocks.

frustration trials were administered. Alley 2 runway times were reciprocally transformed and the transformed speed scores were collapsed into four blocks of three days each. The mean transformed value for a given block was then computed for the first nonfrustration trial, the second nonfrustration trial, and the frustration trial. These mean speed values were employed as the basic datum in a multifactored split-plot analysis of variance involving groups, frustration condition, and blocks. Figure 2 depicts the speed data.

The main effect for groups was not significant, F (3, 40) = .89, but there was a significant frustration condition effect, F (2, 80) = 28.42, $p < .000001$, and a significant first-order Groups $\times$ Frustration Condition interaction, F (6, 80) = 3.36, $p < .006$. In addition, the only other significant effect was that for blocks, F (3, 120) = 8.14, $p < .00006$.

Subsequent comparisons with the Duncan range test ($\alpha = .001$) revealed that all major comparisons were as predicted. The *Ss* of Group SS-A ran significantly faster on the frustration trials ($\bar{X} = 106.59$) than on either the first ($\bar{X} = 89.35$) or second ($\bar{X} = 90.05$) nonfrustration trial. In addition, these same *Ss* ran significantly faster on the frustration test trials ($\bar{X} = 106.59$) than the control *Ss*, Group A-S, ran on the same trials ($\bar{X} = 90.52$) but under conditions of continuous alfalfa reward in the midbox. The designation of a frustration trial for Group A-S animals was arbitrary and was dictated by the reward schedule of the parallel Group SS-A animals.

The other experimental group, Group SS-O, also showed the within-*Ss* FE in that mean frustration trials ($\bar{X} = 106.98$) significantly exceeded mean first ($\bar{X} = 85.50$) and second ($\bar{X} = 90.77$) nonfrustration trials. In addition, and more importantly, the frustration trial ($\bar{X} = 106.98$) of Group SS-O animals was significantly faster ($p < .025$) than the mean ($\bar{X} = 97.48$) of designated frustration trials in the corresponding control group, i.e., Group O-S.

As a test of the relative capacity of alfalfa test trials to energize behavior, i.e., produce the FE, it can be seen that the mean ($\bar{X} = 106.59$) of frustration trials of Group SS-A animals is essentially that of the mean ($\bar{X} = 106.98$) of the frustration trials of Group SS-O *Ss*. Neither experimental group differs significantly in their nonfrustration trials and the corre-

sponding frustration means in their respective control groups, Group A-S and Group O-S, are not reliably different.

The absence of any significant interaction involving blocks argues against the notion that the observed increase in speed on frustration trials is essentially acquired or is contaminated by an association component.

Finally, another observed result which was not anticipated was the greatly depressed initial daily trial, i.e., the first nonfrustration, of both of the control groups, Group A-S and Group O-S. In both groups, these means, 70.16 and 87.27, are significantly below their corresponding second nonfrustration trials, i.e., 90.57, 100.70. The initial nonfrustration trial for Group O-S animals does, however, appear to be essentially in line (compare with 89.35 and the 85.50 of the same trial for Group SS-A and Group SS-O). In Group O-S, then, it is the second nonfrustration trial which appears to be "out of line." At any rate, there is no ready explanation for this first-trial depression of Alley 2 speed in Group A-S and Group O-S *Ss*.

General Discussion

The reported experiments, particularly Experiment II, [illegible] that an FE is [illegible] expectancy for a higher, i.e., preferred, reward quality is not fulfilled. Such a notion is compatible with common [illegible] Tinklepaugh (1928) long ago demonstrated, at least at an anecdotal level, that a [illegible] with a normally [illegible] Bower (1962) sought to [illegible] nonreward occurs after reward [illegible] has been established [illegible] reduced to a lower [illegible] McHose and Ludvigson (1965) and [illegible] Peyser, and McHose (1965) cast doubt on Bower's interpretation by suggesting that his observed graded effects of nonzero reward reduction were co[...]ded by response inhibition stemming ou[t of] the rat's consumption of more or less foo[d in] the first goal box. The argument is that a [...] *Ss* design like Bower's does not prec[lude the] possibility that what appears to be a[n incre]ment in frustration drive with greate[r com]plete reward reduction is, in fact, si[mply a] function of absolute reward magnitude i[n Goal] Box 1. In short, the Bower results ar[e per]fectly compatible with the so-called "de[mo]tion hypothesis," which attributes diffe[rences] in Alley 2 running speed between frust[ration] and nonfrustration trials not to incr[eased] energy on frustration trials, but rather [to] depressed running speed following th[e re]warded nonfrustration trials.

Still later, Daly (1968) objected to cer[tain] inadequacies of the McHose and Ludvig[son] (1965) procedure. While these latter inve[sti]gators had, unlike Bower (1962), emplo[yed] control groups to test for a possible Alle[y] speed depression stemming out of a decre[ase] in hunger drive, they too encountered so[me] methodological difficulties. Even with th[e] controls, they did have their *Ss* experience more than one reward-reduction conditi[on], i.e., a partial within-*Ss* design. They also failed to control for the direction of shift in that only in one group, the group shifted to zero, was the shifted magnitude below the magnitude value employed in the second goal box. Daly's work pointed up further complexities in this area in that her attempt to deal with previous design limitations led in some groups, to differential acquisition performance in Alley 2 even though equal rewards were given in Goal Box 2.

The present approach sought to avoid some of these difficulties by employing a procedure wherein reward "reduction" in the midbox was restricted to a quality dimension. In Experiment II reward magnitude as such was always the same in both goal boxes, except for one group, Group SS-O. Although the previous design complexities in this area prompt caution, it is reasonable to conclude that the present results are compatible with the interpretation that an incomplete reward reduction in the midbox leads to a primary frustration effect as exhibited by faster running in Alley 2 on designated frustration trials. It could be maintained that the present findings result from quality change per se and cannot be unequivocally attributed to quality reduction or downward change. There are studies, for example, which show the invigorating effects of reward

chan[illegible]r se (Meyer & McHose, 1968; Stein[illegible] 1968), and such an interpretation cann[illegible] discounted. On the other hand, the [illegible]l changes in Experiment I which paral[illegible]e reward preferences argue against this i[illegible]rpretation. In addition, a recent replic[illegible]n by the authors[3] of the Crespi (1942) perf[illegible]ance shifts with reward quality change, in [illegible] of reward magnitude, offers further evid[illegible] against a simple change hypothesis.

VARIABLES AFFECTING THE INTERMANUAL TRANSFER AND DECAY OF PRISM ADAPTATION[1]

CHONG SOOK CHOE[2] AND ROBERT B. WELCH

University of Kansas

The study examined the effects of exposure (continuous vs. terminal) and practice (massed vs. distributed) upon prism adaptation, its intermanual transfer, and spontaneous decay. Subjects were measured before and 0, 5, 10, and 15 min. after 30 trials of exposure to 11.3° lateral prism displacement on target-pointing accuracy (each limb separately), placing the arm straight ahead (each limb separately), and setting a pinpoint light source straight ahead. Adaptive pre-post shifts in these measures represented "negative aftereffect," "proprioceptive shift," and "visual shift," respectively. The major findings were that (*a*) negative aftereffect was greater with distributed than with massed practice, (*b*) all four groups experienced intermanual transfer of negative aftereffect, (*c*) proprioceptive shift transferred intermanually for the massed practice but not the distributed practice groups, (*d*) visual shift occurred only for the distributed practice–terminal exposure group, and (*e*) both ipsilateral and contralateral negative aftereffect and proprioceptive shift decayed significantly over the 15-min. postexposure period.

It is now well documented that human beings are capable of adapting to the effects of prismatically displaced vision (e.g., Hay & Pick, 1966; Held & Hein, 1958). Of recent interest is the issue of whether or not these effects transfer, in part or whole, from exposed to nonexposed limb. Some investigators (e.g., H. B. Cohen, 1963; Mikaelian, 1963) have reported no such transfer. However, Hamilton (1964) observed adaptive shifts for both exposed and nonexposed limbs when *S* was allowed free head movement during prism exposure; no transfer occurred when (as in previous studies) *S*'s head was immobilized. He suggested that the freedom to engage in head movements leads to a change in felt orientation of head relative to the remainder of the body, which in turn affects pointing localization for both hands.

The situation is complicated by the fact that a number of studies (e.g., Goldberg, Taub, & Berman, 1967; Kalil & Freedman, 1966) have demonstrated partial intermanual transfer of prism adaptation with *S*'s head in a fixed position during exposure. The crucial difference between experiments which have found intermanual transfer and those which have not may be in the nature of the exposure condition employed. Where intermanual transfer has not occurred *S* has been allowed a noninterrupted view of his limb throughout the prism-exposure period, while in experiments in which transfer was obtained, exposure to the limb occurred only at the termination of each visuomotor response. M. M. Cohen (1967) directly compared continuous and terminal prism exposure with respect to intermanual transfer of prism adaptation and his results lend support to this argument; only terminal exposure resulted in transfer. In an attempt to interpret this result, Taub and Goldberg (in press) have proposed that continuous exposure is actually a form of "massed" practice, whereas the terminal exposure condition represents "distributed" practice. They pointed out that Spatz (1966) had found intermanual transfer of a visuomotor skill (pursuit rotor) only when there was a rest interval between ipsilateral training and contralateral testing. Other investigators (e.g., Irion & Gustafson, 1952; Kimble, 1952) have reported similar results. Taub and

[1] The present investigation formed the basis of a master's thesis by Chong Sook Choe. The research was supported by Grant EY-00560-02 from the National Eye Institute of the National Institutes of Health. The authors wish to thank John J. Uhlarik and Robert I. Bermant for their comments and criticisms of this manuscript.

Goldberg (in press) supported their hypothesis by finding intermanual transfer with a continuous exposure condition when it was interspersed with short rest intervals. Nevertheless, it remains tenable that both variables—type of exposure and type of practice—influence the occurrence and amount of intermanual transfer of prism adaptation. The primary goal of the present experiment was to investigate this possibility.

A second aim was to examine the nature of the adaptive shift underlying the intermanual transfer of adaptation. At least two end products of prism adaptation have been identified—a change in felt limb position (e.g., Harris, 1965) and a change in egocentric visual direction (e.g., Uhlarik & Canon, 1971). The latter investigators have hypothesized that the relative magnitudes of these two components of prism adaptation are determined by which informational source is attended to during prism exposure; it is primarily the nonattended modality that is modified. They argued that with terminal exposure *S* is forced to pay attention to the felt position of his limb throughout its movement, until finally seeing its displaced image. Thus, in this condition felt limb position should remain relatively unmodified, while vision is changed. Conversely, vision "dominates" in the continuous exposure condition and therefore proprioception should be altered. Their results confirmed these predictions. Therefore, it is conceivable that the presence of intermanual transfer of prism adaptation only in experiments using terminal exposure results from the fact that this condition elicits a shift in vision, an effect which necessarily determines pointing accuracy for both limbs. Clearly, this interpretation differs from that suggested by Taub and Goldberg (in press). Finally, there remains the possibility that intermanual transfer of a shift in felt limb position also occurs and represents at least a partial basis for intermanual transfer of the prism-corrective changes in eye–hand coordination.

A third goal of the present investigation was to examine the spontaneous decay of prism adaptation, in both exposed and nonexposed limbs, as a function of exposure condition and type of practice. Some investigators (Hamilton, 1964; Hamilton & Bossom, 1964; Taub & Goldberg, in press) have reported rapid decay of negative aftereffect during postexposure periods of 15 min. in duration. Others (e.g., Dewar, 1970; Goldberg, Taub, & Berman, 1967; Welch, 1971) failed to observe decay during this same postexposure interval. Again, it appears that exposure condition is an important variable. All the studies employing continuous exposure have produced rapid decay; those involving terminal exposure have led to little or no decay. It was possible to directly compare these two conditions in the present experiment. Only two reported studies have examined the effect of type of practice upon decay of adaptation, and their findings appear contradictory. Dewar (1970), using terminal exposure, found that adaptation resulting from massed practice decayed faster than adaptation generated in a distributed practice condition. On the other hand, Taub & Goldberg (in press), who used continuous exposure, appear to have found just the opposite result. The implication that type of exposure and type of practice interact with respect to rate of prism adaptation decay was examined in the present study.

METHOD

Design

All *S*s were measured before and after prism exposure on accuracy of target pointing (visuomotor coordination) and placing the arm straight ahead of the nose (felt limb position). For each task both exposed and nonexposed hands were tested. A third measure was *S*'s accuracy in setting a pinpoint light source straight ahead of his nose (visual straight ahead). The postexposure measures of each of these three tasks were taken at 0, 5, 10, and 15 min. after the termination of the prism-exposure period. For none of the pre- or postexposure measures was *S* allowed visual feedback regarding the accuracy of his performance. Type of exposure—continuous and terminal—was combined with type of practice—massed and distributed—to produce four experimental groups.

Subjects

Sixty-four students from introductory psychology classes at the University of Kansas served as *S*s

in the experiment in order to fulfill a course requirement, All had normal vision without correction and were naive as to the nature of the experiment. They were randomly assigned to four groups, each containing 16 *S*s.

Apparatus and Procedure

Displacement of the visual field was produced by a Risley rotating prism (Bausch and Lomb, No. 71-48-59), mounted in the right eyepiece of a pair of welder's safety goggles. The left eyepiece of the goggles was occluded.

The main testing apparatus was patterned directly after one designed by Uhlarik (1972). The *S* sat in front of a table upon which was placed a horizontal board mounted 43 cm. above the surface of the table. A quarter circle was cut from the board and fitted with transparent Plexiglas. This "exposure slot" could be covered with a section of black posterboard during certain parts of the experiment, to keep *S* from viewing his limb. At the far edge of the exposure slot was a vertical, black pegboard panel, circumscribing an arc whose radius was 57 cm. (centered at *S*'s right eye). The panel extended approximately 11 cm. above and below the horizontal surface. A position transducer (resistance coil), 6 mm. in diameter and 90 cm. long, extended horizontally along the inner surface of the pegboard panel, 6 cm. below the exposure slot. On each of his index fingers *S* wore a rubber finger with a metal probe attached to it. The measure of target-pointing accuracy was taken by requesting *S* to reach forward along the underside of the covered exposure slot and touch the position transducer with the tip of the probe at a point directly beneath the apparent position of the target. The target was a pinpoint of light positioned 2.5 cm. above the surface of the slot. A digital voltmeter, which was located out of *S*'s view, registered the voltage at the point at which the probe made contact with the transducer, thus providing *E* with a measure of *S*'s target-pointing accuracy. The experimental session was divided into three phases: Preexposure, Exposure and Postexposure.

Preexposure Phase. At the outset of the Preexposure Phase an impression of *S*s' teeth was taken to provide the basis for a biteboard used during certain parts of the experiment to stabilize the position of his head. After instructions and several practice target-pointing trials (with visual feedback) the goggles were placed over *S*'s eyes and the variable prism set at 0 diopters (no displacement). Then *S* was required to point directly beneath the light, whose position varied nonsystematically among three different locations—straight ahead, 10 cm. to the left, and 10 cm. to the right. The exposure slot was covered, to preclude visual feedback to *S*. Three responses were made at each of the three target positions with one hand and then this was repeated with the other hand. The order of the target positions was the same for both limbs and for all *S*s. For one half of the *S*s the right hand was tested first and the left hand second; for the remainder the order was reversed. For one half of the *S*s the hand tested first was to be the prism-exposed one; the remainder were tested first with the nonexposed hand. For the measure of felt limb position *S* placed his arm so that it was felt to be located directly in front of his nose. The arm movement was similar to that used for the target-pointing response. Vision was occluded and accuracy was measured four times with each limb, the order of hand tested being the same as for the target-pointing response. The third type of preexposure measure was *S*'s accuracy in setting a pinpoint light source to the straight-ahead position in the otherwise dark room. The *S* pushed a toggle switch (using the hand that would not be exposed to the prism) which caused a dot of light to move laterally at a slow, constant speed (3.57 [illegible]/sec) just above the top of the pegboard panel, at approximately eye level. This light (T1-5 v., run at 1.5 v.) was attached to the end of a rod which projected vertically from a toy car located on an arced track behind the vertical pegboard panel. Four measures were taken, the starting position varying from far right to far left (in a "RLLR" order). The *S* was allowed to reverse the direction of the light if it had gone past apparent straight ahead. A tape recording of white noise was played during this measure in order to mask potential auditory location cues resulting from the sound of the toy car's electric motor. Preexposure target-pointing accuracy was always recorded first. However, measures of felt limb position and visual straight ahead were taken second and third, respectively, for half of the *S*s, and in the reverse order for the other half.

Exposure Phase. During the Exposure [illegible] of the experiment *S* was allowed to see his li[illegible] the exposure slot, which was either co[illegible] partially uncovered, depending upon the experimental condition. A luminous rubber finger was placed over the index finger of the hand to be exposed. The task during this part of the experiment was to reach forward and point to one of three targets—the numbers "1," "2," and "3" constructed of luminous tape and placed at the far edge of the board at points corresponding to the target positions used during the Preexposure Phase. With *S*'s eyes closed, the variable prism was adjusted to 20 diopters, with the base oriented either right or left, producing a lateral visual displacement of approximately 11.3°. The *S* was informed by *E* of the presence and nature of the visual rearrangement. After the room lights had been extinguished, *S* opened his eyes and repeatedly pointed at each of the three luminous numbers as they were called out in a predetermined block-randomized number sequence. The sequence was the same for all *S*s. The luminous rubber finger which *S* wore allowed him to see his target-pointing accuracy. A constant rate of responding was maintained by means of a tape-recorded 2-sec. metronome beat. The *S*'s hand began from a starting position at the near edge of the table and traveled approximately 60 cm. to its destination. Thirty unrecorded prism-exposure responses were made, 10 for each of the three targets.

Th[illegible] instructed to point as accurately as he co[illegible] ot to correct for an error while the po[illegible] ger was in view. It was during the E[illegible] hase that the experimental conditions w[illegible] mented.

[illegible] the Ss were provided with continuous ex- p[illegible] to the limb by completely uncovering the ex[illegible] re slot. The remainder experienced terminal e[illegible], for these Ss the slot was covered except fo[illegible] 3-cm. gap at its perimeter. These two groups w[illegible] further subdivided into massed and distributed [illegible] tice conditions. Massed practice was achieved [illegible] aving S point at a target on every 2-sec. beat [illegible] he tape-recorded metronome for the 30 exposure [illegible] ds, thus providing 1 min. of uninterrupted [illegible] ctice. In the distributed practice condition S [illegible] ponded every 2 sec., and then "rested" for 2 sec., [illegible] a total exposure period of 2 min. (i.e., 1 min. of [illegible] ctice). Thus, as defined by the nature of their [illegible] tivity during the Exposure Phase, there were four [illegible] roups: Continuous-Massed, Continuous-Distrib- [illegible] ted, Terminal-Massed, and Terminal-Distributed.

Postexposure Phase. Immediately after the final prism-exposure trial, the Postexposure Phase began. The S closed his eyes, the exposure slot was covered, the number targets removed, the variable prism reset to 0 diopters, and the luminous finger removed. The S was told that his vision was once again normal.[3] Then no-feedback measures were taken of target-pointing accuracy (three trials for each limb), felt limb position (two trials for each limb), and visual straight ahead (two trials). These three measures constituted the 0-min. Postexposure Test. The order of hand tested was the same as in the Preexposure Phase for a given S, as was the order in which the measures of visual straight ahead and felt limb position occurred. After these initial postexposure measurements had been obtained S was requested to rest quietly in his chair with eyes closed and arms placed at his sides. After 5 min., another set of measures was taken, (the 5-min. Postexposure Test). This procedure was repeated at 10 and 15 postexposure min. Including the time spent in taking the measures, the total length of the Postexposure Phase was approximately 25 min.

[3] The rationale for informing S that his vision was or was not displaced is that in prism exposure involving target pointing, and hence error-corrective feedback, the existence and nature of the visual rearrangement quickly becomes apparent to S. Consequently, it is crucial that he be informed prior to the Postexposure Phase that his vision will once again be normal. Otherwise, his negative aftereffect is likely to be contaminated by the conscious and deliberate correction for errors that he is likely to have used during the Exposure Phase and which he would continue to use if he thought that his vision remained displaced. It is assumed that the aftereffect of prism exposure is, at least with respect to target-pointing, a more valid measure of adaptation in the present experimental situation than is any change in behavior observed to occur during the Exposure Phase.

Results

Three operationally different measures of adaptation were obtained, each defined as the difference between pre- and postexposure performance. A prism-compensatory shift in target-pointing accuracy is commonly referred to as "negative aftereffect" (NA); a shift in felt limb position may be termed "proprioceptive shift" (PS) and a change in visual straight ahead, "visual shift" (VS). For the purposes of the statistical analyses, a pre-post difference in the adaptive direction was given a positive sign while an "antiadaptive" shift was negatively signed. Because magnitude of NA did not differ between the prism base-right and prism base-left conditions, $t\ (62) = .99$, $p > .05$, the data for the two prism orientations were combined for the subsequent analyses. Also, the data were collapsed over hand exposed, order of hand tested, and order of visual and proprioceptive measures. Figure 1 depicts the levels of the three measures of prism adaptation and their decay rates over 15 min. for each of the four experimental groups.

Negative Aftereffect. Clearly, all groups manifested with the exposed limb a mean NA (see Figure 1A), which was significantly greater than zero at the 0-min. Postexposure Test. With respect to the unexposed limb a t test revealed that the adaptive shift at the 0-min. test for all conditions combined was statistically significant, $t\ (63) = 6.19$, $p < .001$, indicating that partial intermanual transfer of adaptation had occurred. A three-factor mixed analysis of variance (Exposure × Practice × Limb) was carried out upon the NA scores at the 0-min. Postexposure Test. The results indicated significant effects for Practice, $F\ (1, 60) = 4.98$, $p < .05$; Limb, $F\ (1, 60) = 100.20$, $p < .001$; and their interaction, $F\ (1, 60) = 5.36$, $p < .025$. It is clear from an examination of Figure 1A that the interaction represented the fact that the difference in NA between massed and distributed practice (in favor of the latter) existed only for the exposed limb.

As a means of testing for the presence of decay of NA in the exposed limb across the four Postexposure Tests, a three-factor

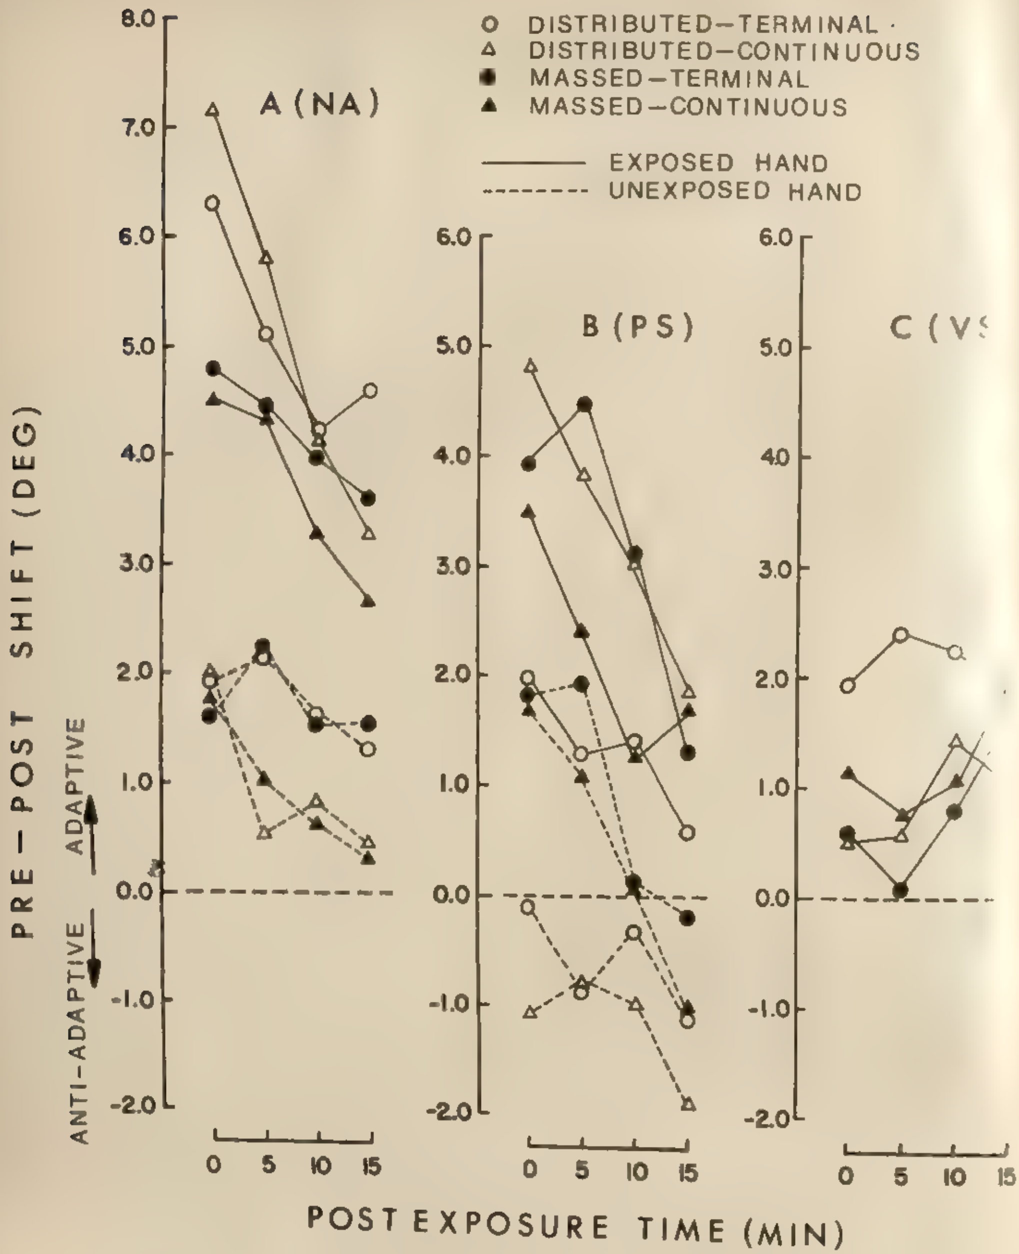

FIGURE 1. Mean Pre-Post Shifts (deg.) at each Postexposure Test. (Abbreviations: NA = Negative Aftereffect, PS = Proprioceptive Shift, VS = Visual Shift.)

mixed analysis of variance (Practice × Exposure × Postexposure Test) was performed on the data. The Postexposure Test effect was clearly significant, F (3, 180) = 20.81, $p < .001$, indicating that a certain amount of decay occurred. The interactions between Practice and Postexposure Test, F (3, 180) = 2.56, $p < .055$, and between Exposure and Postexposure Test, F (3, 180) = 2.59, $p < .055$, were marginally significant. The same analysis carried out on the results for the unexposed limb also revealed a significant F for Postexposure Test, F (3, 180) = 3.58, $p < .025$.

However, none of the remaining factors or interactions was statistically significant.

Proprioceptive Shift. Although it is apparent from inspection of Figure 1B that PS occurred for the exposed limb at the 0-min. Postexposure Test, it is not clear that this was true for the nonexposed limb. In fact, a t test on the PS scores for the nonexposed limb for all groups combined failed to find the mean to be significantly greater than zero, $t\ (63) = 1.15$. However, when each group was tested individually for contralateral PS the means for the terminal-massed and continuous-massed groups each proved to be greater than zero, $t\ (15) = 1.86$, $p < .05$; $t\ (15) = 1.93$, $p < .05$, indicating the presence of intermanual transfer of PS for these groups. A mixed analysis of variance (Exposure × Practice × Limb) on the PS measure for both limbs at the 0-min. Postexposure Test found only the difference between limbs to be statistically significant, $F\ (1,\ 60) = 27.00$, $p < .001$. A Practice × Exposure analysis of variance was carried out upon the PS measures for the nonexposed limb alone and revealed a significant effect for Practice, $F\ (1,\ 60) = 5.71$, $p < .025$ supporting the conclusion that only the massed practice groups experienced intermanual transfer of PS.

An Exposure × Practice × Postexposure Test analysis of variance on PS for the exposed limb revealed that the effect of Postexposure Test was statistically significant, $F\ (3,\ 180) = 8.43$, $p < .001$. This indicates that a decline in ipsilateral PS occurred during the postexposure period. None of the other factors or interactions was significant. The same analysis applied to the results for the nonexposed limb produced similar results—Postexposure Test was the only significant factor, $F\ (3,\ 180) = 3.49$, $p < .025$.

Visual Shift. A t test revealed that mean VS at the 0-min. Postexposure Test for all groups combined was significantly greater than zero, $t\ (63) = 2.60$, $p < .01$. However, individual t tests revealed that only the mean for the terminal-distributed group was statistically significant, $t\ (15) = 2.06$, $p < .05$. A two-factor analysis of variance (Exposure × Practice) on the data for the 0-min. Postexposure Test revealed no significant main effect nor an interaction. When Postexposure Test was added to these factors, in order to examine potential changes of VS over the Postexposure Phase, none of the factors or interactions was significant.

Comparison of Negative Aftereffect, Proprioceptive Shift, and Visual Shift. To examine the effects of practice and exposure on intermanual transfer of NA and PS a four-way mixed analysis of variance (Exposure × Practice × Type of Adaptation × Limb) was carried out on the 0-min. Postexposure Test measures. A significant F was obtained for Type of Adaptation, $F\ (1,\ 60) = 10.44$, $p < .005$. Comparison of Figure 1, A and B, reveals that NA was greater than PS. Limb was another significant factor, $F\ (1,\ 60) = 86.49$, $p < .001$, confirming the results of the analyses reported previously. Also statistically significant were the Practice × Type of Adaptation interaction, $F\ (1,\ 60) = 6.15$, $p < .025$, as well as the Practice × Limb interaction, $F\ (1,\ 60) = 7.02$, $p < .025$. Inspection of Figure 1 indicates that these interactions represented the fact that practice had a differential effect on NA (in favor of distributed practice) for the exposed limb only and on PS (in favor of massed practice) for the nonexposed limb only.

As a means of investigating the possibility that type of practice and type of exposure have differential effects on adaptation as a function of which measure is used, an Exposure × Practice × Type of Adaptation analysis was performed upon VS and ipsilateral PS taken at the 0-min. Postexposure Test. Only Type of Adaptation proved to be statistically significant, $F\ (1,\ 60) = 8.73$, $p < .005$. Examination of Figure 1, B and C, indicates that ipsilateral PS was greater than VS.

In order to examine the relative rates of decay of adaptation for each of the three measures, an analysis (Exposure × Practice × Type of Adaptation × Postexposure Test) was done on VS and the NA and PS measures taken with the exposed limb only. Type of Adaptation, $F\ (2,\ 120) =$

9.66, $p < .001$, Postexposure Test, F (3, 180) = 14.08, $p < .001$, and their interaction, F (6, 360) = 6.28, $p < .001$, all were significant. The interaction appears to be due to the fact that only VS failed to decay over the Postexposure Tests.

Discussion

Contrary to expectation, all four experimental groups demonstrated intermanual transfer of NA. It is possible that the relatively short prism-exposure period (30 trials of target pointing, spread over 1–2 min.) may have been an optimal situation for generating transfer, irrespective of experimental condition. Freedman (1968) reported large intermanual transfer when training was terminated at a preset criterion, while no transfer was observed when *S*s were overtrained. In the present experiment, intermanual transfer of NA was not influenced by type of exposure. This result is contrary to the differential exposure effect on transfer reported by M. M. Cohen (1967). It is not clear whether massed vs. distributed practice affected transfer. Initially, the absence of a main effect for Practice might be viewed as an indication that the type of practice did not affect the intermanual transfer of NA. However, intermanual transfer is traditionally evaluated in terms of the proportion of adaptation in the unexposed limb to that in the exposed limb. Defining transfer in this manner leads to an alternative interpretation; that is, different types of practice do indeed lead to different amounts of transfer. The significant Practice × Limb interaction of NA measured at the 0-min. Postexposure Test indicates that massed practice produced more transfer than distributed practice, and thus supports the second conclusion. At present, it is difficult to determine which of these interpretations is the most tenable. To clear up this problem an additional study is needed which would control the level of adaptation in the exposed limb. Thus, for instance, if a similar Practice × Limb interaction emerged under these conditions, it would support the second conclusion.

Intermanual transfer of PS occurred only for the two massed practice groups. A transfer of modified proprioception from exposed to nonexposed limb has never previously been reported and it is not at all apparent how this might occur. Another finding difficult to interpret is that in the two distributed groups the PS measure for the nonexposed hand showed the change in the antiadapti[illegible] direction. Perhaps the task of pointing [illegible]aight ahead of the nose in the dark is gove[illegible]d not only by felt limb position but also by a [illegible]ponse tendency to point at an imagined [illegible]ight-ahead position. It could be argued [illegible]ther that both proprioception and this [illegible]nse tendency are altered by prism expos[illegible] but that only the latter component (or a [illegible]tion of it) transfers to the contralater[illegible]mb. Aside from the validity of this explan[illegible] it remains of interest that only the [illegible]sed practice groups demonstrated transfe[illegible] PS. Furthermore, regardless of the basis [illegible] this form of transfer, its existence sugge[illegible]hat the intermanual transfer of NA m[illegible] not always be the result of a change in v[illegible]n, as some investigators (e.g., M. M. Cohen, [illegible]967; Kalil & Freedman, 1966; Wilkinso[illegible]71) have apparently assumed.

Both NA and PS revealed a signifi[illegible] decline across the four Postexposure T[illegible] for both limbs. A review of previous lite[illegible]re led to the prediction that NA (for ex[illegible]ed limb) resulting from continuous [illegible]re would decay more rapidly than that [illegible]d by terminal exposure. Such an Exp[illegible] Postexposure Test interaction was fou[illegible]n the present study, although the signifi[illegible]nce level was marginal ($p < .055$). One ex[illegible]nation for this tentative finding is that term[illegible]al prism exposure leads to a relativ[illegible]ge change in vision (cf. Uhlarik & Cano[illegible]) and that a prism-adaptive change i[illegible] visi[illegible] decays less rapidly than does propri[illegible] adaptation. Partial support for this [illegible]pretation is seen in the finding that VS fa[illegible]d to decay during the Postexposure Phase. In fact, there was a nonsignificant *increase* in VS for three of the four groups. The fact t[illegible]t VS appears to be more resistant to decay than PS may be related to the results of a study by Hay and Pick (1966) who found that ove[illegible] 6-day prism exposure period visual adaptation ultimately replaced the relatively transient initial change in felt limb position.

The results of the present investigation help to define the optimal conditions for inducing the various end products of prism adaptation. As already indicated, distributed prism exposure (whether terminal or continuous) led to significantly greater NA than did massed practice, a finding previously reported by Taub and Goldberg (in press) with continuous exposure, but not found by Dewar (1970), who used terminal exposure. It is possible that Dewar's use of the "prism shaping"

techn... of Howard (1968) led to such a lar... ount of adaptation for both groups tha... ffects of the practice variable were "ov... elmed." Examination of Figure 1B rev... an unclear picture regarding the op... al condition for eliciting PS. None of the ...actors or interactions for PS in the ex-p... d limb at the 0-min. Postexposure Test ...ed statistically significant. With respect ...S the most effective condition at the 0-min. ...texposure Test was distributed practice-...minal exposure. The finding by Uhlarik ...l Canon (1971) that terminal exposure ...duces primarily VS and continuous exposure ...marily PS was not supported by the present ...ata when the practice variable was collapsed. ...n the other hand, Figure 1, B and C, suggests ...he existence of this predicted Exposure × ...ype of Adaptation interaction, provided that only the distributed practice groups are examined. It should also be noted that in the study by Uhlarik and Canon (1971) the obtained interaction held only for the "direct" measures (i.e., those taken with the prism displacement present); no interaction was found for the aftereffect measures which, of course, were the only kind taken in the present experiment.

With the present data it is possible to examine the "additive model" of prism adaptation presented by several investigators (e.g., Wilkinson, 1971), which holds that NA = VS + PS. When adaptation as manifested at the 0-min. Postexposure Test was examined for all groups combined, PS + VS = 4.57, while NA = 5.64. This difference of 1.07 proved to be significantly greater than zero, t (63) = 1.74, $p < .05$. While it is possible that the finding of NA > PS + VS in this experiment was due to the fact that NA was measured before PS and VS and, therefore, was perhaps less affected by spontaneous decay, this seems an unlikely event, given that only three measures of NA for each hand (a total period of approximately 45 sec.) were taken prior to the measures of PS or VS. Furthermore, an interesting observation is made when this additive model is tested for each group separately. For the massed practice groups the model held quite well—the difference between NA (4.60) and PS + VS (4.55) was not significantly greater than zero, t (31) = .10, $p > .05$. On the other hand, the model failed to predict the results for the distributed practice groups, in that the difference between NA (6.68) and PS + VS (4.58) was different from zero, t (31) = 2.76, $p < .003$. The tentative conclusion is that distributed prism exposure leads to a third component of prism adaptation, which adds to PS and VS in determining the magnitude of NA. The precise nature of this postulated component remains to be clarified.

[illegible]TRIEVAL OF WORDS FROM WELL-LEARNED SETS: THE EFFECT OF CATEGORY SIZE [1]

[illegible]ONATHAN L. FREEDMAN [2]
Columbia University

ELIZABETH F. LOFTUS
University of Washington

In four experiments, *Ss* learned categories of varying size and were then required to produce a member of one of the categories that began with a particular letter. There was only one word in the category that began with the letter. Reaction times increased as a function of size with small categories (less than 7 words) but at some point levelled off, with no additional increase even with categories as large as 32. These findings suggest that two processes are involved in retrieval—a successive scanning mechanism being used with categories small enough to be held in immediate memory (i.e., about 7) and a different mechanism (probably involving little or no successive scanning) operating for larger sets.

How is information retrieved from long-term memory? Although it is too early to give a detailed answer to this question, some recent work does appear to have eliminated some of the logical possibilities. In particular, there is now substantial evidence that the normal process of information retrieval involves little or no successive scanning of items in the memory store. This conclusion is based on a series [illegible] studies which showed that the amount [illegible] time taken to retrieve a word from a large category was either equal to or only slightly greater than the time taken to retrieve a word from a small category. Landauer and Freedman (1968) used a series of nested categories in which each was a subset of the larger one, thus guaranteeing without an actual count that the categories could be ranked according to size (e.g., living thing, animal, bird). They [illegible]und that it took longer to decide that an item was not a member of a large category than to decide that it was not a member of a small category, but there was no appreciable difference in decision times for positive instances. Collins and Quillian (1969), Meyer (1970), and Landauer and Meyer (1972) using somewhat different procedures report that identification took somewhat longer for larger categories. In contrast Neisser (1964) compared identification time for "animals" and "first names" and found no difference in latency. Although most of these studies did find a small difference favoring the small categories, the magnitude of the difference is very small relative to the size of the categories involved. For example, Landauer and Freedman report that the correct identification time with negative instances was 53 msec. longer for large than for small categories. Given the relative size of the sets to be searched, in order for such a small difference to be caused by the additional time it takes to scan the larger categories, successive scanning would have to be enormously rapid, on the order of a thousand words per second, which seems improbable.

More recently Freedman and Loftus (1971) departed from the previous work that had studied identification time and instead measured the speed with which *S* could actually produce a word himself. Instead of giving *S* a stimulus and asking him to decide whether it was a member of a category, he was given a category and asked to produce a word that belonged in it. Several studies by these authors found that the speed of producing a word was independent of the size of the category to which the word belonged. (Freedman & Loftus, 1971; Loftus, Freedman, & Loftus, 1970).

Although the results of this previous work are fairly convincing, the use of already existing or natural categories presents certain difficulties. Any existing category is already large or small—it cannot be both. Thus, the size of a category is necessarily confounded with the specific category itself. Accordingly, the effects obtained in these studies could be due to certain characteristics of the specific categories used or to the hierarchical system that exists in the language. Despite the fact that some of these studies have used a large number of different categories and found quite consistent results, it is possible that within the language there are certain characteristics common to all large categories that differentiate them from smaller ones. For example, large categories tend to be higher up in any hierarchical structure since naturally as one goes up the hierarchy a category tends to be more inclusive and therefore have more members. Thus, the lack of effect due to category size could conceivably be due to other factors that tend to be correlated with the size of the category and which for one reason or another facilitate retrieval from large categories.

A number of authors (e.g., Juola, Fischler, Wood, & Atkinson, 1971; Tzeng, 1972) have reported studies in which *S*s learned one or two sets, and were then shown a word and asked if it belonged to the set they had learned. As with other studies of identification time, this work generally found small but significant effects of set size. It does appear, however, that in this research the lists, while learned to criterion, were not learned to the point that the *S*s knew them well. In the Juola et al. study *S*s were given the list 24 hr. before the experimental session and were asked to study it until one successful complete recall could be made. In Tzeng's study, there was a short training session. Thus, although *S*s could recall all of the items on the list, it would be difficult to argue that they had learned them to any great extent.

The level to which *S*s had learned the categories is critical. One can see this, for example, by examining more closely Juola et al.'s two-stage model of recognition. Their first stage involves contact between input and long-term memory necessary to assign a recognition strength to the input. If the item is highly familiar, the *S* is assumed to be able to output a fast response, without checking the item against the memorized list. More specifically, the response to a highly familiar item is assumed to be rapid, error prone, and independent of the number of items in the memorized list. If the presented item is only moderately familiar, however, the *S* is presumed to check the memorized list before responding, and the time to search will be a function of the number of items in that list. The above reasoning appears to be an admission that many of the items were not learned very well. Since we are investigating the difference between short- and long-term memory, and since amount of learning is one element in that difference, it is not clear how useful these results are for our purposes. In any case, it seemed desirable to conduct a study in which *S*s were given extensive training on newly constructed categories and production (as opposed to identification) from these categories was investigated. This paper reports four such experiments.

Experiments I and II

Method

Materials. For Experiment I, 50 words were selected from different categories in the Battig and Montague (1969) norms. Twenty of these words were divided evenly among four lists, so that the 5 words in a list began with each of the letters C, M, P, S, and T. The remaining 30 words (with different initial letters) were randomly assigned as fillers to each list so as to create lists of length: 5 (no fillers added), 10, 15, and 20 words.

For the first *S*, the 50 words were typed on a sheet of paper in such a way that the 5-word list was designated List 1, the 10-word list designated List 2, etc. The next *S* studied lists created by rotating the 30 filler words, so that his List 1 had the same 5 target words as the first *S*'s, but had the 15 filler words which were previously on List 4. Thus, for *S* 2, List 1 had 20, List 2 had 5, List 3, 10 and List 4, 15 words. This process was continued for the next two *S*s so that for each set of four *S*s, each group of 5 target words was in a total list of either 5, 10, 15, or 20 words. For each set of four *S*s, 20 new key words with different initial letters were selected. In all, five such sets of lists were created resulting in a total of 20 unique lists.

The lists for Experiment II were constructed in an identical manner to the lists for Experiment I

with the exception that all words in a particular list came from the same category. The categories were: animal, boy's name, girl's name, or country. Each *S* studied one list from each of these categories. So, for example, for *S* 1, List 1 consisted of five key animals, List 2 of 10 girl's names (5 of them key names), List 3 of 15 boy's names and List 4 of 20 countries.

Subjects. Undergraduates at the Columbia Summer School were paid $6 for 3 1-hour sessions and were promised a bonus if they performed well. In Experiment I, 20 *S*s participated of which only 18 completed the experiment. In Experiment II, 16 *S*s completed all sessions. A $2 bonus was paid to all *S*s who completed the experiment.

Procedure. At the first session the *S*s were told that they would be given four lists of words and that their task was to learn them extremely well. They were supposed to learn what words were in each list and also be able to tell what list a particular word was in. The instructions said, "you should learn these words so that they are almost like second nature." During the first session the *S*s were handed a sheet containing the four lists and given 10 min. to study it. They then were given 5 min. to write down as many of the words as they could remember in the appropriate lists. Next, they were shown cards containing a word followed by the number of its list or the opposite order (e.g., camel—1, 1—camel). The *S*s looked at these cards and said aloud both halves. Each word in the list was presented twice in this manner, once with the word first and once with the number of the list first, a different random order being used for each *S*. Finally, the *S*s once again tried to write down as many words as they could remember in each list. At the end of the session they were given a list and told to study it hard, to practice, and an appointment was made for the next session.

The second session began with a recall task in which the *S* tried to write down as many items in each group as he could remember. (Any *S* who could not recall every item was told to go home, restudy, and a new appointment for the second session was made.) If the *S* recalled perfectly, he then received a number of training tasks in which each of his words was presented to him an equal number of times. In the first task, *E* read each of the words aloud, the *S* telling what group it was in and making up a sentence containing the word. If the *S* gave the wrong group, *E* corrected him. In the next task, *E* read the words aloud again in a different random order and the *S* was required to give another word in the same group. He was told to try to give a different word each time but to respond quickly. Whenever he made an error he was so informed. Finally the recall task was repeated, the *S*s were encouraged to study hard and a third appointment was made approximately two weeks hence. The first two sessions were for purposes of training; the third session produced the essential data. Stimuli were presented on a machine similar to that used in previous studies (cf. Freedman & Loftus, 1971). It consisted of a half-silvered mirror behind which a card was placed. When a light went on behind the mirror the *S* could read what was printed on the card. The left side of the cards could be illuminated at a predetermined interval before the right side. As soon as the right side was lit a timer started which was stopped by the *S* speaking into a unidirectional microphone. In this experiment the *S*s were shown the number of a category to the left and then after a pause of .5 sec. (automatically timed) the right side was lit revealing a single letter. The *S*'s task was to say aloud a member of the indicated category that began with that letter. Subjects were instructed to respond as quickly as possible but to be certain not to make mistakes: "speed is essential but so is accuracy." They were given the following example—"you might see the category 'trees' and the letter 'o' and you should say 'oak' as fast as you can." Subjects were given three practice trials and after each one were asked if they fully understood the instructions. If during these trials they made any errors, they were once again told that they should respond quickly but not make errors. The critical trials consisted of a random presentation of the 20 possible combinations of the four categories and the five critical letters. Thus for each category the *S* gave five responses, one beginning with each of the five selected letters. The *E* did not inform *S*s whether they were correct. If the *S* did not respond within 10 sec., the trial was terminated and the next trial started.

TABLE 1

Reaction Times as a Function of Category Size for Experiments I and II

Experiment	Category size 5	10	15	20
I	1.88	3.98	6.25	5.17
II	1.13	1.94	2.37	1.93

Results

In both experiments all of the *S*s learned the lists well enough to produce the total list without errors during Session 2 and to respond correctly to virtually all of the test trials in Session 2. In addition, on the test trials of Session 3, there were fewer than 4% errors in Experiment I and fewer than 2% in Experiment II. On the other hand, there were a considerable number of trials on which the *S*s gave no response within the 10 sec. allowed. For the 5, 10, 15, and 20 item categories, failures to respond were 4, 12, 29, and 28% respectively for Experiment I, and 2, 2, 12, and 9% for Experiment II. Table 1 presents the mean

reaction times for both experiments as a function of the size of the category. These means are based on median times for each *S* for each category, with the error and no response trials excluded.

The results for both experiments are quite similar. Reaction times are faster for categories of 5 than for larger categories and for Size 10 than for 15, but are actually slower for 15 than they are for Size 20. Using the Newman-Keuls procedure (Kirk, 1969) for simultaneous testing of pairwise comparisons, only the following differences are significant in Experiment I: (*a*) Size 5 is different from all other category sizes, $p < .05$. (*b*) Size 10 and 15 differed, $p < .05$. For Experiment II, size 5 is different from all other category sizes, $p < .05$, while no other differences are significant.

Clearly responses to the smallest category are faster than to any of the others while categories of sizes 10, 15 and 20 do not produce consistent differences in reaction times. If anything, the largest category is somewhat faster than the next largest. This is not a significant effect, but is the opposite of what would be expected from a scanning model. Beyond size 10 there is no evidence that larger categories take longer.

Before discussing the significance of these findings in more detail, it seemed advisable to replicate this study once more. The possibility existed that the results obtained were for some reason dependent on the specific list sizes employed and it therefore seemed advisable to investigate the effects of different size categories. In addition, we wanted to include at least two categories of sufficiently small size so that they would ordinarily be considered to fall within the scope of short-term or immediate memory since it occurred to us that perhaps two different processes were involved in the production of members from the smaller as compared to the larger categories. Accordingly, Experiment III was conducted using lists of size 3, 6, 12, and 24.

Experiment III

Method

Subjects. Twenty-eight *S*s were recruited from a local newspaper advertisement. Most were undergraduates from nearby colleges. They were paid $5 for three sessions and were promised a bonus of $3 if they performed well.

Materials. A set of 12 target words and a se[t of] 33 filler words were selected from the list of nouns provided by Paivio, Yuille, and Madi[gan] (1968) on the basis of three criteria: (*a*) the wo[rds] were four to eight letters in length; (*b*) the tar[get] words began with each of the letters F, S, and [M;] (*c*) none of the filler words began with the let[ters] F, S or M. Lists of length 3 (no filler words add[ed]) 6, 12, and 24 were then constructed accordin[g to] the procedures used for list construction in Exp[eri]ment I.

Procedure. The first session was identical to [that] of Experiment I. After the session *S*s were gi[ven] the lists to take home and study, and an appoi[nt]ment was made for the next session approximate[ly] 1 wk. hence.

The second session began with a recall task [in] which the *S* tried to write down as many items [from] each group as he could remember. Any *S* who d[id] not perform perfectly was sent home and his secon[d] session was rescheduled. During the second sessi[on] a series of 90 stimuli was presented on the machin[e] used in Experiment I. The stimuli consisted of th[e] number of a list (category) and a word. There was an interval of .5 sec. between the category number and word. Subjects were supposed to say "yes" when the word was a member of the category and "no" otherwise. They were asked to respond [as] quickly as possible but to make no errors. Of [the] 90 total trials, half were positive and half w[ere] negative because each word on *S*'s list was paire[d] once with a correct list number and once with an incorrect one. Finally, the recall task was repeated, the *S*s were encouraged to study hard, and a third appointment was made approximately 1 wk. hence.

During the third session, stimuli were pres[ented] on the machine and the *S*s' reaction time for nam[in]g a member of a list beginning with a given lette[r] was measured. The critical trials consisted of a ra[ndom] presentation of the 12 possible combinations of [the] four categories and the three critical letters. T[hus] for each category, the *S* gave 3 responses, o[ne] beginning with each of the 3 selected letters. Reac[]tion times were recorded for all *S*s. The *E* did not inform the *S* whether he was correct.

Results

There were fewer than 4% errors. The percentages of response failures were 2, 8, 20, and 18 for the 3, 6, 12, and 24 item lists, respectively. The mean reaction times for correct responses for production of a list member are presented in Table 2. Using the Newman-Keuls procedure revealed that responses to items in categories of size 3 are significantly faster than responses in all other categories, $p < .05$. No other differences are significant. This

finding parallels that of the first two experiments. With small categories, the larger the set, the slower the reaction times; but at some point, a further increase in size does not produce longer latencies, and there is even a decrease in time for the largest category.

Although the results of these three studies were quite consistent, it was decided to collect data on a wider range of category sizes. Accordingly, Experiment IV involved 6 categories ranging from 4 to 12.

Experiment IV

Method

Subjects. Thirty-six *S*s, mostly college students, were recruited from a local newspaper advertisement. They were paid \$3.50 for 3 sessions, and were promised a bonus of \$3.50 if they performed well.

Materials. A set of 24 target words and a set of 58 filler words were selected from the Paivio, Yuille, and Madigan (1968) nouns on the basis of three criteria: (*a*) the words were from 4 to 8 letters in length; (*b*) the target words began with one of the letters B, F, L, and R and (*c*) none of the filler words began with the letters B, F, L, and R. The 24 target words were divided into 6 sets such that each set had 4 words, each beginning with a different letter. Lists of length 4, 5, 7, 12, 22, and 32 were created using the procedure described in Experiment I. A given *S* received four lists, two short lists and two long lists. Thus, the first *S* received the 4, 5, 12 and 22 word lists, typed on a sheet of paper in such a way that the 4 word list was designated List 1, the 5 word list was designated List 2, and so on. The lists for the next 3 *S*s were created as in previous experiments. For the next group of 4 *S*s, the same process was repeated using the original lists of 4, 5, 12 and 32 words. In all, 36 unique sheets of paper were created, each containing 4 typed lists.

Procedure. Upon arriving at the experimental lab, *S* was told that he would be given four lists of words and that his job was to learn them extremely well. He was given a sheet containing the four lists, told to study it every day and an appointment was made approximately four days hence.

The second session began with a recall task in which *S* tried to write down as many items in each category as he could remember. If he missed more than one word, he was required to go home, relearn the list, and return on a different day. Next *S* was given the standard identification task, using the machine described in Experiment I. He was shown cards containing a word and a list number (e.g., camel—1, 2—shirt) and he responded "yes" into the microphone when the word was a member of the category and "no" when it was not. Negative trials were created by pairing words on the list with incorrect category numbers. The *S* saw an equal number of positive and negative trials, with the word to be categorized printed before the list number on half the trials, and after it on the remaining half.

The third session occurred approximately 2 days later. First *S* was asked to write down as many items from each category as he could remember. Again, if he missed more than one word, his third session was rescheduled. Next, *S* was given the "item-production" task; stimuli were presented on the same machine using the same procedure described previously. In all, a random presentation of the 16 possible combinations of the 4 categories and the 4 key letters was presented to *S*. Thus, for each category, *S* gave 4 responses, one beginning with each of the 4 key letters.

TABLE 2

Reaction Times as a Function of Category Size for Experiments III and IV

Experiment	Category size								
	3	4	5	6	7	12	22	24	32
III	1.44			2.69		3.35		2.91	
IV		2.63	2.71		3.59	3.29	3.95		3.30

Results

There were fewer than 5% errors. The percentages of response failures were 4, 5, 4, 8, 11, and 13 for the 4, 5, 7, 12, 22, and 32 item categories, respectively. The mean reaction times for correct responses for the six category sizes are presented in Table 2. Once again there is an increase in RT's as category size increases from 4 to 5 and from 5 to 7; but at that point no further increase occurs, with 12 and 32 actually being somewhat faster than 7. Using the Newman-Keuls procedure, size 4 and 5 are different from all other category sizes, $p < .05$, but not from each other; no other differences were significant.

General Discussion

At first glance, the present results may appear to be at odds with those reported by Juola et al. (1971). Subjects in their experiment memorized a list of either 10, 18, or 26 words, and then were tested for recognition of those words. The recognition test consisted of presenting a series of single words to *S*, and for each word *S* made a positive or nega-

tive response to indicate whether or not the word was a member of the learned list. Response latency was found to increase as list size increased. However, the Juola et al. paradigm is different from the present one in several major respects. Their *S*s learned a single list of words; ours were tested with a production test. Their *S* could respond on the basis of a subjective judgment of the familiarity of the test item (and this is precisely what Juola et al. claim their *S*s do); while our *S*s could not.

The four experiments reported here have produced consistent results—with small categories, the larger the set, the slower the reaction time; at some point, this effect ceases, and additional increases in set size do not affect latencies. Although the failures to respond increased only slightly with category size for the large categories, one might claim that the stable latencies for correct responses are simply an item selection artifact. The argument is that as category size increases, the strength of any given item in the category progressively decreases, until eventually the item's strength does not allow it to be recalled within the 10 sec. limit. Thus, although the average strength of all items decreases with category size, the weakest items move from being recallable within 10 sec. to being response omissions. This would leave the mean correct-response latency unaffected by category size. However, such an item selection notion would also predict that the entire frequency distribution of correct response latencies would progressively shift in a positive direction as category size increases, and this result did not occur.

A more reasonable interpretation of these results is that two different retrieval processes are involved when items are retrieved from small versus large categories. The smaller categories are within the capacity of short-term memory. The individual is able to keep as many as seven items in his immediate memory store. When he is given the category name and then asked to produce an item beginning with a particular letter, he may put the full category in his immediate store, scan it, and find the appropriate item. This would, of course, produce a category size effect, with larger sets taking longer (Sternberg, 1966). However, once the category is too large for the immediate store, this process is no longer feasible. Instead *S* must rely on a mechanism for retrieving information from long-term memory, and as previous research has indicated, this does not involve a successive search is accordingly not affected by the size o set.

This implies that a process equivalen to that involved in short-term memory ma be activated. The critical element, accordi to our notion, is the size of the set to be sear d. If it is small enough to be held in short- rm memory, it will be; and the search proce ill be the familiar successive scan. If the is too large for the short-term store, a diff nt process will be employed, one involving le or no successive scanning. We would ad at if the normal process for searching long- m memory should fail (i.e., *S* does not find e desired item), it seems plausible that *S* w d again resort to successive scanning and the size of the set would once more be That is, very difficult items from lon memory might force *S* to use some successive processing. Thus, we would pothesize three distinct mechanisms o trieval: (*a*) successive scanning for small s (*b*) nonsuccessive scanning for larger sets long as the items to be found are reas easy or for whatever reason the search cessful within a reasonable period; (*c*) siderably slower and tedious successive for large sets when necessary.

The notion of dual strategies is not n with us; evidence has been found by oth investigators, in different situations. For ample, in an experiment by Mandler and Dea (1969), *S*s were shown a list one word at time. As each additional list item was pr sented, *S* had to recall all of the words pr sented up to that time. With each successi input item, the *S*'s organization of the changed; with categorized lists, in particula these changes were quite dramatic. For th first few trials, an *S* usually began recallin items in the order they were presented. Afte roughly five items had been presented, *S* typically began to organize the items into category clusters rather than recall them in their input order. The typical strategy, then, appears to be as follows: *S*s begin by recalling the specific items on the list in STM; when STM capacity is exceeded, they reorganize the STM information. Rumelhart, Lindsay, and Norman (1972) have incorporated these two strategies into a successful simulation of list learning under these conditions.

STIMULUS AND RESPONSE FREQUENCY AND SEQUENTIAL EFFECTS IN MEMORY SCANNING REACTION TIMES [1]

JOHN THEIOS [2] AND DENNIS G. WALTER

University of Wisconsin—Madison

Target set size, stimulus frequency, and response–stimulus interval were varied in a design first used by Sternberg. Significant effects on RT were found due to stimulus frequency, stimulus sequence, response frequency, response sequence, and the interaction between stimulus frequency and target set size. Response–stimulus interval affected only the RT intercept. The data are difficult to account for assuming a serial exhaustive memory scanning process, but can easily be accounted for using a self-terminating scanning process.

Theios, Smith, Haviland, Traupmann, and Moy (1973) have demonstrated large stimulus presentation frequency effects on reaction time (RT) in a Sternberg (1967) type fixed-set memory scanning task. Mean RT to both positive and negative stimuli increased approximately 85 msec. as stimulus presentation probability was decreased from .30 to .05. Theios et al. interpreted these results as supporting a serial self-terminating memory scanning process such as the model proposed by Theios (1973a, 1973b). It is assumed that memory representations of both target and nontarget stimuli are organized probabilistically, trial-by-trial into a limited capacity, push-down memory stack on the basis of stimulus occurrence. More frequent stimuli (both target and nontarget) result in relatively fast RTs since they are more likely to have occurred recently and have their S–R memory pairs located relatively early in the serial scan. Reaction time to infrequent stimuli will be relatively slow since their S–R memory pairs will be located relatively late in the serial scan.

In addition, the Theios (1973b) self-terminating memory model predicts that there should be both stimulus and response sequential effects in memory scanning RTs similar to those found by Bertelson (1965), Rabbitt (1968), Remington (1969), and Smith, Chase, and Smith (1973) in choice RT. Reaction time to a stimulus in a memory scanning task should decrease as a function of recency and frequency of either stimulus or response occurrence in any random sequence of trials. A response frequency as well as a stimulus frequency effect on RT follows directly from the sequential properties of the process.

Finally, the Theios (1973b) model predicts an interaction in RT between stimulus frequency and target set size, since both these variables are assumed to affect the memory scanning process.

The exhaustive scanning process suggested by Sternberg (1966, 1967) can account for response frequency and response sequential effects by a response process such as Sternberg's (1969) binary decision or response translation stages. However, the exhaustive scanning model does not have any explicit mechanism to account for stimulus frequency or stimulus sequential effects in RT. The exhaustive scanning model might possibly account for stimulus frequency and sequential effects by assuming that stimulus recency affects the stimu-

[1] This report is based upon a research thesis directed by the first author and conducted by the second author in partial fulfillment of the requirements for the degree of Master of Science.

The research was supported in part by U. S. Public Health Service Grant MH-19006 from the National Institute of Mental Health. The second author was supported by a University of Wisconsin Fellowship. Use of the Madison Academic Computing Center was made possible in part through grants from the Wisconsin Alumni Research Foundation and the National Science Foundation.

We would like to express our gratitude to Melvyn C. Moy and Peter G. Smith for assistance in computer programming and data analysis.

lus encoding process such that more frequent and recent stimuli are encoded faster than less frequent and less recent stimuli. This would predict stimulus frequency effects on RT to target and nontarget stimuli, stimulus sequential effects, and *no* interaction between stimulus frequency and target set size. This follows since stimulus frequency would affect the encoding process and target set size would affect the memory scanning process, and the effects of the two variables would add rather than interact (cf. Sternberg, 1969).

The present experiment and analyses were conducted to provide further evidence on the question of whether memory scanning is self-terminating or exhaustive. A critical question is whether there will (self-terminating prediction) or will not (exhaustive prediction) be an interaction in RT between stimulus frequency and target set size. The design of the experiment was effectively a replication on our equipment of the essentials of the Sternberg (1967) intact stimulus condition. In addition, however, we analyzed the RT data for stimulus and response probability effects and sequential effects and for an interaction involving stimulus probability and target set size.

Method

Subjects. The *Ss* were 48 University of Wisconsin undergraduates (30 females and 18 males) who participated in order to fulfill an introductory psychology course requirement. It was required that all *Ss* be right-handed.

Apparatus. The apparatus was the same as that described by Theios et al. (1973). The stimuli were the set of digits 0 through 9 presented on an Industrial Electronic Engineers, Inc., Series 10 rear-projection visual readout unit. The *S* sat in an arm chair with a response button mounted in each arm beneath the index finger. A Digital Equipment Corporation PDP-8 computer was programmed to select at random the stimulus for each trial with the probability for the selection of any particular stimulus on a given trial preset by *E*. The computer also measured the RT and timed the response–stimulus interval.

Design. The 48 *Ss* were divided into two groups of 24 each. One of the groups was instructed to press the right-hand button whenever a positive set stimulus occurred and the left-hand button otherwise. The other group pressed the left button on positive trials and the right one on negative trials.

The 10 stimuli were partitioned into positive and negative sets in the same manner as in the Sternberg (1967) study. For a given *S*, 1 digit was presented on approximately 4/15 of the trials, 2 others were presented on approximately 2/15 of the trials each, and the remaining 7 each occurred on approximately 1/15 of the trials. Each *S* was run through four conditions with positive memory set size (M) equal to one, two, three, or four. Each of the 10 digits was assigned to the positive set for one condition and to the negative set for the three others. For M = 1, 2, and 4 the stimuli were assigned to the positive set so that the probability of a positive response occurring was 4/15. The M = 3 condition was always presented first, as a practice condition, and here the probability of a positive response was 3/15 (the digits assigned to the positive set in this condition were the three 1/15 probability digits not used in the M = 4 positive set). Only data from the conditions where M = 1, 2, or 4 were analyzed. Each of the six possible orders of presentation of the M = 1, 2, or 4 conditions was assigned to four *Ss* within each group. Two blocks of trials were run for each condition, with 108 trials in each block. For one block, the time between *S*'s response to one stimulus and the onset of the next stimulus (the response–stimulus interval or RSI) was .5 sec. For the other block, the RSI was 2 sec. Each of the two presentation orders of these blocks was assigned to two members of the four-subject subgroups. The actual assignment of particular digits to the positive set in each condition followed the example of Sternberg (1967).

Procedure. The instructions urged *S* to respond as fast as possible without making errors. The number of permissible errors was never made explicit. The *S* was told that if he made too many errors in any one block of trials, he would be given additional blocks of trials until his error rate was acceptably low. Actually, the largest number of errors permitted in a block of 108 trials was nine. The *S* was then told the numbers in the positive set. After a block of trials *S* was allowed to relax while the error data was being typed out on the teletype. If the number of errors was within the permissible limit, the next block of trials, with the same positive set but with the other level of RSI, was begun. If the number of errors was too large, the trial block was repeated. This procedure was continued, alternating short and long RSI, through all four memory set size conditions until all eight different trial blocks were run.

Results and Discussion

The overall error proportion was less than .03, and trials on which errors occurred were not included in the following analyses. The effect of the between-subjects variable (dominant vs. nondominant hand on positive set) was examined by an analysis of variance along with several of

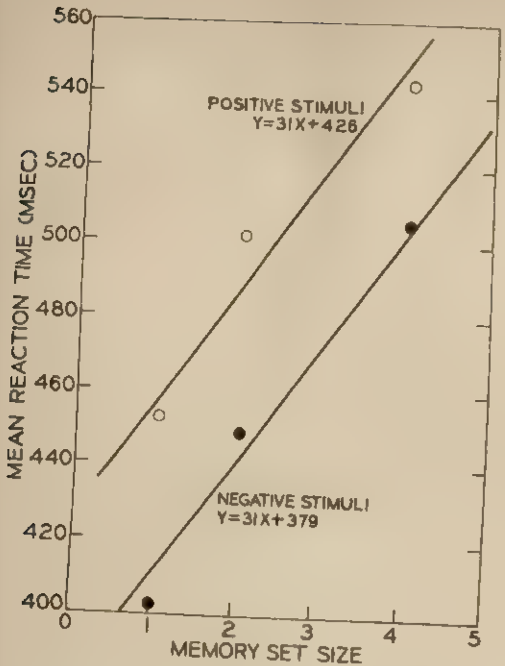

FIGURE 1. Mean reaction time for positive (target) and negative (nontarget) stimuli as a function of memory set size with the best-fitting pair of parallel linear functions.

the other variables. This variable was found to be nonsignificant ($F < 1.00$), and in all further analyses all *S*s were treated as one group.

Figure 1 shows the increase in mean RT over memory set size for positive and for negative trials plotted against the best-fitting pair of parallel straight lines. Separate analyses of variance were performed for the positive and negative data to determine whether the null hypothesis of linearity could be rejected for either. It was found that both the positive and negative data points differed significantly from their respective best-fitting straight lines. For positive data points, $F(1, 94) = 12.88$, $p < .001$, and for negative data points, $F(1, 94) = 6.08$, $p < .05$. However, it was possible to account for 97% of the variance among the six means by the hypothesis of parallel linear functions. The data are of the same general form as Sternberg's (1967) data, and the present study used four times as many *S*s as Sternberg's, meaning that for the present study there is a great deal more power for the analysis of va[r]iance test of the linearity hypothesis.

Stimulus Frequency Effects

An important test of the theore[tic]al models is whether or not stimulus pre[sen]tation probability effects can be found [be]tween items for a given memory set [size]. Figure 2 shows the mean RT for nega[tive] items at each of the levels of probabi[lit]y for each target set size. Note that R[T] is higher for low probability items under e[ach] set size condition. Two analyses of [vari]ance were performed on the data re[pre]sented graphically in Figure 2, the firs[t on] mean RT for negative items with pr[oba]bility 1/15 and 2/15 and with 4 and 1 it[ems] in the positive set and the second on m[ean] RT for negative items with probabil[ity] 4/15 and 1/15 and set size 2 and 4. T[he] pattern of significant effects was the sam[e] for both analyses. With 1 and 47 degree[s] of freedom in each comparison, there were significant main effects due to target set size, $F = 234.28$ and $F = 70.94$, $ps < .001$ for the first and second analysis, respectively, stimulus probability, $F = 8.29$, $p < .01$ and $F = 27.26$, $p < .001$, response stimulus interval $F = 28.24$ and $F = 39.09$, $ps < .001$, along with only one significant interaction, that involving set size and probability, $F = 5.22$, $p < .05$ and F [=] 8.24, $p < .01$.

The finding of a probability effect among the negative items could not be predicted on the basis of an exhaustive scan of the positive set as proposed by Sternberg (1967). However, the finding is consistent with a model in which both positive and negative items are represented in memory and mean RT is inversely related to stimulus frequency and recency (Theios et al., 1973). On the other hand, the possibility must be considered that the probability effect does not reflect the nature of the serial comparison stage, but rather one of Sternberg's (1969) other processing stages, presumably the encoding stage. However, the observed interaction between stimulus probability and target set size leads to the conclusion, on the basis of the Sternberg analysis, that set size and stimulus probability affect the same processing stage. In

the Sternberg papers, the assertion that the serial comparison stage is exhaustive is based on the parallel increase in mean RT for positive and negative items as target set size is increased. The target set size variable and the serial comparison stage are strongly linked. Therefore, the finding of the interaction between stimulus probability and target set size is not compatible with the assumption of a serial comparison stage unaffected by stimulus probability.

One way in which an exhaustive scanning model might be used to explain the probability effects found in the present study is that the serial comparison stage could be presumed to consist of an exhaustive scan of the target set but with the scanning rate faster for high probability probe stimuli. However, the basis for Sternberg's assertion of an exhaustive scan rather than a self-terminating scan is the parallel increase in mean reaction time for positive and negative items over increases in memory set size, rather than an increase which is twice as great for negative items as for positive items. But that result was obtained in a situation (the present design) where target set size and relative stimulus probability were confounded. If stimulus probability affected scan time significantly, it would mean that the removal of the probability effect (so that the "pure" target set size effect could be seen) would result in a reduced slope for mean RT to positive items since items which are in small target sets are also highly probable in the Sternberg (1967) design. Also, there would be an increased slope for mean RT to negative items since the high probability stimuli are negative under the larger set size conditions. The consequence, therefore, of adopting this particular modification of the exhaustive scanning model is to destroy the original rationale for proposing the model. Since stimulus probability affects mean RT, the rationale for the Sternberg (1967) exhaustive scanning model is called into question regardless of whether stimulus probability is presumed to affect the scanning stage, the encoding stage, or any other stage, since the parallel linearity of his obtained functions must be assumed to be

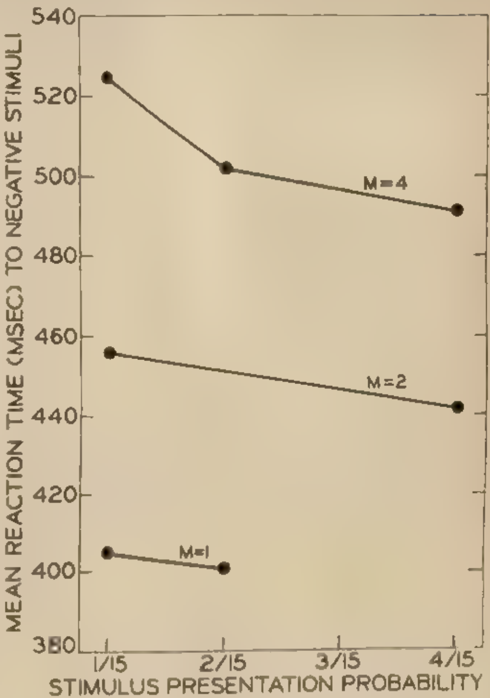

FIGURE 2. Mean reaction time to negative (nontarget) stimuli as a function of stimulus presentation probability and target set size (M).

partially due to variations in stimulus probability as well as to target set size.

Response–Stimulus Interval

The mean RT for the long (2.0 sec) response–stimulus interval (RSI) was significantly higher than for the short (.5 sec.) RSI. The fact that RSI does not have a significant interaction with either target set size or stimulus probability implies that RSI does not affect serial comparison, but rather some other processing stage. It is possible that variation in RSI affects *S*'s "readiness" in a continuous information-processing task. With RSI at .5 sec. the task demands complete attention and continuous concentration for a period of less than 2 min. for a block of 108 trials. For an RSI of 2.0 sec., 108 trials take nearly 5 min. and the length of time between trials is enough so that the *S*'s attention may move away from the task until it is brought back by the onset of the next stimulus. It is not necessarily the case that the RSI affects a precomparison stage.

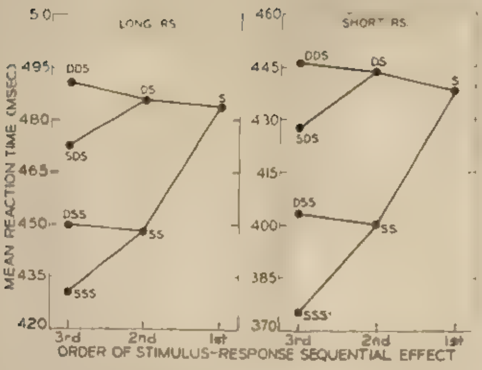

FIGURE 3. Mean reaction time (msec.) as a function of sequence of stimuli for long and short response–stimulus intervals, respectively. [Let S represent any particular stimulus and D represent any stimulus different from S. The point S represents the mean reaction time to stimulus S over all trials. The points DS and SS represent the mean reaction time (over all trials and all stimuli) to stimulus S given that a different (D) or the same (S) stimulus was presented on the previous trial. Likewise, the letter triples represent the mean reaction time (over all stimuli and trials) to stimulus S given that a different (D) or the same (S) stimulus was presented on the previous two trials. For example, the point DDS represents the mean reaction time to a stimulus S given that another stimulus (or two other stimuli) were presented on the preceding two trials.]

It may instead affect response selection or evocation time.

Sequential Effects

If the ordering of a self-terminating memory stack is based on frequency and recency, it follows that the same stimulus occurring twice or more in succession would increase the probability of that stimulus representation moving to an earlier position in the memory buffer. Accordingly it is useful to determine if mean RT is affected by whether the stimulus on a given trial is the same or different from the stimuli on immediately preceding trials. Figure 3 shows the stimulus–response sequential effects in the RT data. The figure shows the mean RT to a stimulus (S) as a function of the stimuli which occurred on immediately preceding trials. If the same (S) stimulus is repeated, reaction time systematically decreases. On the other hand, if the stimulus S has been preceded by different (D) stimuli the rea[ction] time systematically increases.

Response sequential effect. The sequ[en]tial effects in Figure 3 could be due t[o] either stimulus repetitions or response repetitions. That there are response sequential effects in the data is shown in Figure 4. Here RT to a stimulus (S) is given as a function of whether the same (S) response or a different (D) response was given on immediately preceding trials. H[owever,] these response sequential effects are [...] confounded, to some degree, with stimulus repetitions.

"Pure" stimulus sequential effect. [In] order to obtain measures of the pure sti[mu]lus and response sequential effects, [we] considered only runs of trials in which [the] same response is given repeatedly. Fig[ure] 5 shows the pure stimulus and respo[nse] sequential effects. The top branch sho[ws] the pure response repetition effect whe[n] the stimulus is not repeated, but the response is repeated. Reaction time s[...]

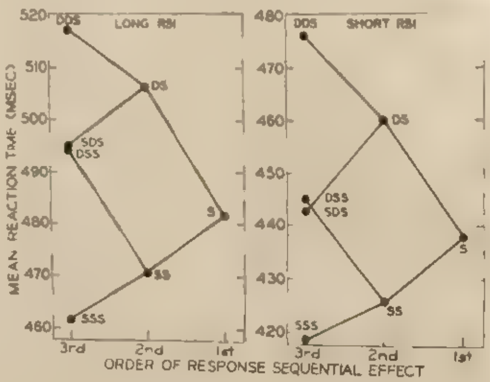

FIGURE 4. Mean reaction time (msec.) as a function of sequence of responses for long and short response–stimulus intervals, respectively. [Let S represent any particular *response* and D any response different from S. The point S represents the mean reaction time for response S over all trials. The points DS and SS represent the mean reaction time (over all trials and responses) for response S given that a different (D) or same (S) response occurred on the previous trial. Likewise, the letter triples represent the mean reaction time (over all trials and responses) for response S given that the same (S) or different (D) responses occurred on the previous two trials. For example, the point DSS represents the mean reaction time for response S given that the same (S) response was made on the previous trial but a different (D) response was made two trials previously.]

tematically decreases with response repetition. The lower branch shows the decrease in RT when both stimulus and response are repeated. As can be seen, the decrease in RT is much greater for stimulus *and* response repetition than for response repetition alone. The difference between the nodes of any two adjacent branches of the sequential tree diagram is a measure of the pure stimulus repetition effect. On the basis of these analyses, it is obvious that there are both stimulus and response sequential effects in memory scanning data, at both long and short response–stimulus intervals.

Application of a Self-Terminating Model

Theios et al. (1973) discussed three models of a self-terminating memory scanning system. The first model had an unlimited capacity serial scanning buffer, the second model had a fixed sized, limited capacity scanning buffer, and the third model had a variable sized, limited capacity scanning buffer equal to the target set size. Each of these three models had two versions, one in which movement up in the memory buffer was the same for target and nontarget stimulus representations ($a_+ = a_-$) and one in which target (positive) representations moved up faster than nontarget (negative) representations ($a_+ > a_-$). The assumption of the equality of the movement parameter can be rejected on the basis of the data from the present experiment. Assuming a_+ equal to a_-, it was not possible to get enough slope in the predictions for positive RT as a function of target set size. Thus, with a_+ greater than a_-, target representations on the average will be located earlier in the memory buffer than representations of nontarget stimuli of equal frequency.

The fact that there is a target set size effect in the data of Figure 2 is sufficient to reject the assumptions of either an unlimited capacity buffer or a fixed sized, limited capacity buffer. The data suggest that the buffer capacity increases with target set size.

Taken together, the data of the present experiment suggest the variable sized memory stack model proposed by Theios et al.

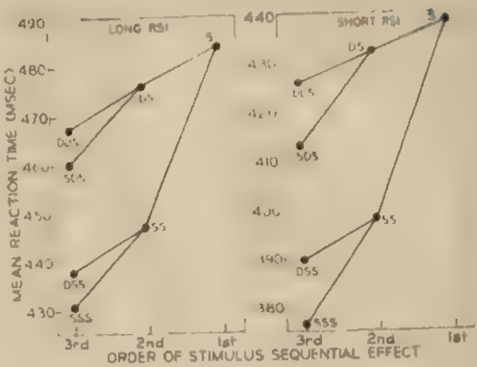

FIGURE 5. Mean reaction time (msec.) as a function of sequence of stimuli (for long and short response-stimulus intervals, respectively) during runs of the same response. [Let S represent any particular stimulus and D represent any stimulus different from S. The point S represents the mean reaction time to stimulus S over all trials. The points DS and SS represent the mean reaction time (over all trials and all stimuli) to the stimulus S given that a different (D) or the same (S) stimulus was presented on the previous trial and given that the response on both trials was the same. Likewise, the letter triples represent the mean reaction time (over all stimuli and trials) to stimulus S given that a different (D) or the same (S) stimulus was presented on the previous two trials and given that the response on all three trials was the same. For example, the point DDS is the mean reaction time to a stimulus S given that different stimuli requiring the same response were presented on the two previous trials.]

(1973). Using a Monte Carlo computer-simulation program, separate quantitative predictions were obtained from the self-terminating memory scanning model described in Theios (1973b) and Theios et al. (1973) for the long and short response stimulus interval conditions. A statistical response protocol corresponding to the self-terminating process was obtained for every response protocol given by a real *S* in the present experiment, under the assumption that the *S*s were homogeneous with respect to the values of the parameters of the process. The size of the memory stack ($Z - 1$) was set equal to the target set size and the time to retrieve a response from long-term memory given an unsuccessful exhaustive scan of the buffer (t_Z) was set equal to the buffer comparison time (t). Chandler's (1969) subroutine STEPIT was used to estimate the values of the remaining five parameters. They were the RT

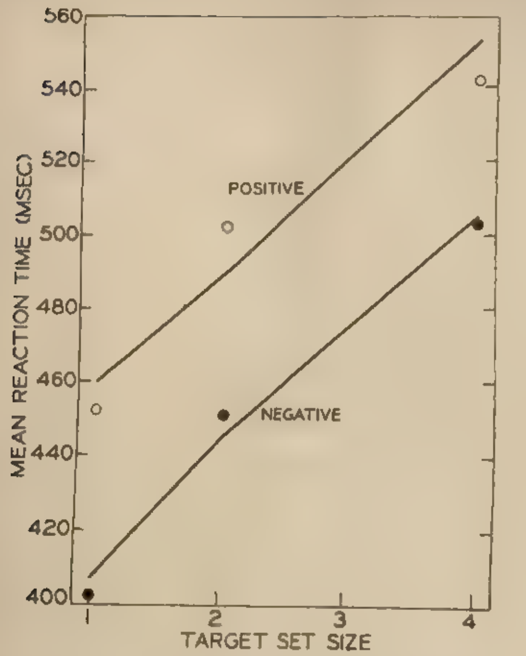

FIGURE 6. Mean reaction time as a function of target set size for positive (target) stimuli (open circles) and negative (nontarget) stimuli (closed circles). [The lines are predictions obtained from a Monte Carlo computer simulation of the self-terminating memory scanning model of Theios, 1973b.]

intercept (the combined encoding and negative response time, C), the difference between positive and negative response selection and output times (D), the memory comparison time (t), the probability of a positive stimulus–response representation moving up to the top of the memory stack after that stimulus is presented (a_+), and the probability of a negative stimulus–response representation moving up to the top of the stack after that stimulus is presented (a_-).

Table 1 shows the mean RT values from :he computer simulation as well as the nean RTs from the present experiment. \ goodness-of-fit analysis of variance was erformed to determine whether the ob- erved mean RTs differed significantly from hose obtained from the two computer mulations. There are 20 comparisons nean differences) involved, and a total of) parameters were estimated from the ata to obtain the predicted means. Thus, ie numerator degrees of freedom are 10. The error term for the F ratio is the average of the squares of the standard errors of the observed means, that is, the within-cell variance, which has 940 degrees of freedom. The test indicated no significant differences between the simulated means and the obtained means, $F(10, 940) = 1.19$, $p > .05$. It is reassuring to note the parameter invariance obtained from the two independent simulations. The parameter estimates for the long and short RSI conditions differ appreciably only in the RT intercept (C). The fit of the model would be almost as good if the long and short RSI conditions were simulated together, using common values for the remaining parameters, i.e., if only 6 parameters would have been estimated.

Figure 6 shows that, contrary to common belief, the self-terminating process predicts that mean RT is an essentially linear function of target set size with approximately equal slopes for target and nontarget stimuli. Figure 7 shows that the self-terminating process predicts the obtained interaction in RT between target set size and stimulus frequency.

Inspection of the estimated values of the parameters in Table 1 indicates that the scanning rates are typical (42 msec.) and

[The lower two points are for a target size of one, the middle two points are for a target size of two, and the upper three points are for a target set size of four. The lines represent predictions obtained from a Monte Carlo computer simulation of the self-terminating memory scanning model of Theios (1973b). The data clearly show the significant obtained and predicted interaction between stimulus probability and memory set size.]

that the a_+ estimates are larger than the a_- estimates reflecting the greater emphasis on the target items in the scanning process. The 79-msec. difference between positive and negative RT intercepts reflects the fact that negative responses were required on 11/15 of the trials whereas positive responses were required on only 4/15 of the trials. Sternberg (1969) has reported similar results. The 79-msec. difference can be accounted for by bias in what Theios (1973b) has called the response program selection process.

CONCLUSIONS

The results clearly indicate that in the Sternberg (1967) fixed-set memory scanning task there are significant (*a*) stimulus frequency effects, (*b*) stimulus sequence effects, (*c*) response frequency effects, (*d*) response sequence effects, (*e*) target set size effects, and (*f*) effects due to an interaction between stimulus frequency and target set size. The obtained interaction is especially difficult to account for using an exhaustive scanning process. However, the observed pattern of results is easy to account for using a self-terminating process (Theios, 1973b; Theios et al., 1973) as was shown by a computer simulation of the present experiment. When viewed against the background of the research literature in the choice reaction time and memory scanning areas, the present results suggest the general theoretical process of human perception, cognition, decision making, and response selection proposed by Theios (1973a, 1973b).

STIMULUS PROBABILITY AND STIMULUS SET SIZE IN MEMORY SCANNING[1]

IRVING BIEDERMAN[2] AND E. WEBB STACY, JR.

State University of New York at Buffalo

In many recent studies of speeded scanning of immediate memory, variations in the size of the positive set (s) were confounded with variations in the probability (P) of the individual items within the positive set: As s increased, P decreased. The present experiment sought to determine whether the effect on RT attributed to s could be accounted for by variations in P. This was accomplished by factorially varying both s and P. Probability effects were confined to items in the positive set and were insufficient to account for the effect of s. The results are discussed in terms of a model in which s and P affect different information-processing stages. The s affects the number of comparisons between the encoded item and the items stored in the memory of the positive set, as proposed by Sternberg. The P affects response selection—information as to the particular digit that was presented is available to the mechanisms for response selection along with the knowledge that there was or was not a match. The response selection mechanisms are assumed to be biased in tune with the P values of the items within the positive set.

The number of things that one has to think about and the expectancy as to the likelihood of occurrence of these things—stimulus number and stimulus probability—have long been regarded as fundamental variables in the study of cognition. The common finding that longer RTs would be produced by an increase in the number of possible stimuli or a decrease in stimulus probability was a result that was compatible with most theories of stimulus recognition. Discriminating among the various theoretical accounts for these effects has been a more elusive task.

One class of models holds that variations in stimulus probability and stimulus number affect only a single commodity such as information (in bits) or repetitions. Examples of such models are those that posit a single decision maker which operates on stimulus information in bits (e.g., Briggs & Johnsen, 1973; Briggs & Swanson, 1970; Hick, 1952) or sequential position in a stack (Theios, Smith, Haviland, Traupmann, & Moy, 1973).

In contrast, Sternberg (1966, 1967) has advocated a model in which the time to scan immediate memory is affected by the number of possible items in memory—not by their probability of occurrence. In a series of character classification experiments, Sternberg (1966, 1967) found that the time to classify a character (e.g., a digit) as a member of an arbitrary subset of characters (the memory or positive set) was a linear increasing function of the number of items, s, in that subset. Moreover, the slopes for the positive (match) and negative (nonmatch) functions were identical. From these data, Sternberg postulated a high speed (25 items/sec), exhaustive, sequential scan of the items in the positive set. However, in Sternberg's experiments, the number of items in the positive (memory) set s was confounded with the probability (P) of the individual items in that set: As s increased, P decreased. By interpreting his results solely in terms of stimulus number, Sternberg was implicitly assuming that there was either

no effect of P[3] or else that P affected some tage other than memory scanning. This onfounding, which Sternberg explicitly acknowledged, was a necessary consequence of controlling for stimulus and response entropy and response probability. For example, in Sternberg's (1967) experiment, when $s = 1$, 2, and 4, the individual items had P-values of 4/15, 2/15, and 1/15, re- ctively, so that the probability of a Yes sponse was always 4/15. Because of the founding between s and P, Biederman l Zachary (1970) suggested that the ower RTs to the larger set sizes might, in part, represent adjustments to stimulus probability within the positive set. (Sternberg, 1966, found no effect of increasing number of negative set items from 2 15, with negative response probability ld constant, so if probability adjustments re at play, they would have to be to sitive set stimuli.) An effect of P had dy been documented in other experiments (e.g., LaBerge & Tweedy, 1964), in faster RTs were produced by more able stimuli even when the different uli were assigned to the same response. he present experiment was designed to al whether such probability adjustments would be found in the Sternberg memory-scanning task. Specifically, the probability of the items *within* a given sitive set was varied. If it is assumed that P affects memorial comparisons and the memorial comparisons proceed at a fixed rate, then an exhaustive, sequential nning theory would predict that such a bability imbalance would have no effect on RTs.

Recently, however, Klatzky and Smith (1972) argued that an exhaustive scanning theory could accommodate such a result by assuming that the adjustments to probability were made at some stage other than the comparison stage; viz., a stimulus encoding stage. The exhaustive scanning theory and the additive factors method (Sternberg, 1969) then predict that variations in P and s should produce additive effects on RT. Such a result was reported by Klatzky and Smith in a letter classification task. Also compatible with an encoding effect of P is Miller and Pachella's (1973) finding that P and stimulus degradation (which would be expected to affect encoding) interact. The RTs to items of low probability of occurrence were more adversely affected by the presence of visual noise than high-P items. Since Sternberg (1967) found that degradation did not interact with variations in positive set size (i.e., memory scanning), the Klatzky and Smith (1972), Miller and Pachella (1973), and Sternberg (1967) experiments are all compatible with a two-stage theory, encoding and memory scanning, for the effects of P and s, respectively.

The design of the present experiment compared the effect of P on positive RTs with the effect on negative RTs. An encoding theory of P-effects would predict that response type would not interact with P. Theios et al. (1973), Krueger (1970), and Miller and Pachella (1973), in fact, reported such a result. However, these investigators all employed positive and negative sets that were of equal size. Such a procedure might well lead to S's functional (i.e., positive) set not being the one specified by E. When sets are of equal size, there is little utility for S to confine his scanning to the set which E designated as positive. Under such conditions, S might reasonably be expected to sometimes scan one and sometimes scan the other set. Or else, S could scan an amalgamation of sets (Hawkins & Hosking, 1969) by combining the high-P items from the negative set with the positive set. The design of the present experiment employed a positive set that was smaller than the negative set hence, less scanning would be required if S confined his scanning to the positive set.

Method

Subjects. Forty-eight undergraduate students at the State University of New York at Buffalo participated in the experiment as part of their course requirement in introductory psychology.

Stimuli and apparatus. The stimuli were the 10 digits, 0, 1, . . . , 9, generated by an IEEE in-line display (Model 10-0K21-1820-L) set in a 3×3 ft. gray frame. The background, pre- and postexpo-

[3] As defined here, P is the probability of occurrence of a particular stimulus.

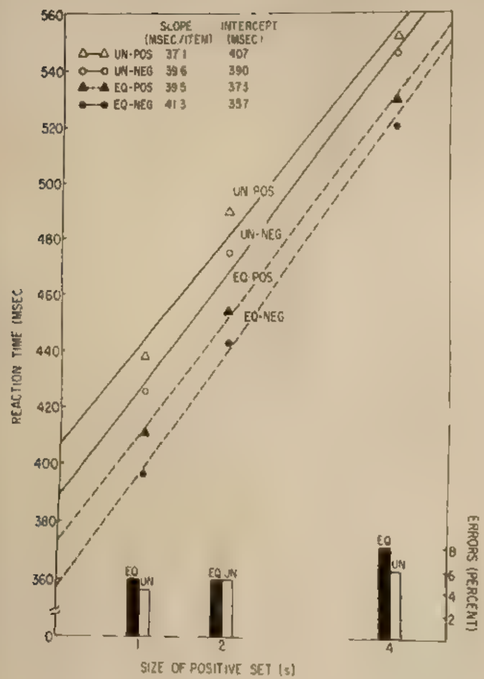

Figure 1. Mean correct reaction time as a function of group (EQ vs. UN), response (POS vs. NEG), and set size. (Slopes and intercept constants shown on figure represent best least squares fit. Lower bars represent error rates as shown on scale on the right of the figure.)

sure fields were black. The *S*'s index fingers rested on plastic keys which, when depressed, activated a microswitch which stopped a timer that was started by the onset of the digit. A warning buzzer of .5-sec. duration sounded 1 sec. before each stimulus presentation of .5 sec. The interstimulus interval was 5 sec. After each response, *E* verbally provided error and speed feedback (to the nearest .01 sec.). Approximately 2 min. intervened between blocks of trials.

Design and procedure. Each *S* was fully instructed about the nature of the task and the relative frequencies of each of the 10 digits. A bar graph display of these relative frequencies remained in *S*'s view throughout the experiment. Left and right keys were assigned to Yes and No responses according to *S*'s preference.

The design closely followed that of the first session in Sternberg's (1967) experiment. The first block for all *S*s always consisted of 45 trials with a positive memory-set size of three digits. The second through fourth blocks each consisted of 90 trials with memory set sizes of one, two, or four digits in counterbalanced order. Half of the *S*s were run in a condition (UN) where, for memory sets of Size 2 and 4, one of the digits in that set was more probable than the other digit(s). The remaining *S*s, like those in Sternberg's experiment, had memory sets where the positive digits were equiprobable (EQ). The stimulus sets and probabilities are shown in Table 1. For Set Size 2 in the EQ condition, both digits had a probability of 2/15. In the UN condition one of the digits had a probability of 3/15 and the other digit had a probability of 1/15. For Set Size 4 in the EQ condition, each of the four digits had probabilities of 1/15. In the UN condition, one of the four digits had a probability of 2/15 and the remaining three digits each had a probability [illegible] For Set Sizes 1, 2, and 4 the probability of a [illegible] response was 4/15. For $s = 3$, all *S*s had a [illegible] probable condition where the probability of [illegible]tive response was 3/15. (Therefore, the probability for any one digit when $s = 3$ was 1/15.) For EQ *S*s, therefore, 1 of the 10 digits had a probability of 4/15, 2 had probabilities of 2/15, and the remaining 7 had probabilities of 1/15. In the UN condition, 1 digit had a probability of 4/15, 1 had a probability of 3/15, 1 had a probability of 2/15, 4 had probabilities of 1/15, and 3 had probabilities of 2/45.

Each *S*'s positive sets were selected from one of the three groupings used in the Sternberg (1967) experiment. The high and low *P*s were balanced over the different digits. Thus, for example, one-third of the *S*s had a grouping that when $s = 1$ the positive digit was "5"; when $s = 2$, the positive digits were 4 and 9; and when $s = 4$, the positive digits were 0, 1, 3, and 7. In the UN condition, each digit in $s = 2$ and 4 occurred as the more probable digit an equal number of times. For example, for eight of the *S*s in the UN condition, when $s = 2$ the more probable ($P = 3/15$) digit for four of these *S*s was "4" and for the remaining four *S*s the more probable digit was "9." The assignment of *P*s to digits remained constant throughout *S*'s session. Before each block, markers were placed on the bars of *S*'s display designating the positive digits.

TABLE 1

Probabilities of Stimulus Digits in the Positive Sets for the Equal and Unequal Probability Groups

Size of positive set	Group: Equal	Group: Unequal
$s = 1$	4/15	4/15
$s = 2$	2/15, 2/15	3/15, 1/15
($s = 3$)	(1/15, 1/15, 1/15)	(1/15, 1/15, 1/15)
$s = 4$	1/15, 1/15, 1/15, 1/15	2/15, 2/45, 2/45, 2/45

Results

Figure 1 shows the overall Yes–No RT and error functions for both EQ and UN conditions. The slopes for the EQ functions average 40.4 msec/item which is

almost identical to the UN functions which average 38.4 msec/item, and these, in turn, are similar to those reported by Sternberg in his (1967) experiment (mean slope = 35.6 msec/item). Thus, instructing *S* about the probability variations and explicitly manipulating *P*s within the positive set had little effect on the rate and nature of processing. The 30-msec. average difference in intercepts between the EQ and UN groups most likely represents individual differences in the groups: the EQ group was 43 msec. faster at the outset of the experiment, in the $s = 3$ condition, and 26 msec. faster in the $s = 1$ condition. Differences in RTs among the three digit groupings were negligible, $F < 1.00$.

The data for probability adjustments within the positive set are shown in Table 2. An analysis of variance of the positive stimuli of the $s = 2$ and 4 condition of the UN group revealed that the main effects of *s* (2 vs. 4) and *P* (high vs. low) were significant, $F\ (1,\ 23) = 19.40$, $p < .001$, and $F\ (1,\ 23) = 11.85$, $p < .01$, respectively. The $s \times P$ interaction was highly variable from subject to subject and was not significant, $F\ (1,\ 23) = 1.42$. Table 2 shows that the effect of *s* on Yes RTs is too large to be completely attributable to *P*. Three comparisons are relevant here: (*a*) The differences in *P*-values between $s = 2$ and $s = 4$ in the *EQ* condition was only half the difference between high and low *P*s in the $s = 2$ UN condition (.133–.067 = .061 vs. .200–.067 = .133). Yet the former yielded an effect on RT of 77 msec. which was more than twice the effect on RT produced by the latter *P* difference (28 msec.). (*b*) A similar case can be made for the $s = 4$ UN condition. Here the difference in *P* values was .089 (.133–.044) —slightly greater than the difference in *P* values in the EQ condition. Yet, again, the 48-msec. UN difference was less than the effect of *s* in the EQ condition. (*c*) Within the UN conditions, the effect of *s* was clearly greater than the effect of *P*. The RTs to the .133 stimulus in the $s = 4$ condition were slower than the .067 stimulus in the $s = 2$ condition. Thus when *s* and *P* were directly pitted against each other, *s* was the more potent variable.

Is the effect of *s* independent of the effect of *P*? The data were more equivocal on this point but certainly did not provide strong evidence for an interaction between *s* and *P*. Although not statistically reliable, the within-subjects effect of *P* was greater in the $s = 4$ condition than in the $s = 2$ condition, even though the difference (but not the ratio) in *P*-values was greater in the $s = 4$ condition. However, before this suggestion of an interaction between *s* and *P* is given much weight (which would be evidence against a two-stage theory), one must first consider how the interaction could be affected by rescaling the probability variable since the differences in *P*-values for the different set sizes were not taken at the same points on the *P* scale. The variation in *P* for $s = 4$ occupied a lower range of the scale (.044 to .133) than did the variation in *P* for $s = 2$ (.067 to .200). Hence, if one wished to assume a transform between objective and subjec-

TABLE 2

Mean Correct Reaction Times (RTs) for Yes Responses as a Function of Group, Set Size (*s*), and Probability (*P*)

Set size	Group						P-effect (Low *P* minus high *P*)
	Equal		Unequal				
	P	RT (msec.)	High P	RT (msec.)	Low P	RT (msec.)

tive P that expanded the smaller values of the P scale, the interaction between s and P could be eliminated. Such an assumption could be justified on the basis of studies (e.g., Hohle & Gholson, 1968; Miller & Pachella, 1973) that have demonstrated that differences between small P-values produce larger effects on RT than equal differences in larger P-values. It is possible to construct a between-subjects test of the $P \times s$ interaction—which avoids the scaling problem—by comparing the data from the EQ and UN groups. This

TABLE 3

MEAN CORRECT REACTION TIMES (RTs) FOR YES RESPONSES AS A FUNCTION OF SET SIZE (s) AND PROBABILITY (P) WITH CORRECTION FOR GROUP DIFFERENCES

Set size	Probability .133	Probability .067	P-effect (.133 minus .067)
2	480(Equal)	512(Unequal)	32
4	528(Unequal)	557(Equal)	29

Note. A total value of 26 msec., the difference between the equal and unequal groups in the $s = 1$ condition, has been added to the equal RTs.

can be done by equating for the between-group differences on the basis of the common $s = 1$ condition which was 26 msec. faster in the EQ group. Thus if 26 msec. is added to the EQ values as shown in Table 3, then the larger P-effect found in the $s = 4$ group for the within-s analysis is eliminated.

Figures 2 and 3 show the effect on RTs of variations in item probability, set size, and response. Variations of P within the positive set had a considerably greater effect than variations of P within the negative set. The average slope of the functions relating RT to P within the positive set, are 14 times as steep as the corresponding negative functions: -48 msec. per .1 increase in P for the positive slope and -3.4 msec. per .1 increase in P for the negative slope. (By comparison, if the effect of s is described in terms of P, then the resulting slope, -60 msec. per .1 increase in P, is steeper than the function relating RT to P within a given sized positive set.) Probability thus had only a negligible effect on RTs to items within the negative set. In five of the six negative set probability functions, the F ratio for the effect of P was less than 1.00. In the UN group, $s = 2$ condition, there was a significant effect of P: $F(3, 69) = 4.91$, $p < .01$. However, the function for that condition is nonmonotonic and the effect is primarily attributable to the point at $P = .067$ which is *slower* than the point at $P = .044$.

Repetition effects were examined as a function of response type, probability, set size, and group. (Since a number of Ss did not have any entries for repetitions for some of the low probability stimuli in some conditions, the nonrepetition RTs for the corresponding cells for these Ss were not included in the analyses.) Stimulus repetition effects were larger than response repetition effects. Trials in which the stimulus was repeated from the preceding trials resulted in RTs that averaged 25 msec. less than RTs from trials in which the successive stimuli were different but the response was the same. When a different response was required, RTs were 6

msec. longer than when the response was repeated but different stimuli were presented. Table 4 shows that larger stimulus repetition effects were associated with larger set sizes. Response type, *P*, and groups did not yield a consistent effect on the magnitude of the stimulus repetition effect. The magnitude of the response repetition effect did not vary systematically with any of the major experimental variables. Since there were relatively few repetition trials the results shown in Figures 1, 2, and 3 would be only negligibly affected if only nonrepetition trials were used.

Table 5 shows the correct RTs, error RTs, and error rates for the major experimental conditions. Yellot's (1971) correction for fast guessing and the speed-accuracy trade-off applied to these data had only a negligible effect on the comparisons described above.

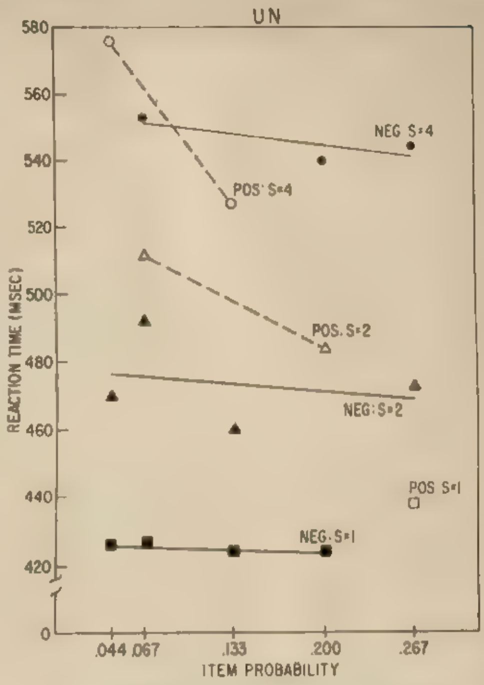

FIGURE 3. Mean correct reaction times as a function of probability and response in the UN condition.

DISCUSSION

Variations in *P* produced by variations in *s* led to considerably greater effects on RT than identical variations in *P* with *s* held constant. Thus it is clear that not all the effect of *s* can be attributed to *P*. The results of this memory scanning experiment are thus consistent with the information conservation studies of Hyman (1963) and Hohle and Gholson (1968) in showing that the effect on RTs of variations in set size of equiprobable stimuli is greater than the effect which is produced by variations of *P* within a given set size. The interaction between *s* and *P* was not significant although there was a trend, within-*s*, for larger *P* effects to be present in the larger positive sets (although this was not the case in the between-*S* comparison).

In the present experiment, if it is assumed that *P* effects reflect the functional set (i.e., the set which is scanned), then the lack of such effects in the negative set would indicate that the negative set was rarely functional (or scanned). What might have occurred in the Kreuger (1970), Theios et al. (1973), and Miller and Pachella (1973) experiments, was that their *S*s, faced with positive and negative sets of equal size, varied the set which they scanned from trial to trial. What determines which set gets scanned? What does the *S* treat as positive? This decision could *not* primarily be based on response probabilities since in the present experiment as well as Sternberg's (1967, 1969) experiments the probability of a positive response was only 4/15. Moreover, variations of response probability independent of stimulus probability have only

TABLE 4

STIMULUS REPETITION EFFECTS (IN MSEC.) AS A FUNCTION OF RESPONSE (POSITIVE OR NEGATIVE), SET SIZE (*s*), AND STIMULUS PROBABILITY

Set	Stimulus probability .044	.067	.133	.200	.267	*M*
Positive						
s = 1					5[a]	5
s = 2		[b]	13	41		27
s = 4	9	93	71			58
Negative						
s = 1	12	0	12	6		−2
s = 2	23	8	21		3	14
s = 4		54	12	50	36	38
M	7	39	26	28	15	

Note. Entries are the difference, in msec., between mean RTs for response nonrepetition and stimulus repetition trials. Positive entries indicate that the repetition trials were of shorter latencies.

[a] Includes both stimulus and response repetition effects.

slight effects on RT (Biederman & Zachary, 1970). It would appear that the number of items is the most potent determinant of what gets scanned in memory: Left to his own devices, S scans the set with the smaller number of items.[4] It seems reasonable to assume, however, that when positive and negative sets are of equal size, other variables (e.g., probability, repetition, value) would determine which stimuli are scanned on a given trial. Also, if S had insufficient time or memory to determine the complement of a positive set, he might scan the positive set even though it was larger than the negative set.

The interaction between P and Response Type observed in this experiment is contrary to what would have been expected from an encoding theory of stimulus probability as advanced by Klatzky and Smith (1972) and Miller and Pachella (1973). These investigators reported that P did not interact with memory set size but did interact with stimulus degradation. An encoding theory of probability effects might be reconciled with the above findings if it is assumed that prior to the presentation of the probe, S "prepares" only for the positive set items, and the effect of this preparation is on the encoding stage. If the amount of preparation was related to P then larger P effects in the positive than in the negative set might be expected. However, such a theory is inconsistent with the complete absence of any interaction between degradation and response type in the Sternberg (1967) experiment.

If P does not affect encoding, then where does it have its effect? One possibility might be at the response selection stage following memory scanning. If positive set matches are signaled not simply by a match signal but by the digit itself along with a match signal, then response selection could be biased in tune with the probabilities of the positive set stimuli. After all, S knows what the digit was that provided the match. Such a theory would be consistent with the finding that the effects of P and S–R compatibility interact (Sanders, 1970). In fact, with naming tasks (which are of very high compatibility), there is little or no effect of probability (Miller & Pachella, 1973; Theios, 1974). Of the studies discussed above, the only finding that is apparently incompatible with this view is the interaction between P and degradation reported by Miller and Pachella. In that experiment, degradation was produced by the presentation of a light field immediately prior to the presentation of the digits of a CRT display. The field, which reduced the contrast between the digits and background, decayed over time. That is,

[4] Perhaps it is for this reason that it is so difficult to follow the instruction, "Don't think about alligators."

if *S* waited, the digits became clearer. It is possible that such a discriminability manipulation could have induced a response selection strategy which was biased in favor of high-*P* stimuli (assuming that response selection is achieved by a combination of digits and match signals). But even if another method of producing degradation revealed an interaction between *P* and degradation, *P* effects could still be localized at the response selection stage if it was assumed that the *P* bias was to a visual representation of the digit.

STIMULUS ENCODING AND DECISION PROCESSES IN RECOGNITION MEMORY [1]

JAMES F. JUOLA,[2] GLEN A. TAYLOR, AND MICHAEL E. YOUNG

University of Kansas

Recognition memory for words and pictures was tested using a fixed, memorized-set procedure (Experiment I) and a continuous procedure (Experiment II). Test items were presented twice each at lags of 4, 12, or 24 intervening items, and any item could be tested using the same or different stimulus form (word or picture) at each lag. A recognition model that assumes successive encoding, decision, and response stages was used as the theoretical framework for interpretation of the results. The analysis indicated that stimulus form and lag affected encoding processes in similar ways for Experiments I and II. Differences were obtained for the decision stage, however, as stimulus form apparently affected decision processes in Experiment II but not in Experiment I.

In binary-classification tests of recognition performance, *S* must categorize a stimulus as being either an *old*, or target stimulus (i.e., one that has been presented before), or a *new* stimulus, or distractor (i.e., one that has not previously been presented). Recognition test procedures are of two principal types: (*a*) the target set consists of a number of items that have been studied prior to the recognition test, or (*b*) the target set consists of all items previously presented during a continuous series of test items.

The former procedure has been used to study both short-term recognition (Sternberg, 1966) and long-term recognition (Juola, Fischler, Wood, & Atkinson, 1971), and Atkinson and Juola (in press) have developed a model to account for the data. The model proposes three processing stages (encoding, decision, and response) that are executed sequentially during recognition. The encoding stage includes analysis of the test stimulus and the construction of an internal representation that is unique to the form and modality of input. This representation is called the perceptual code. Each perceptual code is then mapped onto the particular long-term memory location assigned to various perceptual codes of the same item. This representation in memory is called the conceptual code. The generalized activation level of the information represented by the conceptual code is converted into a familiarity value for the test item. Thus, the encoding stage includes all the processes involved in identifying a test stimulus and retrieving a subjective estimate of its familiarity.

The decision stage of the model operates on the familiarity output by the encoding stage. Familiarities are evaluated with respect to two decision criteria such that values below a low criterion lead to immediate negative responses and values above a high criterion lead to immediate positive responses. If the familiarity falls between the two decision criteria, the response stage is delayed until after a more extensive search of memory has been completed. This search process might be similar to the serial and exhaustive scanning model proposed by Sternberg (1966, 1969). The major difference between the two models is that in Sternberg's representation a decision to respond is made only after an exhaustive search of the target set has been completed, whereas in the model described above, a decision can be made either before or after this search. A decision made on the basis of familiarity alone is rapid, but error prone, and a

decision made after the extended search is slower, but accurate.

One of the main purposes of the present study was to extend the recognition model to account for data from continuous recognition experiments. In the continuous task, a series of items is presented, and S is instructed to make negative responses to all items on their initial presentations and to make positive responses to all repeated items (e.g., Shepard & Teghtsoonian, 1961). Studies by Hintzman (1969) and Okada (1971) have shown that both the number of presentations and the lag between successive presentations affect performance. In general, repeated tests result in faster positive responses and fewer errors, with mean positive response latency increasing as a nonlinear function of lag between tests. These results cannot be accommodated by the Sternberg model, probably because the target items generally are not retrievable as a set which could be scanned for the presence or absence of the test item (Okada, 1971).

Similar effects of repetitions and lags have been observed in studies using the memorized target set procedure (Fischler & Juola, 1971; Juola et al., 1971). Repetitions have been shown to reduce both the mean error rate and mean response latency for target items, whereas the error rate increases and latencies show either a slight increase or decrease for repeated distractors. These results have been interpreted in terms of the model by assuming that repetitions facilitate the encoding stage and increase mean familiarity values for both targets and distractors (Juola, 1973). For target items, the proportion of the familiarity distribution below the low criterion is assumed to be equal to the miss rate. The proportion between the two criteria and that above the high criterion are assumed to be equal to the proportions of slow and fast positive decisions, respectively. Thus, target repetitions should result in fewer errors, fewer slow decisions, and more fast decisions (and therefore a faster mean execution time for correct positive decisions). For distractors, the proportion of the familiarity distribution above the high criterion is assumed to be equal to the false alarm rate. The proportions between the two criteria and below the low criterion are assumed to be equal to the proportions of slow and fast negative decisions, respectively. Thus, repetitions of distractor items should result in more errors and a slower mean execution time for correct negative decisions. Repetition effects on the encoding and decision stages should be additive to produce faster mean response times for targets. For repeated distractors, latencies could be either greater than or less than the times for responses to distractors on their first tests, depending on the relative changes in mean execution times for the encoding and decision stages.

The analysis of repetition effects on negative and positive responses has proved useful in separating stimulus encoding and decision effects on recognition performance. Another technique that has been used for this purpose involves the use of different stimuli to represent a given test item. For example, Juola (1973) studied repetition effects for items tested twice using the same or different visual stimuli (words or pictures) on both tests of targets and distractors. The results indicated that the encoding stage was executed more rapidly for all repeated items; however, this effect was much larger for those items tested with the same stimulus form on both presentations. The decision stage was apparently independent of the stimulus forms used.

In the present study, a similar manipulation of stimulus forms was used to help in isolating encoding and decision processes and their relative contributions to recognition performance. In Experiment I Ss were tested using the fixed target set procedure. Targets and distractors were presented twice each at three different lag conditions, and either the same or different stimulus forms were used at all lags. Experiment II included the same manipulations as Experiment I in a continuous recognition task.

Method

Experiment I

Subjects. The *S*s were 50 right-handed, female undergraduates who participated for credit in an introductory psychology class. During the experiment, 3 *S*s were dismissed for reported difficulty in identifying the visual stimuli, and the data for 7 additional *S*s were discarded for failure to meet an arbitrary error criterion of 10%. The data are thus based of an *N* of 40.

Materials. The stimuli were selected from a pool of 96 different items, each of which was represented by a word and a picture. The words were common one- or two-syllable nouns, three to eight letters in length, and the pictures were easily identifiable, outline drawings of the objects named by the nouns. The stimuli were placed on 6 × 9 in. white cards for presentation in an Iconix tachistoscope. The words were typed in Orator typeface with an IBM Selectric typewriter, and they varied in length from .8 cm. to 2.0 cm. Xerox copies of the original drawings were affixed to cards, and they varied between .9 cm. and 3.8 cm. in diameter. When placed into the tachistoscope, the stimuli appeared about 1.0 cm. (i.e., about 36 min. of visual angle from *S*'s viewpoint) below a central, dark fixation point.

Design. The 96 items were randomly divided into two sets of 48 items each. The first set was used to generate target lists for 20 *S*s, and the remaining 48 items were used as distractors. For a second group of 20 *S*s, the target and distractor sets were reversed so that for the experiment as a whole, all items were used equally often as targets and distractors. Both target sets were randomly ordered into two different lists to provide the target lists used for four groups of 10 *S*s each.

The test session consisted of 192 trials during which all items were tested twice. The *S*s were randomly assigned to three different test sequences. In these sequences, item presentation order was randomly determined with the constraint that either 4, 12, or 24 intervening trials occurred between successive presentations of the same target or distractor items. Sixteen targets and 16 distractors were repeated at each of these three lag intervals, which, after the first 24 trials, were distributed uniformly throughout the test sequences. Half of the target and distractor items were tested as words (W trials) and half were tested as pictures (P trials) on their first presentations. At each of the three lag conditions for repeated targets and distractors, four items previously tested as words were tested again as words on their second presentations (WW trials), four items tested as words were retested as pictures (WP trials), four items tested as pictures were retested as words (PW trials), and four items were tested as pictures on both presentations (PP trials).

Procedure. Each *S* was contacted about 24 hr. before the experimental session and was given a target list of 48 nouns. The *S*s were told to memorize the list in serial order before being tested on the following day. The experimental session began with a written, serial recall test for the target list. M[...] *S*s correctly recalled all the target words; howe[...] those who made errors were retested until the wo[...] were recalled in correct serial order.

The *S* was then seated in front of the tachist[...] scope, and the exact nature of the test procedur[...] was explained. A series of 20 practice trials on [...] modified Sternberg task was run to familiarize [...] with the procedure. For these trials, *S* was tol[...] to make a positive response if a digit from 0 to 4 [...] presented and to make a negative response i[...] test digit was 5–9. All 10 digits were presented [...] in a random order.

The procedure for the practice trials was identi[...] to that for the experimental test sequence. [...] trial started when *E* placed a test stimulus [...] into the tachistoscope and gave *S* a ready sign[...] The *S* then depressed a foot switch that initiate[...] a millisecond timer. The tachistoscope was pr[...] grammed to illuminate a preexposure field [...] dark fixation point 10 msec. after *S* pressed the foot switch. This field was maintained for 490 [...] and was followed immediately by a 350-ms[...] posure of the test stimulus. The field rem[...] dark until the next trial. The *S* was instructed [...] rest her hands on a box upon which two 3.2-cm circular buttons were mounted about 9.0 cm. apart. When either button was pressed, it activated a microswitch that stopped the timer. All *S*s were instructed to indicate a positive response to target items by pressing the right-hand button and to indicate a negative response to distractors by pressing the left-hand button.

The practice trials were followed by a brief res[...] period during which *S* was told that targets and distractors could be tested either as words or as pictures, and she was instructed to respond as rapidly as possible on each trial while being careful to avoid making errors. During the test session no feedback was provided for correct responses, but *S*s were informed of all errors. The session averaged about 45 min. in length during which *S*s we[...] allowed to take a maximum of three rest periods at irregular intervals.

Experiment II

Subjects. The *S*s were 22 right-handed female undergraduates who participated for credit in an introductory psychology class. During the experiment 1 *S* was dismissed for reported difficulty in identifying the visual stimuli, and the data for an additional *S* were discarded for failure to meet an arbitrary error criterion of 10%. The data are thus based on an *N* of 20.

Materials. The stimuli and apparatus were the same as those used in Experiment I.

Design. The test sequences used in Experiment II were identical to those used in the previous study. The sequences were randomly assigned to *S*s.

Procedure. The test session began with a description of the testing procedure. A series of 20 trials using the digits 0–9 as stimuli was run to

familiarize *S* with the task. For these trials, *S* was told to make a negative response to any digit on its first presentation and a positive response to any repeated digit. All 10 digits were presented twice in a random order. All other details of the practice trials and the actual test session were identical to those of Experiment I. The only difference for the present study was that, rather than making positive responses to items belonging to a previously memorized set, *S*s were instructed to make positive responses to any items previously presented during the test session, regardless of whether or not the actual stimulus form (W or P) was the same on both tests of an item.

RESULTS

The mean response latencies,[3] standard errors of the mean latencies, and mean proportions of errors for all conditions of Experiments I and II are presented in Table 1. The data presented here are from Trials 25 to 185 or 186 only (depending on the specific test sequence), over which the distributions of all types of trials were approximately uniform.

In both experiments mean response times were slower to pictures than to words for items on their initial presentations. (This trend was obtained for 37 of 40 *S*s for targets and 38 of 40 *S*s for distractors in Experiment I and for 18 of 20 *S*s in Experiment II.) The latency data for repeated items were analyzed separately for targets and for distractors in Experiment I and for Experiment II. Three $2 \times 2 \times 3$ repeated measures analyses of variance were run, with factors corresponding to the stimulus form (W or P) used on the first presentation of the test item, the stimulus form used on the second test, and the lag between presentations, respectively.

[3] The latency data were based on 89.7% of the total trials run in Experiment I and 92.2% of the trials in Experiment II. The data excluded were for Experiment I: 5.8% *S* errors, 3.6% *E* errors, and .9% "long" responses (eliminated using the correction technique described by Wescourt & Atkinson, 1973); for Experiment II: 4.9% *S* errors, 2.8% *E* errors, and .1% long responses.

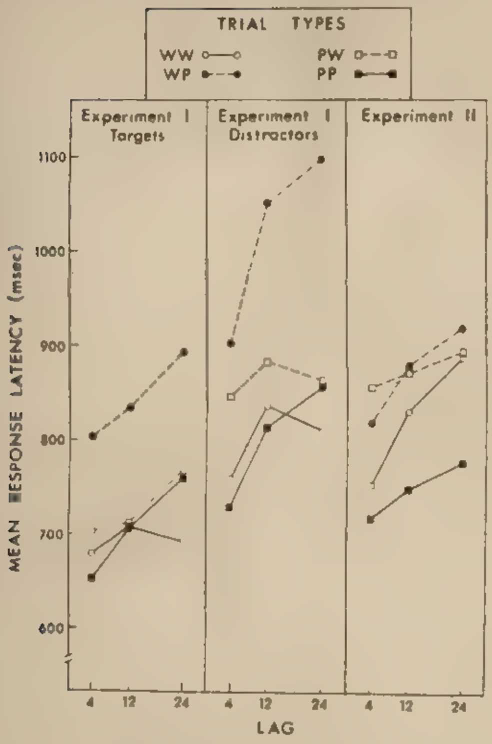

FIGURE 1. Mean response latencies for four types of items on second test presentations as functions of lag between first and second presentations.

All main effects of stimulus form were significant. In Experiment I, responses to repeated targets were faster if they had been tested as pictures on their first tests, $F\ (1, 39) = 34.21$, $MS_e = 9{,}375$, $p < .01$, and as words on their second tests, $F\ (1, 39) = 60.69$, $MS_e = 8{,}223$, $p < .01$. Responses to repeated distractors were also faster if they had been tested first as pictures, $F\ (1, 39) = 31.48$, $MS_e = 22{,}659$, $p < .01$, and then as words, $F\ (1, 39) = 23.48$, $MS_e = 28{,}796$, $p < .01$. In Experiment II, response latencies were shorter for repeated items tested first as pictures, $F\ (1, 19) = 9.51$, $MS_e = 8{,}940$, $p < .01$, and responses were faster for items tested as pictures on their second presentations, $F\ (1, 19) = 17.60$, $MS_e = 5{,}042$, $p < .01$. In general, the response time data indicated that latencies were shorter for repeated items if the same stimulus forms were used on both tests than if they differed. This conclusion was supported by the significant interactions between the forms use[illegible] the first and second tests, $F\ (1, 39) =$ [illegible] 7.89, $MS_e = 9{,}919$, $p < .01$, for ta[illegible] in Experiment I; $F\ (1, 39) =$ [illegible] $= 33{,}317$, $p < .01$, for distra[illegible] periment I; and $F\ (1, 19) =$ [illegible] $= 8{,}872$, $p < .01$, in Experime[illegible]

The main effects of lag were [illegible] cant, indicating that response [illegible] fo[illegible] repeated items increased as a f[illegible] the number of intervening test[illegible] the first and second tests of [illegible] $F\ (2, 78) = 19.09$, $MS_e = 10{,}190$, [illegible] for targets in Experiment I; F (2[illegible] 30.30, $MS_e = 15{,}015$, $p < .01$, fo[illegible] tractors in Experiment I; and [illegible] $= 39.42$, $MS_e = 3{,}508$, $p <$ .0[illegible] tractors in Experiment II. In [illegible] I, lag interacted with the stimu[illegible] used on the second tests of targets, F (2, [illegible] $= 3.82$, $MS_e = 8{,}977$, $p < .05$, and di[illegible] tractors, $F\ (2, 78) = 6.39$, $MS_e =$ [illegible]20, $p < .01$. In Experiment II, how[illegible] interacted with the stimulus form[illegible] on the first tests of repeated items, F (2, [illegible] $= 5.30$, $MS_e = 4{,}848$, $p < .01$. None [illegible] the other interactions approa[illegible] cance. The interaction effects of [illegible] and stimulus forms are apparent in [illegible] where, for Experiment I, the W[illegible] functions showed a large and nea[illegible] increase across lags whereas the [illegible] and PW functions increased only slig[illegible] In Experiment II, the WW and W[illegible] exhibited the greatest lag effe[illegible] the PW and PP functions showed [illegible] nearly parallel increase.

A comparison of the latency data [illegible] initial vs. repeated presentations (av[illegible] across lags) in Experiment I showed that responses were faster on second tests than first tests for at least 35 of 40 *Ss* in all conditions but one. The exception was for distractor items tested first as words then as pictures, for which 32 of 40 *Ss* were slower on the second tests than on initial presentations. Although a similar analysis of the data from Experiment II involves a confounding of response type (positive or negative) with presentation number, it was noted that at least 36 of 40 *Ss* in all conditions were faster on the second tests.

The error data for initial presentations of test items were analyzed using Wilcoxon matched-pairs signed-ranks tests. The difference between the mean proportions of errors to words and pictures was not significant for the target data from Experiment I; however, significantly more errors were made for distractor pictures than words ($p < .01$, two-tailed test). The error rate was also higher for picture stimuli than for words on initial tests in Experiment II ($p < .05$, two-tailed test).

The error data for second test presentations were analyzed separately for the four trial types collapsed across lags and for the lag data collapsed across trial types. A Friedman two-way analysis of variance by ranks indicated that there were no significant differences between the four trial types for the target and distractor data of Experiment I. For Experiment II, however, the Friedman analysis was significant, χ^2 (3) = 9.6, $p < .05$. Multiple sign tests indicated that the only significant difference was between WP trials (mean error rate = 7.1%) and PP trials (.5%).

Although the error rate increased as a function of lag for targets in both Experiments I and II, neither increase was significant. A Friedman analysis showed that lag had a significant effect on the error rate for distractors in Experiment I, χ^2 (2) = 9.3, $p < .01$, and multiple sign tests indicated that fewer errors were made at Lag 24 (2.9%) than at Lag 4 (4.4%) or at Lag 12 (6.6%).

A comparison of the error data for initial vs. second presentations (averaged across lags) in Experiment I showed that the error rate decreased with repetitions for all target conditions (Wilcoxon test, $p < .01$). For distractors, the error rate increased from Presentation 1 to Presentation 2 for those items tested first as words ($p < .01$), but there was no significant difference in the error rate for P trials vs. PW and PP trials. For Experiment II there was no significant difference in the error rate for W trials vs. WW and WP trials, but the error rate was less for PW and PP trials than for P trials ($p < .01$).

Discussion

The present studies were designed to investigate stimulus form and lag effects on recognition performance and to test the generality of a recognition model. The results will be interpreted in terms of the model in that differences in error rates for different target or distractor conditions will be assumed to represent differences in the relative familiarities of those items. The assumption that errors are generated only from the decision stage will necessarily have to be modified if evidence exists that errors can result from failures in other processing stages, such as in stimulus encoding or response selection. On the other hand, differences in response latencies that are not accompanied by differences in error rates will be assumed to represent differential facilitation of encoding processes.

In both experiments, responses were faster to word stimuli than to pictures on initial tests. This is to be expected since the pictures were original drawings that had never before been seen by *Ss*. According to the model, these differences should reflect greater expected durations for the encoding stage on P trials than on W trials. The decision stage should not be affected by stimulus form since the familiarity value of any test item is determined by information derived from the conceptual code onto which the perceptual codes of the word and picture are mapped. This interpretation is supported by the error data from initial target presentations in Experiment I which showed no significant differences on W and P trials. For initial tests of distractors in both Experiments I and II, however, significantly more errors were made on P trials. These results could be taken to indicate that distractor pictures result in different familiarity values than distractor words. However, it is also possible that, as for target items, they are about equally familiar and the error rate difference is due to a greater probability of misidentifying the pictures than the words. This effect could have been mitigated for targets since *Ss* had previously studied the names of the pictures.

Responses were faster in both experiments for repeated items that were tested twice using the same stimulus form (i.e., for WW and PP trials) than if the forms were different (i.e., for WP and PW trials). In Experiment I, there were no error rate differences between these four types of trials, but stimulus forms did affect the error rates for repeated items in

Experiment II. The Experiment I results are consistent with other data (Juola, 1973) and with the interpretation that the decision to respond before or after an extensive memory search is based only on the familiarity value derived from the conceptual code of the test item. Although repetitions might facilitate execution of the encoding stage, especially if the stimulus forms are also repeated, this facilitation apparently ends once the appropriate conceptual code is uniquely identified. The decision process in recognition tasks employing the fixed target set procedure appears to be independent of the stimulus form used at the time of test or during earlier presentations of the test item.

The error data for repeated items in Experiment II indicate that memory for stimulus form might be used in the decision process. This decision could occur in at least two levels of processing: (*a*) during the construction of the perceptual code of the test item or (*b*) during extended memory search if the familiarity derived from the conceptual code is of an intermediate value. In either case a decision could be based on obtaining a match between the perceptual codes constructed on two presentations of an item. Thus for the continuous paradigm, it is possible that the decision stage is not separable from the encoding stage of recognition.

An analysis of the lag data also supports the contention that encoding and decision processes are separable in Experiment I and confounded in Experiment II. In Experiment I, response latencies for all types of trials increased with lag, but this increase was more pronounced for items presented as pictures on their second tests. Lag effects for repeated items were apparently independent of the forms used on the initial tests of target and distractor items. The lack of any effects of stimulus form of initial items on the lag data suggests that the stimulus form effects for repeated items were due solely to differences in the encoding stage. The larger lag effects for WP and PP trials than for WW and PW trials indicate that not only is the encoding stage for picture stimuli affected more by repetitions than that for words (e.g., the repetition effect was much larger for PP trials than for WW trials), but also the facilitative effect of repetitions decays more rapidly for items tested as pictures.

In Experiment II, increasing lags between presentations also caused increases in response latencies for repeated items. However, the pattern of interactions between stimulus form and lag effects differed from Experiment I in that the stimulus forms used on the initial tests, but not those used on second tests, interacted with lag. The lag effects on response latencies for repeated items were much greater for those tested as words on their initial presentations than for those tested as pictures. This result is consistent with the hypothesis that *S*s compare the perceptual code of the test item with retained visual information from earlier tests of the item. For WW and PP trials, a decision can be made during or immediately after the construction of the test item's perceptual code. For WP and PW trials, this decision cannot be made until the alternative perceptual code is activated (or reconstructed) which might first necessitate access of the common conceptual code. This representation of the decision process is predicated on two assumptions: (*a*) visual information for both words and pictures is retained in long-term memory (Hintzman & Summers, 1973) and (*b*) the visual information for words decays faster (or becomes nondiscriminative sooner) than that for pictures (Snodgrass, Wasser, Finkelstein, & Goldberg, 1973).

The model derived from earlier recognition studies using the fixed memory set paradigm is consistent with the data from Experiment I, but it needs to be modified to handle the Experiment II results. For the case in which the target items are members of a well-defined set, the decision to make a positive or negative response cannot be based upon matching a current perceptual code with the trace of one presented earlier, since both targets and distractors can be repeatedly tested. For the continuous procedure, however, decisions can be based upon matches obtained during the encoding stage of recognition. In either experimental paradigm, a decision can be determined by the familiarity (or activation level) of the conceptual code that represents the test item. If, however, the familiarity is of some intermediate value that does not allow for relative certainty of discrimination between targets and distractors, a more extensive search of memory might be executed before a decision is made. This search could involve the retrieval of the target set and the scanning of its contents for the presence or absence of the test item if the set is well-learned, whereas, for the continuous paradigm, this search might involve the retrieval of alternative per-

ceptual representations of the test item in a search for one that had been constructed earlier.

RETRIEVING ATTRIBUTE AND NAME INFORMATION FROM SEMANTIC MEMORY[1]

ELIZABETH F. LOFTUS[2] AND WILLIAM COLE

University of Washington

In two experiments, Ss retrieved instances of well-learned semantic categories (e.g. ANIMALS). In Experiment I, two types of restrictors were used: Sometimes the instance had to possess a certain attribute (e.g., it had to be small), and sometimes its name was restricted (e.g., it had to begin with the letter *M*). Prior knowledge about the type of restrictor differentially influenced the retrieval of these two types of items. In Experiment II, Ss produced category instances that simultaneously satisfied both an attribute and a name restriction (e.g., ANIMAL–SMALL–M). Ss invariably took longer to respond when the name restrictor was presented before the attribute restrictor rather than afterward. A dictionary–network model, which embodies the notion that intrinsically different processing strategies operate in the retrieval of attribute vs. name information, accounts nicely for these results.

One technique for studying semantic memory is to ask *S*s simple questions about material they already know and to measure how long it takes them to answer these questions. The reaction times (RTs) obtained are then used to make inferences about the processes used for retrieval.

In several experiments that have used this technique, *S* was required to produce a member of a category that satisfied some restriction. For example, he might be asked for the name of a *fruit* that is *yellow*, or an *animal* that begins with the letter *Z* (e.g., Freedman & Loftus, 1971; Grober & Loftus, in press; Loftus & Suppes, 1972). In the Freedman and Loftus study, category–adjective and category–letter pairings (hereafter referred to as adjective and letter stimuli, respectively) were randomly "mixed" together in a long sequence of presentations. In the Grober and Loftus study, this mixed condition was included, but, in addition, *S*s received two nonmixed conditions: one in which they saw only adjective stimuli, and the other in which they saw only letter stimuli. It was thus possible to compare the speed of producing a *fruit–yellow* when it occurred in a mixed vs. a nonmixed condition. A major finding was that RT to an adjective stimulus w[as] independent of whether *S* knew that h[e] would be seeing an adjective; that is to say, RT to an adjective was equal in mixed and nonmixed conditions. However, *S*'s responses to letter stimuli were dramatically affected by his expectations; he responded significantly faster in the mixed condition. Because mixing had a differential effect on adjective and letter stimuli, two retrieval processes were thought to occur; that is, the process of retrieving a category member when the restriction is on a *quality* or *attribute* of that member (e.g., it must be yellow) was thought to be different from the process of retrieving a member when the restriction is on the name of that member (e.g., the name must begin with the letter *Z*).

An alternative interpretation was proposed to us by a grant review panel at the National Institute of Mental Health. The panel argued that the adjective–letter difference might not be the result of intrinsically different processing strategies, but rather of the fact that the letter and adjective cues impose different degrees of constraint or uncertainty. When *S* is in a nonmixed–letter condition, he first sees a category for some interval of time, and then a letter appears. He must respond as

quickly as possible with a member that begins with that letter. During the interval between the category and letter, there is a fixed number of stimulus alternatives that *S* can expect as the forthcoming restricting letter. When *S* is in the nonmixed–adjective condition, however, the set of alternatives he can expect is ill-defined and innumerable. In a mixed condition, there is a great deal of uncertainty as to the identity of the forthcoming restriction; any letter or adjective is possible. The reason that "unmixing" reduces RT for the letter stimuli may be that uncertainty is considerably reduced; the reason it has no effect for adjective stimuli may be that uncertainty is hardly reduced at all.

Experiment I was designed to test the feasibility of the "uncertainty" interpretation. As in earlier studies, *S*s saw nouns paired with adjectives or letters that were presented in mixed and nonmixed conditions. However, sometimes *S* was told at the beginning of the trial that the forthcoming restrictor would be one of two or one of four possibilities. Compared to a condition in which no information is given at the start of the trial, both the two- and four-cue conditions considerably reduce the uncertainty as to the identity of the forthcoming restrictor.

Experiment I

Method

Subjects. The *S*s were 24 undergraduates at the University of Washington. Each participated in one experimental session lasting approximately 45 min.

Materials. Fifty-four noun categories were selected, and each category was paired once with the first letter of a common category member (e.g., FRUIT–P) and once with an adjective descriptive of some common category member (e.g., FRUIT–YELLOW). Thus, 108 unique pairs were created, and each pair was hand printed in block letters on a 5 × 8 in. index card. Each card, then, contained a noun category on the left side and a restricting letter or adjective on the right.

The 108 items were presented in nine blocks of trials. In three blocks, adjective (M–A) and letter (M–L) stimuli were randomly mixed together. Of the remaining six blocks, half contained only adjective stimuli (O–A), and the other half contained only letter stimuli (O–L). Within each type of block (mixed, O–A, or O–L), *S*s received before each trial either zero, two, or four cues, among which was the restrictor being used on that trial. For example, in the two-cue O–L condition, just before the presentation of FRUIT–P, *S* might be told that on this trial the restrictor would be either A or P. The *S* was then shown the category, FRUIT, and after a 1-sec. interval, one of the two cues mentioned was shown. The *S*'s task was to produce from memory an item that belonged to the noun category and began with the restricting letter. On the four-cue trials, before each stimulus was displayed, *S* was given four items, among which was the forthcoming restrictor. On the zero-cue trials, the stimulus cards were displayed without preliminaries.

The three cue conditions (zero, two, or four) and three types of blocks (mixed, O–A, and O–L) resulted in nine distinct blocks of trials. A Latin square balancing procedure determined the ordering of the nine blocks that each *S* received.

Each O–A and each O–L block contained nine adjective and nine letter stimuli, respectively, while the mixed blocks contained a random selection of nine letter and nine adjective stimuli. A new randomization was performed for each *S* with the restriction that throughout the experiment as a whole, a stimulus, such as FRUIT–P, appeared an equal number of times in each of the three cue conditions and as often in a mixed condition as a nonmixed one.

Procedure. Each *S* was told that we were investigating typical memory processes, that he would see category names followed by either an adjective or a letter, and that he was to produce an item that belonged to the category and fit the restriction imposed. The cue conditions were explained, and each *S* was informed before each block of trials which condition was in effect for the block. Sixteen warm-up trials preceded the session, illustrating the varieties of conditions in the experiment.

The *S* sat in front of a screen in which was a window covered by half-silvered glass. The index card containing the stimulus was placed in the dark enclosure behind the mirror and was revealed by illuminating the enclosure. The *S* spoke his response into a microphone placed in front of him.

A trial consisted of the following: (*a*) in two- and four-cue conditions, the cues were spoken by *E*. (*b*) a warning tone was sounded and, following a brief interval, the noun category was illuminated; (*c*) after a 1-sec. interval, the restrictor was automatically illuminated, and simultaneously an electric timer with a dc clutch was started; and (*d*) *S*'s verbal response activated a voice key that stopped the clock and terminated the illumination of the stimulus. If *S* did not respond in 15 sec., the trial was terminated by *E*.

Results

Only correct responses (97%) are included in the following statistical analyses. Responses were grouped into 12 classifica-

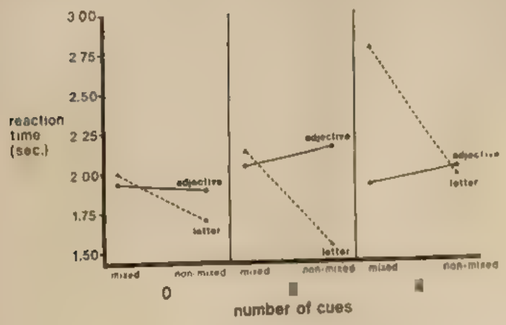

FIGURE 1. Mean reaction times for adjective and letter stimuli in mixed and nonmixed conditions. Data are shown separately for the zero-, two-, and four-cue conditions.

tions depending on type of restrictor (adjective or letter), number of cues (zero, two, or four) and presentation sequence (mixed or nonmixed). Median latencies were obtained for each S's responses in each of the 12 classifications. For each classification, group mean latencies were obtained by averaging medians for individual Ss, and these are plotted in Figure 1. A three-way analysis of variance with repeated measures was done on the latency data. The significant findings were as follows: a nonmixed presentation led to faster responding than a mixed presentation (1.86 vs. 2.12 sec.), F (1, 23) = 6.57, $p < .05$, and this variable interacted with type of restrictor, F (1, 23) = 13.47, $p < .01$. From Figure 1 we can see that the interaction results from the fact that mixing had no effect on adjective trials, but had a substantial and consistent effect on letter trials. Apparently, Ss disregard the cues on adjective trials, but not on letter trials.

Although Ss were somewhat faster when given no cues than when given two or four cues (with zero cues, $\bar{RT}$ = 1.88 sec.; with two, 1.95 sec.; with four, 2.15 sec.) this effect was not statistically significant, F (2, 46) = 1.85, $p > .10$. Furthermore, number of cues did not interact with any of the other factors ($p > .10$).

Discussion

In Experiment I, Ss were asked to retrieve category members that were either (*a*) restricted in that they had to possess a certain attribute, or (*b*) restricted in that their *name* had to possess a certain feature. The RT for producing the first type of member was independent of whether S knew in advance that the restriction would be on the attribute. However, the RT for producing the second type of member was reduced when S knew in advance that the restriction would be on the name. Reducing the uncertainty as to the identity of the forthcoming restrictor with advance cues did not facilitate RT, as an uncertainty interpretation would predict, but in fact slightly increased RT. These data argue against the proposal that the differential effect on adjective and letter stimuli of mixing trials is due to differential uncertainty, and support the notion that intrinsically different processing strategies may be operating.

Although the number of cues had no statistically significant effect in Experiment I, one cannot help but notice that the RT's in the four-cue letter conditions were unusually long. One tentative hypothesis (suggested to us by E. B. Hunt) is that S pays attention to the cues, yet interference is produced by an "overloading" of short-term memory. When adjective stimuli are presented, S acts as if he is ignoring the cues. Confirmation of this possibility must await the outcome of further research. Whatever the explanation, the fact that providing four cues prior to a stimulus has differential effects on the responses to adjective and letter stimuli strengthens o view that intrinsically different processin strategies are operating.

Before suggesting what strategies may be operating in the retrieval of attribute vs name information, we describe a second e periment that bears on the uncertainty iss In this experiment, Ss were presented with stimuli consisting of a noun category plus both an adjective and a letter (e.g., ANIMAL–SMALL–M) and had to produce a member of the category that satisfied the two restrictions. That is to say, the response had to be a member of the category that began with the given letter and to which the adjective was applicable (e.g., MOUSE). The Ss saw the category first, but the order in which the adjective and letter restrictors were presented was varied: on half of the trials the adjective came .5 sec. before the letter (e.g., ANIMAL–SMALL–M), while on the remaining trials the letter came first (e.g., ANIMAL–M–SMALL). Reaction time was taken from the onset of the last restrictor.

When the to-be-presented stimulus is ANIMAL–SMALL–M, during the interval between

SMALL and M there is a fixed number of stimulus alternatives that *S* can expect as the forthcoming restrictor. However, when the letter comes first, and *S* is anticipating the adjective, the set of alternatives he can expect is ill-defined and innumerable. In other words, there is a great deal of uncertainty as to the identity of the forthcoming restrictor—any adjective is possible. An uncertainty hypothesis predicts *S* would respond more quickly in the former case than in the latter.

Experiment II

Method

Subjects. The *S*s were 16 students at the New School for Social Research. Each participated in one experimental session lasting approximately 50 min.

Materials. Forty-six noun categories were selected, and each category was paired with a letter and an adjective (e.g., ANIMAL–SMALL–M). Two index cards were prepared for each category: One contained the adjective restrictor on the left side and the letter restrictor on the right, while the other card contained the reverse arrangement. Throughout the experiment, then, each category was presented as often with the adjective before the letter as with the adjective after the letter.

Procedure. Each *S* was told that we were investigating human memory. He was told he would be presented with a category name followed by a letter and an adjective, and that he was to provide a word that belonged in the overlap defined by the triplet. For example, if shown the stimulus ANIMAL–SMALL–M, he was to produce the name of a small animal that began with the letter M. It was explained that sometimes the letter would appear before the adjective, and sometimes afterward.

The *S* sat in front of a screen in which was a window covered by half-silvered glass. An index card containing the restrictors was placed in a dark enclosure behind the window and was revealed by illuminating the enclosure. The *S* spoke his response into a microphone placed in front of him.

A trial consisted of the following events: (*a*) *E* spoke the name of the category; (*b*) 2 sec. later the first restrictor was illuminated; (*c*) after a .5-sec interval, the second restrictor was illuminated, and simultaneously an electric timer with a dc clutch was started; and (*d*) *S*'s verbal response activated a voice key that stopped the clock and terminated the trial. If *S* did not respond in 10 sec., the trial was terminated by *E*. Twenty warm-up trials preceded the experimental trials.

Results

Only correct responses (96%) are included in the following analyses. Responses were grouped into two classifications depending on whether the adjective came before or after the letter. Median latencies were obtained for each *S*'s responses in each of the two classifications. For each classification, group mean latencies were obtained by averaging medians for individual *S*s. These computations yielded a value of 1.00 sec. when the adjective came first, and a value of 1.45 sec. when the adjective came second. These means are significantly different, $t(15) = 5.612$, $p < .01$.

Two median RTs were also computed for each category, one for responses to adjective–letter stimuli and the other for responses to letter–adjective stimuli. For 43 out of 46 categories, *S*s produced a response more quickly if the adjective occurred before the letter restrictor; for only 3 categories, the reverse result occurred.

When the letter comes first, and *S* awaits the adjective, there is a great deal of uncertainty as to what the restrictor will be. An uncertainty interpretation correctly predicts that *S*s will take longer to respond in this condition.

General Discussion

The present experiments required *S*s to retrieve well-learned category members from semantic memory. In the first experiment, noun categories were paired with either an adjective or a letter, and these stimuli were presented in a randomly intermixed sequence of trials or in a nonmixed sequence. Reducing the uncertainty as to the identity of the forthcoming restrictor with advance cues did not facilitate RT, as an uncertainty interpretation would predict.

In the second experiment, noun categories were paired with both an adjective and a letter. An uncertainty interpretation seems to correctly predict that *S*s will take longer to respond when the letter restrictor is given first. In spite of the fact that an uncertainty interpretation makes a correct prediction in Experiment II, it in no way explains the results of Experiment I. What is needed is a model that can handle both of these results.

The Dictionary–Network Model

The model we propose attaches some importance to the finding of Experiment I that

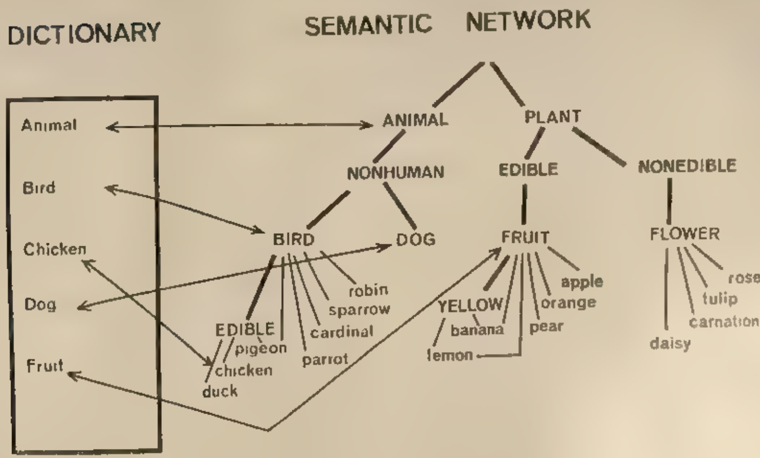

FIGURE 2. The dictionary–network model of semantic memory

the time to respond to an adjective stimulus is independent of whether *S* knew he would be seeing an adjective, but the time to respond to a letter stimulus is not independent. This finding suggests to us that intrinsically different processing strategies may be operating, and this notion is embodied in the following model.

First, we assume that when a word is stored in semantic memory, at least three kinds of information about that word are included: semantic, phonemic, and orthographic information. The assumption is reasonable since we know that *S*s use these three kinds of information when they search for particular words (Brown & McNeill, 1966).

We call the model the dictionary–network model, for reasons that will become obvious. It includes a "dictionary," as diagrammed in Figure 2, which is simply a listing of the lexical items of the language. As to the question of what constitutes a lexical item, we realize that it could be a word, a morpheme, an idiom, or some other unit, but we do not attempt to decide on the question of how the listing is ordered. The dictionary includes both phonemic and orthographic information about each of its entries, and, furthermore, each entry serves as an address telling where semantic information can be found. Thus, we have a content-addressable system in which each entry provides direct access to the portion of semantic memory that represents the meaning of that entry.

The semantic network is a highly complex arrangement of interconnected concepts or categories. Information about the subsets of each category as well as its supersets is included. Within each category [illegible] clusters of items that have [illegible] mon may exist. So, for ex[illegible] and yellow fruits may b[illegible] another in memory.

To illustrate, the word *animal* [illegible] an entry in the dictionary. Since [illegible] nary itself contains phonemic and [illegible] information about the word *ani*[illegible] use this information to answer questions like "What letter does the word [illegible] begin with?" To answer a question about the meaning of the word, it is [illegible] part of the semanti[illegible] information. Figure [illegible] pr[illegible] network that might be e[illegible] someone's semantic m[illegible] can use the information [illegible] semantic network to answer que[illegible] animal?" or "What is the name of [illegible] animal?"

Using this as a general [illegible] begin to describe how *S* manag[illegible] an answer to the kinds of questions he is asked in our experiments. How does he find (*a*) a category member to which a particular adjective is applicable (e.g., edible birds); and (*b*) a category member beginning with a [illegible] letter (e.g., an animal beginning with *D*)

Consider case *a* in which *S* must name an edible bird. We now assume that the retrieval process has at least three major steps. In keeping with our earlier view (e.g., Freedman & Loftus, 1971), the first step consists of entering the appropriate category—*birds*. The next step consists of finding an appropriate cluster of items and picking a member of it. Once this member is found, the third step

involves looking up the "name" of the item by reentering the dictionary via a pathway from that member to its name. Thus, *S* finds that the edible bird he has picked is called a *chicken*. At first glance, the notion that one could find a member without knowing the name of that member may seem awkward. But, on second glance, there is no reason why a particular type of category member, or any other concept for that matter, must necessarily have available a single name for it. Clearly, there can be concepts without names.[3] For example, one can comprehend the concept of a "navigational instrument used in measuring angular distances, especially the altitude of sun, moon, and stars at sea," without the name *sextant* being accessible (Brown & McNeill, 1966). The dictionary-network model is a reasonable system that allows access of conceptual meaning via the lexical entry in the dictionary, as well as permitting use of the meaning as a direct guide to the lexical entry.

Consider case *b*, in which *S* must name an animal beginning with the letter *D*. Again, *S* begins by entering the *animal* category, which is accomplished by looking up *animal* in the dictionary and going directly to the portion of memory that contains information on the meaning of *animal*. The next step is somewhat different for questions of this type. Here we assume that *S* systematically proceeds along pathways leading from animal instances to the dictionary representations of the names of those instances. This quasi-parallel simultaneous search proceeds toward the dictionary from all possible members (though a less dominant member may start off more slowly or slightly later). The dictionary is used to determine whether a given *animal* instance is one that begins with the letter *D*, and the search terminates when one is found.

Effect of Advance Knowledge

An explanation in terms of the model of the differential effects on adjective and letter trials of advance knowledge about the type of restrictor is straightforward. On adjective trials, the first step of the process is to enter the category. The next step, which involves finding the appropriate cluster to enter, cannot begin until *S* knows what cluster he is to enter. The *S* essentially must wait until the adjective is presented before he can begin this next step. Thus, knowing that an adjective is forthcoming should be of no help; that is, RT to O–A stimuli should equal RT to M–A.

For letter stimuli, a different situation exists. Here, the first step of the process is entering the category. The next step is a quasi-parallel simultaneous search toward the dictionary. That is to say, some number of pathways leading from category instances to the dictionary representations of those instances is traced. This step can be started during the interval between the presentation of the category name and the restricting letter if *S* knows a letter is forthcoming. Thus, RT to O–L stimuli should be faster than RT to M–L stimuli.

Effect of Order of Presentation of Attribute and Name Restrictors

Turning now to Experiment II, the dictionary–network model can easily handle the main result, viz., that *S* is faster to produce a category member subject to two restrictions when the adjective restrictor is presented first. The reasoning is as follows. Whether the adjective comes first or second, the first step of the retrieval process is to enter the noun category. When the adjective does appear first, *S* can then enter an appropriate cluster of items. At this point, he systematically proceeds along pathways leading from instances that are within that cluster to the dictionary representation of the names of those instances. The dictionary is used to determine whether any of the instances begin with the appropriate letter, and the search terminates when one is found. As before, this quasi-parallel simultaneous search can be started during the interval before the restricting letter appears, since *S* knows a letter is coming.

When the letter appears first, however, the picture is somewhat complicated. The *S* may do one of two things. First, after entering the category, he may begin to trace pathways toward the dictionary, attempting to find a member that begins with the given letter. Once he finds the member, he must go back

[3] This point is not particularly original. For example: "Concepts need not have names [Collins & Quillian, 1972, p. 316]," and "Concepts ... need not correspond in a one-to-one fashion with words. In fact, most concepts have no simple natural language equivalent [Rumelhart, Lindsay, & Norman, 1972, p. 216]." As to the question of what form of representation the nonverbal aspect of a concept takes, we do not attempt to decide that issue here.

to the semantic network to see if the adjective applies to it. This strategy requires an extra "trip" between the dictionary and the network. Alternatively, to save the trouble of this extra trip, *S* might simply wait until the adjective arrives, essentially converting a "letter-adjective" trial into an "adjective-letter" trial. Either way, the prediction is a slower RT when the letter appears first.

We might mention that our prediction for Experiment II is not obvious: Other quite reasonable models would not make this prediction. For example, one type of set-theoretic model assumes that once a category is entered, its members are sequentially searched in a relatively fixed order and that the search is terminated when an appropriate instance is located (see, e.g., Rosch, 1973). To the extent that retrieval involves such a successive consultation of the memory store, the speed of retrieval should not be a function of the order of presentation of adjective and letter. If each instance is successively examined to see if it meets both specifications, and the search terminates when such an instance is found, there is no reason to expect that presentation order will affect RT.

A slightly different serial model assumes that *S*s enter a subcategory defined by the category name and the first restrictor and begin searching in a fixed order for an instance which satisfies the second restriction. This model would predict that RT is faster when the letter is presented first. The reasoning is as follows: When the letter is presented first, a very small subcategory is usually defined, and finding an instance that fits the adjective restrictor should be a very easy matter. For example, if given *Animal-M-small*, searching the category *animals beginning with M* should result in rapid production of a small animal beginning with *M*, since roughly half of the members of that subcategory could conceivably (depending on *S*'s criterion) be considered small. When the adjective is presented first, the subcategory defined by the noun and the adjective is searched to find an instance that fits the letter restrictor. Since the standard of acceptability is much higher now (the instance must begin with a particular letter), the expected length of search for an instance meeting this standard is longer. In other words, a serial search for an instance meeting the letter restriction would inv[illegible]e consultation of many more items.

A Final Comment

Can anything be said abou[illegible] [illegible]e absolute speed of responding to a lette[illegible] [illegible]n adjective stimulus? Is one case more d[illegible] [illegible] than the other? At the present ti[illegible] [illegible]e have no definitive answer to this que[illegible] Response times depend to a large exte[illegible] character-istics of the pool of possible [illegible]ses; adjective and letter stimuli restri[illegible] to different response pools. If, for exa[illegible], the pool happens to contain a "dor[illegible]" category member, that is, one with a [illegible]quency of being given as an exempla[illegible] category, then (other things equal) th[illegible]nse will be relatively fast (Freedman [illegible]tus, 1971; Loftus & Suppes, 1972). In [illegible]ven experiment, then, whether adject[illegible]uli will be faster or slower than lette[illegible]uli depends largely on the particular adj[illegible] and letters we choose to include, and t[illegible] of responses to which they refer. F[illegible] reason, the dictionary–network model i[illegible]n the issue of the difficulty of adjecti[illegible] letter restrictors per se.

SHORT REPORTS

PARTIAL CATEGORY CUING: THE ACCESSIBILITY OF CATEGORIES

RICHARD E. PARKER [1] AND LINDA WARREN

Williams College

In order to investigate the hypothesis that the retrieval of some retrieval cues reduces the probability of retrieving other retrieval cues, experimental *S*s were given half of the category names from a categorized word list at the time of recall, while control *S*s were given no category names at the time of recall. The results supported the hypothesis and were interpreted as supporting a hierarchical model of retrieval from the memory store.

Rundus (1973) offered a conception of the retrieval process which by its own nature tended to limit the accessibility of information in memory. He introduced a hierarchically organized model of the memory store with retrieval from retrieval cues (RQs) down to words being accomplished by means of a series of random draws. All draws were assumed to be with replacement. The probability of any particular word being accessed from a particular RQ was equal to the ratio of that word's strength of association with the RQ to the sum of the strengths of association with the RQ of all the words associated with the RQ. This is the ratio rule. It was also proposed that both the presentation and recall of a word increased the strength of association between the word and the appropriate RQ. This combination of hypotheses produces the position that the retrieval of one word increases its own probability of retrieval, while at the same time reducing the probability for the other words associated with the same RQ. This ultimately leads to the termination of recall.

Another implication of the model is that the presentation of list words as cues for retrieval, by increasing their own strength of association with an RQ, should reduce the probability of retrieval for other words. This is the well-known negative effect of giving list elements as cues for retrieval, first reported by Slamecka (1968). In order to test this prediction directly, Rundus (1973) varied the number of words from a category given to *S* as cues. According to the model, giving proportionally more list elements as cues for a category should cause proportionally fewer other words from that category to be recalled. His results supported this prediction.

Rundus (1973) also proposed that the retrieval of RQs obeyed this same set of rules, which is the point of interest of this paper. In his model, the experimental list served as the center for a series of random draws with the RQs associated with the list serving as the pool. As before, the probability of retrieval was dependent on the ratio rule, and the presentation and retrieval of an RQ strengthened its association with the list. Thus, according to Rundus's model the presentation or retrieval of one RQ should increase its probability of retrieval, while at the same time reducing the probability of retrieval of the other RQs. Therefore, for the recall of a categorized word list, if *S*s were given only some of the category names as RQs, then the retrieval of the other RQs should be impaired. The purpose of this experiment was to test this higher level hypothesis.

Method. There were 16 control *S*s and 16 experimental *S*s with conditions run in a random order. Each *S* was paid $1 for his services.

Two sets of 40 words, each set consisting of 20 categories, 2 words per category, were selected from the Battig and Montague (1969) norms such that none were proper nouns. The sets of words were so composed since an examination of Tulving and Pearlstone's (1966) data indicated that the maximal effect would be obtained by the use of a large number of small categories. These category names and members were recorded on magnetic tape in a blocked fashion, with the category name first, followed by the two category members. For the experimental condition, the names of the categories were typed on index cards. For the control condition, a set of 10 numbers was typed on index cards.

Each *S* was tested individually. All *S*s were fully advised concerning the procedure and the composition of the lists before the presentation of the first list. All *S*s were told that their object was to recall as many category members as possible and that the category names were presented solely for their benefit. In addition, experimental *S*s were told that their optimal strategy would be to first recall as many words as they could without using the index cards on which the category names were typed. After doing this, they could try to use the index cards to facilitate further retrieval. These instructions were designed to decrease any tendency to recall cued categories earlier than noncued categories, always a concern in studies of cued recall.

After the instructions, *S* was presented, by means of a tape recorder, one of the lists of 20 category

[1] Requests for reprints should be sent to Richard E. Parker, who is now at the Department of Psychology, University of California, San Diego, P. O. Box 109, La Jolla, California 92037.

TABLE 1

CATEGORY RECALL DATA EXPRESSED AS MEAN PER S BY LIST, CONDITION, AND CATEGORY TYPE

Type of category	List 1		List 2	
	Experimental	Control	Experimental	Control
Cued	8.8	5.1	8.4	3.7
Noncued	2.9	4.8	2.6	4.6
Total	11.7	9.9	11.1	8.3

names and 40 category members at a 2-sec/item rate. If he was in the experimental condition, S next read aloud, from index cards at a 2-sec/item rate, 10 of the category names. According to the model, this should increase the strengths of association to the list of the 10 category name RQs. After this, the index cards were placed face down beside S, and he was given 2.5 min. for written recall. In order to cue each of the categories equally often, half of the experimental Ss read the category names that had been presented in the odd serial positions, while the other half read those presented in the even serial positions. In both cases, these names were read in the same order in which they had been presented originally.

If S was in the control condition, the procedure was the same except that the cards containing the 10 numbers were substituted for the cards containing the 10 category names.

Thirty seconds after the end of the recall interval each S was presented the other list of 20 category names and 40 words. This was deemed desirable since Rundus's (1973) results indicated a rather small effect for the manipulation. All Ss remained in the same condition for both the first and second lists.

Results and discussion. In order to determine whether or not giving experimental Ss category names as RQs introduced a differential guessing strategy, the intrusion data, by condition and trial, were compiled. All values varied around 9% of the total correct recall, indicating no differential guessing strategy. The words per category recalled by the two groups were also calculated. They varied between 1.6 and 1.7 for both lists, with the control group tending to recall slightly more words per category. However, the difference was clearly not significant. For the experimental Ss, there was no difference in the number of words per category recalled in cued and noncued categories.

The data of primary concern are the category recall data contained in Table 1. In Table 1 and hereafter, List 1 refers to the first list studied by S, regardless of its content, while List 2 refers to the second list studied by S, also regardless of the words in the list. For the purpose of data analysis, each control S was yoked with an experimental S who had studied the two lists in the same order. This yoking was used solely to provide a distinction between "cued" and "noncued" categories for control Ss. A category was scored as recalled if either category member was recalled. The category rec[illegible] data for List 1 indicated that experimental S[illegible] called slightly more categories than control [illegible] $(1, 30) = 6.51$, $p < .05$, effect size $\omega^2 = .04$. T[illegible] type of category, whether cued or noncued, had highly significant effect, $F(1, 30) = 52.93$, $p < .001$, $\omega^2 = .32$; and the Category Type $\times$ Conditi[illegible] interaction was also highly significant, $F(1, 30) = 41.10$, $p < .001$, $\omega^2 = .25$. Thus, the data indicate that experimental Ss recalled more cued [illegible] than control Ss but recalled fewer noncued [illegible] than control Ss. This is as predicted by [illegible] (1973) model. As is apparent from Table 1 [illegible] data for List 2 were very similar to the data f[illegible] List 1. Thus, the category recall data suppor[illegible] proposition that the retrieval of some cate[illegible] reduces the probability of retrieving other catego[illegible] The same effects were present for the word re[illegible] data: Experimental Ss recalled 70% of the cued words as opposed to 22% of the noncued words; control Ss recalled about 38% of each type of word

Another possible explanation of these [illegible] be based on the retention intervals of cued a[illegible] cued words. Maybe the effect is due to a [illegible] retention interval for the cued words. If t[illegible] a shorter retention interval for the c[illegible] for the noncued words, then it would not be possib[illegible] to evaluate the validity of Rundus's (19[illegible]) model. To test this possible explanation, experim[illegible] response sheets were divided into fifths on [illegible] of total number of correct words recalled. [illegible] data for both List 1 and List 2 are given in Tab[illegible] in terms of the percentage of total cued-wor[illegible] noncued-word) recall and in terms of t[illegible] amount of recall for each fifth. For each S wh[illegible] recalled some cued word [illegible]nd some non[illegible] ($n = 14$ for List 1, n [illegible] for List 2), the median recall position occupied by cued and noncued words was also calculated. For List 1, the mean of these median positions for cued words was 10.5 and for noncued words, 6.5, by randomization test, $p <$ .0[illegible] Thus, for experimental Ss the cu[illegible] appeared later in the recall outpu[illegible] words. This is the exact opposite of what a reten[illegible] tion interval argument would require. As the m[illegible]

TABLE 2

PERCENTAGE (AND MEAN NUMBER) OF WORDS RECALLED [illegible] CUED AND NONCUED CATEGORIES FOR EACH FIFTH OF THE EXPERIMENTAL Ss' RE[illegible]

Fifth	List 1		List 2	
	Cued	Noncued	Cued	Noncued
1	15.3 (2.14)	34.3 (1.59)	20.0 (2.75)	20.0 (.86)
2	18.6 (2.60)	24.3 (1.13)	19.8 (2.73)	20.6 (.89)
3	21.5 (3.01)	15.4 (.71)	19.7 (2.71)	20.9 (.90)
4	23.6 (3.31)	8.9 (.41)	19.7 (2.71)	20.9 (.90)
5	21.0 (2.94)	17.0 (.79)	20.7 (2.85)	17.7 (.76)
Total	100 (14.0)	100 (4.6)	100 (13.8)	100 (4.3)

amount of recall data in Table 2 indicate, this difference was basically due to the difference in total amount of recall. Since *S* knew that the category names would be available later, he may have tended to withhold cued-word recall. This may have contributed to this result. Any such tendency, of course, could have only had the effect of reducing the magnitude of the obtained results. In any case, the retention interval for cued words was not shorter than the retention interval for noncued words. Similarly, for List 2 the mean median word position for both cued and noncued words was 9.9. Thus, these data indicate that the argument of different retention intervals is not tenable. The lengths of the retention intervals did not differ in the required direction.

It should be noted that both the reading of the 10 category names and the freedom to use them later as cues were necessary in order to eliminate the above possibility of different retention intervals. Having *S* merely read the 10 category names and not to have them available later would create the problem of different retention intervals. It would be to *S*'s advantage to recall the cued categories first before he forgot their names. Furthermore, according to the model it was necessary to have *S* read the cues in order to establish different strengths among the RQs. Thus, the dual manipulation was necessary.

A second alternative explanation for the obtained results is that experimental *S*s spent more time trying to retrieve from the cued categories to the neglect of the noncued categories. However, this explanation does not seem viable for the current experiment both because of the long recall interval and because experimental *S*s recalled more cued words than noncued words in each fifth of their output. This is apparent from the mean amount of recall data in Table 2.

In conclusion, the results clearly indicate that when an *S* is given some of the category names from a categorized word list as RQs at the time of recall, his recall of these categories is enhanced. This result is consistent with the findings of Tulving and Pearlstone (1966). Moreover, at the same time, *S*'s recall of the other categories is reduced. This is the more surprising and revealing result. It is also consistent with Rundus's (1973) model of the recall process. While the present data support Rundus's model, it should be noted that his model is not entirely adequate. In particular, it is not able to account for sequential aspects of recall. Even in free-recall experiments the output order does become stereotyped (e.g., Bousfield, Puff, & Cowan, 1964). This is in addition to other designs in which *S* is specifically asked to order his output. In any case, the present data do support Rundus's conception of the recall process. By so doing, they support a hierarchical model of the memory store, with retrieval of one RQ reducing the probability of retrieving other RQs.

EVIDENCE FOR RETROACTIVE INTERFERENCE IN RECOGNITION FROM REACTION TIME[1]

ANDRIES F. SANDERS[2]
Institute for Perception, TNO, Soesterberg, The Netherlands
LESLIE WHITAKER AND CHARLES N. COFER
Pennsylvania State University

Retroactive inhibition (RI) was measured in the A–B, A–D; A–B, C–D; and rest-control paradigms. No RI was evidenced for any group by the conventional measure of number of correct responses in a recognition test of retention. However, strong indications of interference were found using a reaction time measure of response latency to the first-list pairs tested at retention. This extends the Postman and Stark results and indicates that the associative matching test is not entirely free of interference in the sense of generalized response competition.

The hypothesis that retroactive inhibition (RI) in the A–B, A–D paradigm may be due to suppression of the repertoire of first-list responses was proposed by Postman and his associates (Postman & Stark, 1969; Postman, Stark, & Fraser, 1968) on the basis of the fact that when learning of both lists and the test for retention of the first list are carried out by an associative-matching procedure no or very little RI occurs. This finding, of course, contrasts with that seen in studies in which the responses must be recalled. Consequently, Postman et al. (1968) suggested that RI might occur on the basis that first-list responses were not available at time of test, maintaining, however, that the first-list associations are still intact as they can be manifested on the matching test. It should be clear, however, that suppression of the first-list response repertoire is simply a mechanism additional to any specific item interference that may arise, as it does, for example, in the A–Br paradigm (Postman & Stark, 1969) and that item-specific interference cannot be ruled out because suppression of the first-list response set may occur (Postman & Underwood, 1973, p. 24).

Various experiments have been reported in which item-specific interference has been obtained, either in addition to or in the absence of evidence for loss of the first-list response set (Birnbaum, 1970, 1972; Delprato, 1972; Weaver, Duncan, & Bird, 1972; Weaver, Rose, & Campbell, 1971; Wichawut & Martin, 1971). Postman and Underwood (1973) have suggested limitations on the permissible conclusions to be reached from some of these studies, all of which involved the recall method. It has seemed to the authors that a further exploration of the associative-matching procedure itself would have merit. First, it would be desirable to replicate the findings of Postman and Stark (1969). Second, it is possible, with a matching test, to add information to what is provided by the number of correct matches by measuring reaction times. T[illegible] measure has often been proposed as an index of a[illegible] strength, although it may perhaps be give[illegible] tive interpretations in a matching test as op[illegible] to a recall test. In the matching results report[illegible] by Postman and Stark performance w[illegible] close to perfect in the A–D and certain other p[illegible], and one could therefore argue that perfo[illegible] the matching test was not sensitive to diff[illegible] associative strength but that reaction time [illegible] be. While it would obviously be possible t[illegible] an experiment in which matching performance would not be at a virtually perfect level, perfor[illegible] in the Postman and Stark experiment was very high. Since the conclusions concerning the supp[illegible] the first-list response pool come fro[illegible] ment, evidence from another me[illegible]sure of [illegible] ance seems desirable.

METHOD

The experiment involved three independent gr[illegible]ps of 10 female *S*s each, one for each of th[illegible] A–B, A–D; A–B, C–D; and A–B, control [illegible] paired associates of each list co[illegible] single letters as stimuli and one-syllable fo[illegible]-letter adjectives as responses.[3] A study–test procedure was followed, with the test part of each trial being in a recognition format, as described below. The control group performed an arithmetic task f[illegible] interval after A–B learning of the same duration as required for interpolated learning (IL) in the other groups.

Subjects. The *S*s were volunteers from classes in introductory psychology at the Pennsylvania State University who received credit toward their grades for participation in experiments. Assignment of *S*s to conditions was made randomly prior to arrival at the laboratory.

Materials. There were two sets of stimulus terms (A_1, A_2) which were combined to generate four basic

[3] The materials were the same as those used by Postman and Stark (1969). We are indebted to L. Postman for providing them.

lists. In each group *S*s were assigned so that four *S*s learned A_1–B_1 as original learning (OL), while two *S*s learned each of A_1–B_2, A_2–B_1, and A_2–B_2 as OL.

Several rules were employed in the construction of the pairs: (*a*) Stimulus letter and first letter of the response were different; (*b*) there was no phonemic overlap between the name of the stimulus letter and the response term; and (*c*) there was no apparent associative connection between the stimulus letter and the response. In the A–D list the responses to the same stimuli did not begin with the same letter as in the A–B list. Rule *c* was also applied in the construction of the A–D and C–D lists.

Procedure. A given study–test trial consisted, first, of the presentation of the 10 pairs one after another for 3 sec. each and, second, of 10 recognition tests in each of which one stimulus term was presented simultaneously with all 10 response terms. There was an interval of 2 sec. between the study trial and the first recognition test of the following test trial. An *S*'s response on the recognition test items advanced the memory drum so that the next stimulus term and the 10 responses were exposed. The interval between the tenth recognition test of a test trial and the next study trial was 2 sec. This procedure of alternate study and test trials continued until *S* had achieved 3 successive perfect trials following the first trial on which he responded correctly to all stimuli. Consequently, the first list was overlearned. There were 10 study–test trials of the second list (A–D or C–D), the first presentation of this list following 2 min. after the completion of OL. In the control group, this 2-min. interval was followed by 9 min. of work on an arithmetic task which required simple addition of digits, with the total number of digits added in successive 30-sec. periods being displayed to *S* as knowledge of results. At the completion of the interpolated task, there was a 3-min. rest interval after which *S* was given 3 consecutive test trials, each conducted as in OL, for the A–B list. (No study trials or knowledge of results were given on these test trials.)

In the study trials four different orders were used for the presentation of the pairs. The orders of presentation of the stimuli in the test trials were different from any of these, and there were 10 different orders of the responses in each test trial. In these orders each of the 10 response positions was correct once, with a different correct position (randomly chosen with restrictions) over the series of test trials. After each test trial *S* was told the number correct she had achieved on that trial. After the interpolated task, the first retention trial was given in the same trial order as the last test trial in OL.

Apparatus and manner of response. Three Stowe memory drums were used to make unnecessary any changing of tapes between lists. A reaction-time apparatus provided 10 buttons for *S*, and *S* was to press the one which corresponded to that one of the 10 responses simultaneously displayed on the memory drum which she thought to be correct. She was told to be sure of the response before making it but to respond as quickly as possible once she had made her choice. Thus, each *S* was urged to give fast but accurate responses. The numbers from 1 to 10 were affixed to the memory drum, each corresponding to one of the 10 responses displayed on each one of the 10 recognition tests of a test trial, and *S* called out the number of the response as she pressed the corresponding button. This enabled *E* to determine whether the response was correct. The *E* read the reaction time of the response from a digital counter in hundredths of a second. The *S*'s reaction, as indicated, advanced the drum, there being a ½-sec. delay between the button press and the appearance of the next stimulus and a new order of the 10 responses. Six Hunter timers were employed to control the drum during the study trial.

Results

First-list learning. The mean number of trials to the first perfect trial was 6.9 ($s^2 = 3.2$) for the A–D group, 7.3 ($s^2 = 4.7$) for the C–D group, and 8.7 ($s^2 = 9.1$) for the control group. Statistical analysis of these means yielded no significant differences.

To compute reaction times (RTs), the data for each *S* were handled in the following way. From the 10 RTs for each test trial the median and the first and third quartile (Q) values were determined. The median was used rather than the mean in order to avoid undue influence of extreme scores. Then, for the group of *S*s, the mean values of the median, Q_1, and Q_3 were determined over the values for individual *S*s on each trial. It is interesting to note that the mean of the median individual RT scores dropped significantly from the first trial on which all responses were correct to the final overlearning trial, $F\ (1, 27) = 24.4$, $p < .001$. This was true for all groups as shown by the failure of the Groups × Trials interaction to reach significance. The groups did not differ in the means of their Q_1, median, or Q_3 RT values on the final overlearning trial, $F\ (2, 27) = .220, .863, .905$, respectively.

Second-list learning. Although 10 trials were given on the second list, the first perfect trial was actually reached by Group A–D in 2.4 trials and by Group C–D in 2.3 trials. By this measure, Group A–D shows no negative transfer in comparison with Group C–D. However, the means (in sec.) of the median RT on the first perfect second-list trial were 4.26 for Group A–D and 3.25 for Group C–D. This difference is significant, $t\ (18) = 1.80$, $p < .05$. When difference scores were computed, i.e., when the mean of the median RTs for the final overlearning trial was subtracted from the mean of the median RTs for the first perfect IL trial, Group A–D had a significantly higher difference score than Group C–D, $t\ (18) = 2.31$, $p < .05$. These reaction time differences suggest the occurrence of negative transfer in Group A–D relative to Group C–D, although trials to criterion on the second list did not.

First-list retention tests. The three groups gave virtually identical and almost perfect scores for

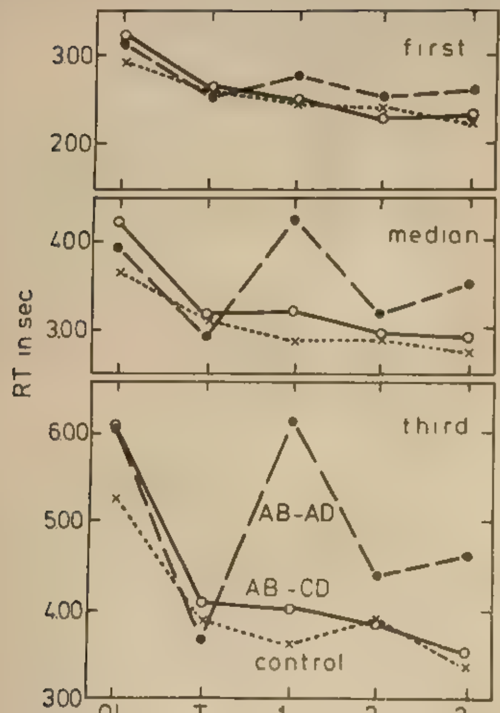

FIGURE 1. Means of quartile1 (Q_1), median, and Q_3 reaction times (RTs) for Groups A–D, C–D, and control on the first perfect trial in original learning (OL), the final overlearning trial in first-list learning (T), and the three retention test trials

correct recognition, thus confirming the results for this measure reported by Postman and Stark (1969). However, a different picture appears for the reaction time measure, as shown in Figure 1 for mean Q_1, mean median, and mean Q_3 scores for each of the three retention tests, the first perfect trial in OL, and the final overlearning trial (T). It may be seen that for all three measures the groups are comparable for T and for the first perfect trial in OL. In addition, they are quite similar for Q_1 over the test trials, the analysis of variance producing insignificant *F*s (2, 27) of 1.268, .641, and .882. However, the groups differ for the mean of the medians at Retention Tests 1 and 3, F (2, 27) = 10.304, $p <$ .01, and =3.825, $p < .05$; the similar smaller difference in the second test is not significant, F (2, 27) = .886. A similar pattern occurs for Q_3. Here the differences for Tests 1 and 3 are also significant, that for Test 2 not. The respective *F*s (2, 27) are 13.359 ($p < .01$), .888, and 4.512 ($p < .01$). Figure 1 shows that the significant differences arise from the longer reaction times for Group A–D, as compared with the other groups which do not differ from one another.

The foregoing analysis indicates that the fastest responses (those at Q_1) in the retest of A–D do not differ from those found in C–D or in the rest control. However, the responses with reaction times at the median and at Q_3 in A–D do differ from those in the other groups, significantly so at the first and third retention tests. On the first of these tests, it is worth noting that half of the *S*s in A–D show longer median RTs than the slowest *S* in C–D, and eight A–D *S*s show longer RTs than rest-control *S*s. There is no comparable dispersion of RTs for Group A–D in the final overlearning trial of OL.

Three other analyses of the data were made. The first was based on the notion that in the retention tests for A–B in Group A–D *S* may start by recalling the appropriate response from the second list, not making at once the switch from the second- to the first-list pool of responses. As he encounters the first-list response set over the tests of the first retention trial *S* might be able to reinstate the first-list response pool so that he would not make and have to reject the initial responses to later stimuli in the trial. Such a process would predict a decline in RTs over the first retention trial. An analysis was therefore made by listing for each *S* his median RT on Recognition Tests 1 through 10 during the first retention trial and averaging across differences for Tests 1 and 3 are also significant, that trial. While an analysis of variance for the rest-control group's data for test position was significant, F (9, 162) = 3.48, $p < .01$, the analysis was not significant for the other groups. Hence, there is no evidence for recovery of the List 1 response pool over the 10 recognition tests in either Groups A–D or C–D.

The second analysis followed that of Runquist (1957) who related the number of correct responses to a given stimulus–response (S–R) pair with its resistance to RI in a recall task. In the present study, RTs on the first retest for pairs which yielded incorrect responses during OL were compared with RTs for pairs always correct. The analysis showed that the median RT for previously missed pairs was greater than the median RT for pairs always correct for 22 of 27 *S*s. (Three *S*s made no errors in acquisition.) This is significant by sign test at $p < .05$. The 5 *S*s whose median RT for missed responses was less than or equal to the median RT for their correct responses were distributed as follows: 2 controls and 3 AB–CD *S*s. It is difficult to argue that this is strong evidence for strength of specific S–R bonds, however, particularly in the light of a correlational analysis by *S* of the RTs on the following trials: (*a*) first OL 100% correct trial, (*b*) final OL trial, (*c*) first retention test, (*d*) second retention test, and (*e*) third retention test. While some correlations reached a significant level ($r = .540$, $t \geq 1.8$) for some *S*s, no correlations showed a consistent trend either for all *S*s or within each group. Thus, there was no evidence to support the role of individual associative strengths as measured by RT in interlist transfer or retention.

The third analysis was an attempt to determine whether the responses in Group A–D whose reaction times were at Q_1 were distinguished from the rest of the responses. The only factors that could be examined were the serial position of the item in the first retention trial and the position of the correct

button for each item on that trial. Neither an analysis of variance nor a correlational analysis yielded significant relations between either of these factors and reaction times of first-list retention-test responses.

Discussion

There are four major findings from this experiment, aside from the replication of Postman and Stark's (1969) failure to find RI in A–D on an associative-matching test so far as correct responses are concerned. (*a*) Reaction times in second-list learning were elongated for Group A–D with respect to those for C–D. (*b*) Reaction times at the first retention test for List 1 were elongated in Group A–D as compared to the other groups, and this elongation persisted over the remaining retention tests. (*c*) Some responses in A–D (those at Q_1) did not show this elongation. (*d*) Efforts to relate specific associative strength, position in the test order, serial position of the item, and position of the correct button failed to relate to reaction times on the first retention test.

If one defines negative transfer and RI as the occurrence of any deficiencies of performance in the A–D paradigm as compared to C–D and the rest control, then both have been found in this study in the reaction time measure, despite the absence of negative transfer in terms of trials to criterion in second-list learning and the absence of RI in terms of correct responses on the matching test. The interpretation of these findings is somewhat puzzling in view of the presence of the correct responses on each test in every trial.

One could interpret operationally defined RI in terms of diminished associative strength of first-list responses. Such an interpretation finds no direct support in our data, however. A second interpretation that fits both the negative transfer and the RI found is a response competition notion. Thus, negative transfer in terms of reaction time would be produced in the A–D case if, when *S* sees a stimulus term, he thinks of a first-list response. He will, of course, fail to find this response in the set of alternatives provided and will have to find in the set that response which goes with the stimulus. The same process would produce RI if the second-list responses, at the end of 1L, now are dominant and one occurs when a stimulus is presented. Again *S* would not find that response among the set of alternatives on the first-list retention test and would either have to identify the correct response in the set or attempt to remember what it was for that stimulus and then confirm the memory by checking for the response among the alternatives.

This kind of interpretation, which at least seems plausible, essentially amounts to that of generalized response competition. Hence, the negative transfer and the RI found in the present data suggest the presence of generalized response competition in the associative-matching situation, not detected by the simple measure of number of correct choices.

CLARIFICATION OF THE ROLES OF ABSOLUTE AND RELATIVE FREQUENCY ON LIST DIFFERENTIATION

MILDRED MASON[1] AND LEONARD KATZ
University of Connecticut

Three different ratios (.20, .50, and 1.00) of List 1 to List 2 trials were investigated under two levels of absolute frequency (6 or 12 trials apportioned between the two lists). A list differentiation test immediately following List 2 learning employed three response categories ("List 1," "List 2," "neither list"). Results clearly pointed to the effects of absolute frequency on list differentiation. Contrary to Winograd's finding, list differentiation improved consistently as the relative frequency of List 1 to List 2 trials increased.

The notion of list differentiation (*S*'s discrimination of the previous list membership of test stimulus items) has played a large role in interference theories of memory (see Keppel, 1968). Until relatively recently, however, the phenomenon has been somewhat lacking in both data and explanation. Winograd (1968) found that given an equal number of trials on both lists, list differentiation (LD) improved with absolute frequency. An explanation of LD has been complicated by the further finding (Winograd, 1968; Winograd & Smith, 1966) that an unequal number of learning trials on two lists produces better LD than do balanced frequencies.

However, the issue of whether unequal frequencies do, in fact, improve LD has not been satisfactorily settled. Reported relative frequency effects may be questioned on two counts. First, as Winograd (1968) pointed out, absolute frequency and relative frequency are unavoidably confounded in designs where the number of trials on one list are held constant while varying the number of trials on the second list (e.g., in comparing a three trial–three trial group with a three trial–six trial group). Second, relative frequency effects may possibly be due to differential guessing strategies available to *S*s in the unbalanced frequency conditions. In previous studies LD was tested following List 2 learning by assuring *S*s that every item seen on the LD test had either been on List 1 or on List 2, with *S*s required to make a forced choice into one of the two categories. Conceivably, *S*s with many trials on one list and few trials on the other list could have assigned unfamiliar test words to the list with the fewer trials. This would artificially inflate correct responses on the weaker list and would account for the putative superiority of the three trial–one trial group to the three trial–three trial group.

Bower (1972) also has raised the possibility of differential guessing strategies in an attempt to reconcile the Winograd data on unequal frequencies with the Anderson and Bower (1972) list marker theory of list differentiation. The data on the superiority of unbalanced frequencies on LD constitute an embarrassment to a strength theory of LD as well as to the list marker theory.

The present study was designed to clarify the role relative frequency plays in LD. Two major methodological differences exist b[illegible]he present study and previous studies. First, the independent variables of absolute and relative frequency have been unconfounded by varying the distribution of List 1 and List 2 trials within fixed levels of absolute frequency. This technique has the further advantage of keeping the total temporal dispersion equal for all relative frequencies within any one level of absolute frequency (see Hintzman & Waters, 1970). Second, the list differentiation test used in the present study presented *S* with a forced choice into three "list" categories, instead of two: *S*s were told that each word on the LD test had either been on the first list they learned, on the second list they learned, or not on either list.

In all other important aspe[illegible] position, duration of word exposure, intertrial interval, and interlist interval) the present study attempted to replicate or remain similar to the Winograd (1968) studies.

Method. The desig[illegible] the total number of trials for List 1 and List 2 combined was one of two levels of absolute frequency: a total of 6 or a total of 12 trials. Within each level, three relative frequencies of List 1 to List 2 trials were employed; the ratios were .20, .50, and 1.00. Thus, *S*s in the 6-trial condition received one of the following conditions: 1 trial on List 1, 5 trials on List 2 (1–5); 2 trials on List 1, 4 trials on List 2 (2–4), or 3 trials on each list (3–3). Counterparts in the 12-trial condition were 2–10, 4–8, and 6–6.

Three lists of 20 nouns each were matched for frequency on the Thorndike–Lorge (1944) count; 48 of the 60 nouns were taken from the lists used by Winograd (1968). Each *S* received two of the lists for learning, with the third list serving as the set of distractor items on the LD test. The three lists were counterbalanced across conditions, each list serving as first list, second list, and distractor list for ⅓ of the *S*s in each condition. Five different orders of each list were used. All words were projected onto a screen in the front of the room by a Kodak Carousel slide projector activated by Hunter

[1] Requests for reprints should be sent to Mildred Mason, Department of Psychology, University of Connecticut, Storrs, Connecticut 06268.

timers to advance at 4-sec. intervals. The intertrial interval was 15 sec.; the interlist interval was 45 sec.

The *Ss* were initially instructed that they were participating in an experiment on memory and that they were to try to learn each word as it appeared on the screen. At the end of List 1 learning, *Ss* were instructed that they would be shown a second list of words and that they were to learn those words also. After the last trial of List 2, test instructions were given and test materials handed out. The LD test itself started 35 sec. after the last word of List 2 was shown, and consisted of the 60 words from all three lists arranged in random order on three pages. The LD test required *Ss* to make a forced choice for each word into one of the three categories "List 1," "List 2," and "neither list" on the test booklet. The LD test was timed with a stopwatch, with *E* saying "next" at 4-sec. intervals indicating that *S* was to proceed to the next word. Two different orders of the LD test were used, with half of the *Ss* in each condition receiving each order.

The *Ss* were 72 undergraduates, who participated in partial fulfillment of requirements for an introductory psychology course. There were 12 *Ss* randomly assigned to each condition. Groups of between 1 and 4 *Ss* served simultaneously.

Results and discussion. Figure 1 presents the mean number of correct list identifications for List 1 and List 2 combined. List differentiation appears to be a function of both absolute and relative frequency. An analysis of variance was performed on the combined number of correct List 1 and List 2 identifications for each *S* in each level of absolute and relative frequency. The effect of absolute frequency was significant, $F(1, 66) = 15.65$, $p < .001$. The effect of relative frequency was in the *opposite* direction of that found by Winograd (1968). List differentiation was best when the two lists were presented an equal number of times and was worst when List 1 was presented only 20% as often as List 2. The linear component of the relative frequency effect was significant, $F(1, 66) = 5.22$, $p < .05$; the quadratic component was negligible.

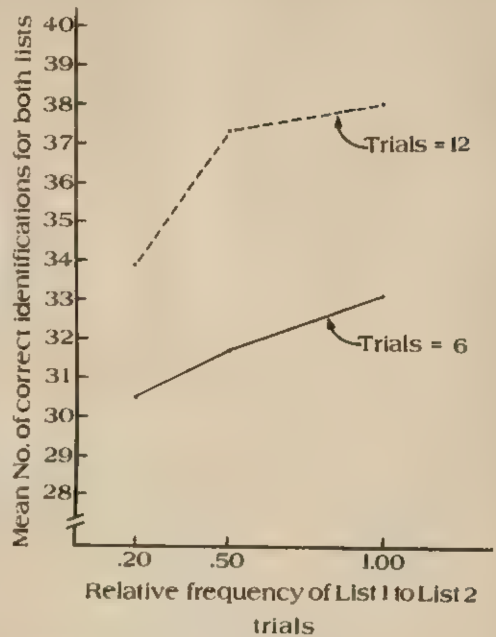

FIGURE 1. List differentiation as a function of absolute frequency (total trials List 1 plus List 2) and relative frequency of List 1 : List 2.

The mean square for the interaction was also nonsignificant and small.

The mean number of correct identifications in each of the three response categories for the six conditions is shown in Table 1. The "Selected" data columns present the mean number of times a particular category was selected, ignoring whether the choice was correct or incorrect. The contention that a forced-choice LD test into two categories biases LD in favor of the less frequent list is supported by the "Selected" data in Table 1. It is precisely at the most unbalanced distribution of trials (relative frequency = .20) that the "neither list"

4–8	9	0	5	18	1	8
6–6	1	0	0	14	2	7

category is used more than would be predicted by chance; χ^2 (2) = 8.89, $p < .02$.

The manner in which the total number of errors within each response category was distributed within the other two response categories is shown in Table 2. The data clearly show more assignments of List 1 items to the distractor category ("neither list") in Conditions 1–5 and 2–10 than in the other condition; χ^2 (2) = 42.61, $p < .001$, for the 6-trial conditions, and χ^2 (2) = 25.11, $p < .001$, for the 12-trial conditions. If there had been no distractor category and if we assume that List 1 items assigned to the distractor category would have been placed in the List 1 category, it is easy to see from the data of Table 2 that there would be a higher frequency of "correct" List 1 responses in the most unbalanced frequencies—the result reported by Winograd (1968). Thus we may conclude that previous reports of LD being poorer in the balanced frequency conditions are indeed due to *S*s in these conditions not having the optimal guessing strategy available to *S*s in the unbalanced frequency conditions (i.e., "if list membership of an item is not known, assign it to the weaker list").

The finding that LD *improves* as relative frequency increases is difficult to account for with either a strength theory or a list marker theory. In addition, both theories run into other specific problems with the data. A strength theory of LD would predict that more List 2 responses would be assigned to List 1 as the number of trials on both lists approached equality. As can be seen from Table 2, this did not occur at the lower level of absolute frequency. At the higher level of absolute frequency, the number of List 2 errors assigned to List 1 was actually less for the 6–6 group than for the 2–10 group, χ^2 (1) = 4.17, $p < .05$. Similarly, strength theory would predict that more List 1 responses would be assigned to List 2 when relative frequency = 1.00 than when relative frequency = .20. This did occur in the lower absolute frequency condition, χ^2 (1) = 5.81, $p < .02$, but not in the higher absolute frequency condition, where the trend was rever[illegible]. We suggest that subjective organization of the lists accounts for these results and conclude with Winograd (1968) and Hintzman and Waters (1970) that absolute frequency affects list organization in addition to the effect it has on strength.

A list marker theory would predict a high[illegible] rate for the distractor items than for Li[illegible] as can be seen from Table 1, did not occ[illegible] importantly, a list marker theory would predict that distractor items have an equiprobable ch[illegible] of incorrectly acquiring a List 1 or a List 2 marker. With the counterbalanced stimulus lists used in this study, the possibilities of associative generalization are the same. The data from Table 2 clearly show that distractor items were incorrectly assigned to List 1 and not to List 2. Furthermore, distractor items are most likely to be [illegible]gned to List 1 when List 1 is weak relative to Li[illegible] 2, χ^2 (2) = 39.71, $p < .001$, for 6 trials, and χ^2 [illegible] 9.74, $p < .01$, for 12 trials. The confusion is cl[illegible] temporal dimension.

Hintzman and Waters (1970) showed th[illegible] LD performance was based on simultaneo[illegible] pendent discriminations on a frequency and a recency dimension. We would [illegible] or temporal, dimension to account for LD [illegible]ing as the number of trials on both lists reached e[illegible]ty. Within either level of absolute frequency [illegible] time is equal among levels of [illegible]ative fr[illegible] Results of the present experim[illegible] strongly sug[illegible] that the way this total te[illegible] dimension is partitioned into two successive time blocks ("List 1" and "List 2") affects temporal discriminability and hence LD. Whether the manner in which the total time is partitioned into two ca[illegible] the retention of temporal information or affects the decision process involved (Hinrichs, 1970) is a matter for future inves[illegible]

RECALL ACCURACY OF EIDETIKERS[1]

CHARLES J. FURST,[2] KENNETH FULD, AND MICHAEL PANCOE
Dartmouth College

A large group of second-, third-, and fourth-grade schoolchildren were shown pictures and asked to recall them verbally. The children were also asked to report whether or not they could see a projected image of the stimulus picture after it had been removed. Recall scores were compared for those children who reported such eidetic images and those children who did not. It was found that the eidetikers recalled considerably more material than noneidetikers, and this result was discussed in the context of questions raised about the nature of eidetic imagery.

In the recent revival of interest in eidetic imagery (EI), the question has been raised as to the uniqueness of this memory phenomenon. Neisser (1970) suggested that since there have been no demonstrable differences in capacity between children who report EIs and those who do not, EIs should be regarded as ordinary visual memories which are somewhat arbitrarily construed by their beholders to be located in front of their eyes. The most thorough available modern evidence fails to demonstrate a strong superiority in visual recall for eidetikers (Leask, Haber, & Haber, 1969), although Haber and Haber (1964) had earlier reported a slight difference in favor of these children.

We recently had the opportunity to check on the recall accuracy of eidetikers during the course of screening a large number of children for EI (for subsequent electroencephalographic studies), and these results are reported here. Free-recall reports of visually presented material were obtained and scored for accuracy, using an open-ended but reliable scoring system. In view of Neisser's (1970) assertion, it was decided that the most relevant test would be of the null hypothesis that no differences in recall accuracy would exist between children reporting EIs and those not reporting EIs. Accordingly, no distinction was made in the recall reports of the children between those items recalled from an EI and those recalled from other types of memory.

Method. A total of 192 children, comprising the second, third, and fourth grades of a local public school, were tested for eidetic imagery. Of these, 21 satisfied the criteria for being included in the eidetic group for this study. These criteria were a reported EI to both of the stimulus pictures, the duration of at least one of which was greater than 15 sec., and visual scanning (as judged by *E*) accompanying the reported eidetic episodes. The remaining children constituted the control group, with the exception of 7 children who were not included in the study because they reported EIs that did not meet the above criteria.

[2] Requests for reprints should be sent to Charles J. Furst, Department of Psychology, Dartmouth College, Hanover, New Hampshire 03755.

The audiotapes of the screening sessions were incomplete or unscorable for 38 *S*s, including 3 from the eidetic group. This left an eidetic group of 18 *S*s and a control group of 129.

The children were individually conducted to a room near their classroom, where they were told that *E*s wished to show them pictures and ask them how they "see things and remember them." They were first given a demonstration of a chromatic afterimage to a colored square on a gray background. This was to aid them in distinguishing between "seeing" an object that was no longer present from merely remembering it.

Each *S* was then shown the first stimulus picture, a detailed colored illustration from a child's storybook, mounted on a gray cardboard backing. The mounted picture was placed on an easel in front of *S* for 30 sec. and then removed, revealing a blank cardboard surface on the easel of the same color as the picture backing. The child was asked to look at the board and to report whether or not he could still see any parts of the picture there. If *S* replied that he could, he was pressed to make sure that he distinguished this "seeing" from remembering and also as to the location of this image. He was asked to describe the image and to report when it had disappeared. When the image had disappeared, the child was asked to recall everything he could remember about the picture. All *S*s not reporting EIs were asked to report all details of the pictures which they could remember. The session was recorded on audiotape. In addition, *E* recorded the duration of any reported EIs and his judgment of whether or not they were accompanied by visual scanning of the easel board. At the conclusion of the recall of the first picture, a second stimulus picture was presented in a similar fashion.

The audiotapes were scored by two persons for number of items accurately reported. The system used gave 1 point for each object in the picture correctly reported and 1 point for each "attribute" of an object. Attributes were defined to include such things as color, article of apparel, or activity, but not location in the picture. For example, a report correctly stating that the picture contained *two elephants, wearing blue bow ties, standing in the road* would score 1 point each for *elephant*, *blue*, *bow tie*, and *road*. An additional point would be added

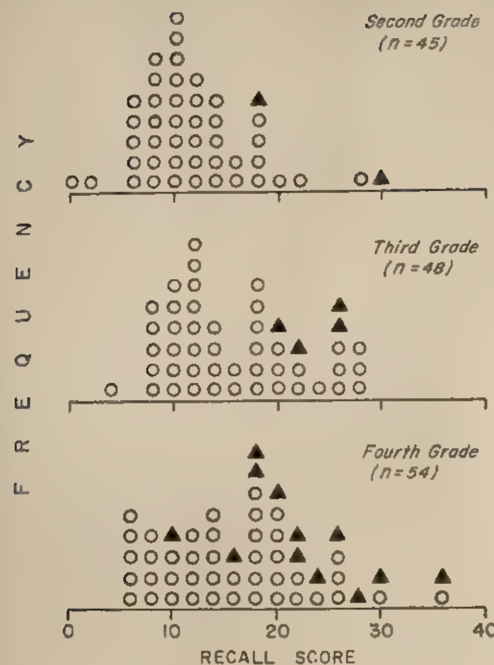

FIGURE 1. Frequency distributions of recall scores for controls (open circles) and eidetikers (triangles).

for stating that there were a pair of elephants but not for the verb *standing*, which would have been interpreted as indicating location rather than an activity. Interscorer reliability was quite high with this method ($r = .99$). No distinction was made between items reported from an EI and those reported from a subsequent memory after the EI had faded. Each S was given a recall score which was the sum of his scores for both stimulus pictures.

Results and discussion. Mean number of items correctly reported is shown in Table 1. An analysis of variance shows the difference between eidetikers and controls to be significant, $F\ (1, 141) = 73.1$, $p < .001$, as well as a main effect of school grade, $F\ (2, 141) = 34.9$, $p < .001$. The interaction was not significant ($F < 1$). The children reporting EIs were clearly superior to controls in their recall

TABLE 1

MEAN VISUAL RECALL SCORES FOR EIDETIC AND CONTROL GROUPS

Group	Grade: Second	Third	Fourth
Eidetikers	24.5	24.3	22.8
SD	7.8	3.2	6.9
Controls	11.9	16.1	16.3
SD	5.3	6.3	7.1

by a ratio of about 3:2. Distributions of recall sc[illegible] are given in Figure 1. An examination of Fi[illegible] 1 reveals that although the eidetikers were gene[illegible]ally near the top of the distributions, there were exceptions, and there were many noneidetic children wh[illegible] did as well as the eidetikers.

These results contradict Neisser's (1970) ass[illegible] that eidetikers do not have a demonstrably [illegible] recall of visual scenes than other people. H[illegible] Haber (1964) reported only slight superi[illegible] visual recall for their eidetikers, although th[illegible] scores were not given. Haber and Haber's [illegible] categories were predefined (i.e., *E*s decided be[illegible] hand what the admissible items would be), wh[illegible] the system used here was more open-ended [illegible] how a visual scene is coded tends to be a hi[illegible] idiosyncratic affair (Bartlett, 1932), an open-end[illegible] scoring procedure might be a more sensitive test [illegible]

The study reported here did not separate out information supplied from a supposed EI and information recalled subsequently through a more commonplace visual memory. As stated above, thi[illegible] was because it was desired to test the hypoth[illegible] differences between children who report E[illegible] others. We often found it diffi[illegible] to determin[illegible] when a child reported an item from an EI and when it was being supplied from memory.[3] R[illegible]son (1969) suggested that the presumed super[illegible] of an eidetiker might be due t[illegible] prolonge[illegible] time, since he would be able to [illegible]ew" th[illegible] some time after the original [illegible]cture had been [illegible]moved. Some such explana[illegible] [illegible]is would be the most direct. However [illegible] are still viable. For ex[illegible], it is pos[illegible]ible that children who report EIs are more talk[illegible] [illegible] hence, report more ite[illegible] during r[illegible] interestingly, it might [illegible] that children with the most vivid visual imagery of a perfectly [illegible]dinary type tend to localize their images in front of their eyes.

Although the eidetikers in this study showed a clear superiority in visual rec[illegible] was not so far off the distributions of sc[illegible] their classmates that one would be justified in con[illegible]cluding from these data alone that they posse[illegible]sed a special ability. Stromeyer and Psotka (1970) have recently reported a remarkable objective demonstra[illegible]tion that an eidetic image can be "photograph[illegible]" in the sense of being highly detailed in texture, at least for one talented adult S. It is still unresolved whether or not the type of eidetic imagery commonly reported by children is of this type. Stromeyer and his co-workers (C. F. Stromeyer, personal communication, 1971) have been unable to demonstrate this, but it remains possible that childhood eidetic

[3] Some of the children reported brief EIs which disappeared before material from it was verbally reported. Other children started out reporting material "seen" on the board and then afterward said that most of the report had been from memory, when the EI had faded. For the 20 reports from which scores for eidetically seen and remembered material could be distinguished, 45% of the material correctly reported came from the EI. There was great variability around this average percentage ($s = 31$), with no relationship between the total recall score and the percent of the material recalled from the EI.

imagery is extremely detailed but fragmentary, and therefore, different from ordinary visual memory.

PROCESSING THE TERMS *RIGHT* AND *LEFT*: A NOTE ON LEFT-HANDERS[1]

GARY M. OLSON[2]
Michigan State University

KEVIN LAXAR
Naval Submarine Medical Research Laboratory, Groton, Connecticut

A simple word–picture verification task using the terms *right* and *left* was run with left-handed *S*s. Unlike right-handers, these *S*s showed no evidence for processing asymmetries between *right* and *left*. In all other respects, however, their performance was comparable to right-handers.

Olson and Laxar (1973) reported a series of investigations which supported the claim that the mental representation of *right* is less complex than that of *left*. Their experiments eliminated simple scanning biases as the source of their effects and suggested rather that asymmetries in the reaction times to simple word–picture displays were due to characteristics of central information processing. These experiments were all run with right-handed *S*s, and it would be of interest to know what comparable performance is like with left-handers. The present paper provides evidence on this question.

The assumption that *right* is the less complex term is quite plausible for right-handers. Their handedness coincides with cultural and social conventions to make right the natural reference direction in the sagittal plane, just as one can argue that aboveness and forwardness serve as reference directions in other planes (Clark, 1973; Olson & Laxar, 1973). However, the picture is much less clear for left-handers. Three possibilities seem to have equal a priori plausibility: (*a*) because left-handers live in an essentially right-handed world, their internal model of space conforms to that of right-handers; (*b*) although social and cultural conventions favor right as the reference direction, the left-hander's handedness is the more dominant factor, yielding *left* as the simpler term; and (*c*) since the criteria leading to *a* and *b* are in conflict, no performance asymmetry comparable to that found with right-handers should emerge. This last possibility could signify either the absence of an underlying conceptual asymmetry or conflict between alternative sets of representations.

Method. The design and logic of this experiment were identical to Experiment I in Olson and Laxar (1973). There were four different displays, containing either the word RIGHT or LEFT in block letters centered in a small square and a black dot located either to the left or right of the square. The *S*s' task was to decide as quickly as possible whether the word correctly named the side on which the dot appeared. The displays in which the word correctly named the side were the *true* conditions, and the other two displays were the *false* conditions.

The displays were presented to *S*s in blocks of 28 trials, each display appearing seven times per block. The first 4 trials in a block were warm-ups and were not analyzed. Each *S* was given four blocks of trials for a total of 96 experimental trials plus 16 warm-ups, all within a single 45-min. session. The order of presentation within each block was independently randomized for each *S* and each block.

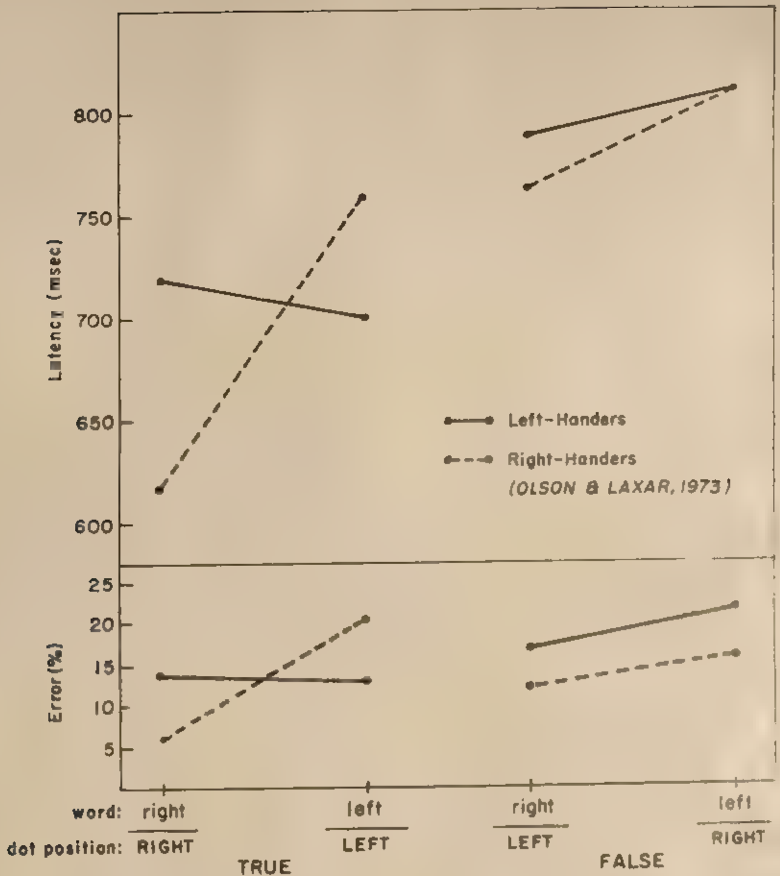

FIGURE 1. Mean reaction times for correct responses and error percentages for right- and left-handed *S*s.

The *S*s sat in a special experimental booth which contained the viewer for a three-field tachistoscope and a response panel at desk-top height immediately below the viewer. This panel contained two keys for *true* and *false* responses and a start button centered above the keys. The *S*s initiated each trial by pressing the start button with one of their middle fingers while their forefingers were positioned on the two response keys. The position of the *true* key was counterbalanced across *S*s. One second after they pushed the start button one of the four displays flashed on and *S*s responded *true* or *false* as quickly as possible. A fixation point was used to direct *S*s to look at the word first. On each trial *S*s were informed of their time and correctness.

The *S*s were 16 left-handed civilian and military personnel, 14 males and 2 females. Left-handedness was judged by asking each *S* which was her or his preferred hand. All *S*s wrote with their left hands.

Results and discussion. Mean latencies were computed for correct responses only for each Block × Display × *S* combination, yielding 16 means for each *S*. Since the performance of the 2 females did not differ from that of the males, sex of *S* was ignored in all of the analyses. The mean latencies and error rates for the four displays collapsed over blocks are shown in Figure 1. Comparable data from Experiment I of Olson and Laxar (1973) are also shown.

A repeated measures analysis of variance of the 256 means for the effects of stimulus word (RIGHT–LEFT), dot position (right–left) and test block (1–4) revealed the following significant effects: (*a*) *true* displays were verified more quickly than *false* ones, yielding a reliable interaction between RIGHT–LEFT and the positions right–left, F (1, 15) = 28.47, $p <$ .001; (*b*) *S*s became faster as the experiment progressed, F (3, 45) = 13.32, $p < .001$. The Dot Position × Blocks interaction approached significance, F (3, 45) = 2.34, $.05 < p < .10$. Analysis of errors revealed no significant F ratios, although the Stimulus Word × Dot Position interaction, F (1, 15) = 3.87, $.05 < p < .10$, and the main effect of blocks, F (3, 45) = 2.41, $.05 < p < .10$, approached significance.

As in the previous experiments with right-handers, stimulus-response (S–R) compatibility effects were very strong. These can be summarized as follows. For each *S* one of the *true* displays referred to the same side as the *true* response key, and this repre-

TABLE 1

SUMMARY OF SIGNIFICANT F RATIOS FOR ANALYSIS OF VARIANCE CONTRASTING LEFT- AND RIGHT-HANDERS

Source of variation	Primary effect	Interaction with handedness	MS for appropriate error term

** $p < .05$.
*** $p < .001$.

sented a compatible (C) relationship. The other *true* display represented an incompatible (IC) relationship. This was also true for the *false* displays. For each S the average difference between the correct reaction times for C and IC responses (IC − C) was computed for *true* and *false* displays separately. The mean difference of 171 msec. for *true* displays was significant, $t(15) = 5.52$, $p < .001$, while the difference of −16 msec. for *false* displays was not. By comparison, the right-handers of Olson and Laxar (1973) had a mean difference of 116 msec. for *true* displays and 17 msec. for *false* ones. An analysis of variance revealed that these S–R compatibility effects for left-handers did not interact with any of the effects revealed by the main analysis, while t tests showed that there was no difference between right- and left-handers.

A comparison of the results for right-handers and left-handers in Figure 1 reveals that their performance was quite different. These data were subjected to an unweighted-means analysis of variance with handedness as a between-Ss factor and stimulus word, dot position, and test block as within-Ss factors. There was no main effect for handedness. Table 1 summarizes the F ratios for the primary within-Ss sources of variation and their interactions with handedness. The only significant F ratio among the other higher order interactions was the triple Stimulus Word × Dot Position × Test Block interaction, $F(3, 72) = 2.93$, $p < .05$. These analyses confirm what can be seen in Figure 1. Of the three possibilities listed in the introduction, c appears to be supported. The absence of any higher order interactions either in the main analysis or in the secondary analysis for effects of S–R compatibility suggests that within this task there was no consistent pattern of trade-offs between right-normalized and left-normalized spatial models. However, no distinction between the absence of a reference direction and conflicting spatial models can be drawn from our evidence. Since our definition of left-handedness was whether S categorized himself as left- or right-handed, perhaps a more sensitive index of handedness or of hemispheric lateralization of function might offer greater insight into the left-hander's conceptualization of space.

The striking contrast between right-handers and left-handers on this task is consistent with the findings of other investigators. For instance, others have found that the performance of left-handers in tasks requiring spatial abilities is neither parallel to nor complementary to that of right-handers, but rather is intermediate (Luria, McKay, & Ferris, 1973). Disorders of spatial orientation are most acute in the right–left dimension (Corballis & Beale, 1970; Howard & Templeton, 1966), and there is evidence that right–left difficulties are much greater for left-handers (Gerhardt, 1959; Hécaen & de Ajuriaguerra, 1964). These facts along with the data reported here reinforce our earlier view that "the conceptualization of the right–left dimension is much more labile, flexible, and subject to disruption than that of the other two spatial dimensions [Olson & Laxar, 1973, p. 289]."

SYLLABLE-DEPENDENT PRONUNCIATION LATENCIES IN NUMBER NAMING: A REPLICATION[1]

STUART T. KLAPP[2]

California State University, Hayward

Previous experiments have shown that the latency for the initiation of pronunciation of words and two-digit numbers depends on the number of syllables to be named. However, Henderson, Coltheart, and Woodhouse have recently shown that the presence of decades (e.g., 20, 30) was confounded with syllables in the number studies, and that this confounding could have accounted for some of the previous data. The present experiment is a successful replication of the naming latency effect for number stimuli controlling for this variable.

Several recent studies have reported that when single words or two-digit numbers are read aloud, the latency from stimulus onset until the *beginning* of overt vocalization increases as the number of syllables to be pronounced increases (Eriksen, Pollack, & Montague, 1970, Experiment III; Klapp, 1971, Experiment I; Klapp, Anderson, & Berrian, 1973, Experiment I). However, Henderson, Coltheart, and Woodhouse (1973) failed to obtain the syllable dependence in latency for naming *numbers*. The purpose of the present investigation was to reassess this phenomenon in light of the considerations raised by these investigators.

In their Experiment I, Henderson et al. (1973) used the same general procedure and material as were employed in the previous number studies (Eriksen et al., 1970; Klapp, 1971). The stimuli were two-digit numbers of two-, three-, and four-syllable pronunciation. The *S*s responded by pronouncing a number as quickly as possible after presentation, and time to initiate vocalization was determined as a function of the number of syllables to be pronounced. The results were ambiguous, with faster latencies for two syllables than for three or four syllables, but with no difference between the latencies for three and four syllables. These ambiguous results contrast with the monotonic increase in latency as a function of syllables reported under apparently identical conditions in the previous studies. However, in the Henderson et al. study there was no control condition to assess whether there were differences in the sensitivity of the equipment to the initial sounds associated with responses of different lengths. Klapp (1971) and Klapp et al. (1973) used a control in which *S*s examined the stimulus for a few seconds, and then pronounced it when a signal appeared. Latencies measured from this signal should be and were independent of the number of syllables. Since Henderson et al. did not provide these control data for their equipment, it is difficult to evaluate the extent to which the relative latencies assigned to the different classes of numbers may be an artifact of equipment activation. Further instability in the data could have resulted from the attempt to assess the relatively small effect of syllables from a somewhat limited number of observations—four trials per stimulus number for each of 15 *S*s, compared to eight trials for 12 *S*s in Klapp (1971

Although the results of the Henderson et al. (1973) Experiment I may be attributed to methodological factors, the results of their Experiment II are quite another matter. They pointed out that in the previous studies, including their own Experiment I, the two-syllable numbers were primarily decades (e.g. 30, 40, etc.), while decades did not appear among the three- and four-syllable numbers. They then showed that two-syllable decades were pronounced with shorter latencies than two-syllable teens (e.g., 13, 14, etc.). Since these stimuli have matched initial sounds, the lack of the above mentioned sound activation control is of no consequence in evaluating this particular comparison. Thus, confounding of decades could account for the previously reported shorter latencies for two-syllable numbers compared with three- and four-syllable numbers. Furthermore, most if not all of the overall effect of syllables reported previously by Eriksen et al. (1970) and by Henderson et al., Experiment I, was attributable to a shorter latency for two as compared to three and four syllables, with little or no effect of three compared to four syllables (although Klapp, 1971, did report a substantial three to four syllable effect). Therefore, Henderson et al. concluded that the previous reports of syllable-dependent latencies for naming numbers may well be attributed to the confounding of decades with syllables without the need to assume that response latency is related to number of syllables. Although these considerations are a problem only with number stimuli and do not apply to experiments demonstrating syllable-dependent response latencies for words (Klapp et al., 1973), it nevertheless appeared desirable to attempt a replication of this effect using new number stimuli not subject to this confounding.

Method. The stimuli were two-digit numbers ending in 7 (yielding four syllables in total pronuncia-

[1] This research was supported, in part, by the Small Grants Program of the Research Foundation of California State University, Hayward. The author wishes to thank Nancy Lankford, who gathered the data, and Alicia Klapp, who prepared the stimulus material.

tion, e.g., 27), in 6 (three syllables, e.g., 26) or in 4 (also three syllables, e.g., 24). According to the principle that vocalizations of more syllables require longer response latencies, the numbers ending in 7 should have longer latencies than the other numbers. However, which digit is used to terminate the number should not matter unless the two-syllable digit 7 is used. Therefore, numbers ending in 4 or 6 should yield latencies which are identical to each other while shorter than for numbers ending in 7. The particular digits 4 and 6 were selected to be distinctively different in vocalization, while equated for syllables. The first digits used in generating the two-digit stimulus numbers were 2, 3, 5, 8, and 9. These particular digits were selected to avoid teens and identical digits (e.g., 66). These five first digits were used with the three ending digits to generate a complete set of 15 stimulus numbers which were prepared on 35-mm. slides using Instantype numbers and projected to subtend a visual angle of 2° high by 3.7° wide. The numbers were presented in 15 blocks, each comprised of all 15 numbers in random order. A brief rest pause occurred after each block. The last 12 blocks were included in the analysis, while the early blocks were regarded as practice.

The *S*s were adult native speakers of English fulfilling a course requirement or serving for $2 pay. The *S*s were alternately assigned to control and experimental conditions until 8 *S*s had been assigned to each condition. Thereafter, all *S*s were assigned to the experimental condition, for a total of 13 *S*s in this condition. Data from an additional *S* in the experimental condition were rejected because 36% of the latencies exceeded 800 msec., including 20% of the total in excess of 1 sec. and several in excess of 2 sec.

The *S*s were seated in a sound-isolation chamber into which the numbers were projected on a rear-projection screen through double-glass sound insulation. The *E* was in an adjacent chamber containing apparatus which automatically provided the sequence of events for each trial. The response latency was measured by an electronic timer which was started when a photocell was activated by the onset of the image or signal light on the projection screen. This timer was stopped by a voice-activated trigger operated by a microphone placed in near contact with *S*'s mouth. Sensitivity was adjusted to the maximum possible, while avoiding frequent activation by breathing.

For the *control* condition, each trial lasted 7.9 sec., during which the stimulus number was present for 6 sec. After the number had been visible for 3 sec., a visual signal light appeared and the timer was started. The *S*s were instructed to pronounce the number as quickly as possible after the appearance of the signal, and the initial vocal sound caused the timer to stop. Any trials on which *S* pronounced the wrong number, corrected himself, or generated stray sounds were repeated at the end of the following block of 15 trials, and these data were included in the analysis.

TABLE 1

PRONUNCIATION LATENCY (IN MSEC.)

Condition	Stimuli: 3 syllable, Number ends in 6	3 syllable, Number ends in 4	3 syllable, $\bar{X}$	4 syllable, Number ends in 7
Control	267.9	269.9	268.9	269.0
Experimental	422.5	419.9	421.2	427.8

For the *experimental* condition, each trial lasted 6.9 sec., during which the number was presented simultaneously with the starting of the timer and remained visible for 3 sec. The *S*s were instructed to pronounce the number as quickly as possible after its appearance, and the initial vocal sound caused the timer to stop. Except for the change in sequence, the procedure was identical to that of the control condition.

Results. For the *control* condition, .4% of the trials had to be repeated due to number mispronunciation, while stray noise or equipment error necessitated repeating another 2.5% of the trials. On an additional .2% of the trials the latency exceeded 800 msec. These trials were assumed to represent inattention on the part of *S*, and the means were calculated without these data. Means were determined for each *S* for the sets of numbers ending in 7, 6, and 4, and the analysis was performed on these means. The results appear in Table 1. Latencies for the numbers with the three different endings did not differ significantly, $F\ (2,\ 14) < 1$, and the overall mean latency for three-syllable numbers was within .1 msec. of that for four-syllable numbers. Thus, the equipment was activated by the sounds of the different classes of numbers with apparently equal speed. This is certainly to be expected, since these sets of numbers were balanced with respect to initial sound.

For the *experimental* condition, the rates of repeated trials were 1.2% for number mispronunciation and 1.7% for stray noise or equipment error. For 1.6% of the trials the latency exceeded 800 msec. and, as in the control condition, the means were calculated excluding these data. There was no change in the direction of the data trend for effect of syllables as a result of discarding these long latencies. As is evident from Table 1, the mean latency was longer for four-syllable numbers than for either of the three-syllable conditions which, as expected, yielded approximately equal latencies. The three conditions differ significantly from each other, $F\ (2,\ 24) = 5.6$, $p < .01$, with both Newman-Keuls contrasts between four-syllable numbers ending in 7 compared to three-syllable numbers ending in 6 or in 4 significant beyond the $p < .05$ level. Four-syllable numbers yielded longer latencies than three-syllable numbers for 11 of the 13 *S*s ($p < .05$, sign test), with the remaining two *S*s showing

latencies which differed by less than 2 msec. between these conditions. Thus, the syllable effect for naming numbers has been replicated in an experiment which controls for the considerations raised by Henderson et al. (1973). The magnitude of the effect was 6.6 msec., which approximates the 5-msec. three- vs. four-syllable effect reported by Eriksen et al. (1970), but which is considerably less than the corresponding 14-msec. effect reported by Klapp (1971).

Discussion. The conclusion that syllable dependent response initiation latencies occur for numbers as well as for words suggests that this phenomenon is not due to perceptual analysis of the visual stimuli into syllabic units (Spoehr & Smith, 1973), since syllables are represented at the graphemic level only for words and not for the two-digit numbers. Although such perceptual analysis may occur for words, it cannot account for the syllable dependency in response latencies for numbers. Klapp et al. (1973) suggested an interpretation which assumes that a vocalization must be programmed before it can be emitted, with longer programming time for more syllables. This interpretation correctly predicts that the effect of syllables on pronunciation latency would occur for various modes of presentation, including numbers as well as words, and even extending to pictorial representations (Klapp et al., Experiment IV

SHORT-TERM MEMORY FOR SOUNDS AND WORDS[1]

EDWARD J. ROWE[2]

LESLIE J. CAKE[3]

Memorial University of Newfoundland, St. John's, Newfoundland, Canada

Memory for triads of words and meaningful environmental sounds was compared following a 20-sec. retention interval, during which *S*s shadowed passages of either poetry or music. Words were recalled better than sounds after music distraction, while the reverse was true following poetry distraction. This interaction suggests that short-term retention of sounds and words might be mediated by different memory processes.

Memory for common environmental sounds has only recently begun to be explored. Miller and Tanis (1971) compared recognition memory for long lists of printed words, spoken words, and sounds and found accuracy scores of 84%, 75%, and 69%, respectively, on a two-alternative forced-choice test. Thus, sounds were recognized at about the same level as spoken words, but at a much lower level than comparable performance reported by other investigators for recognition of meaningful pictures, where the accuracy level usually exceeds 90%. Lawrence and Banks (1973) improved upon the procedure employed by Miller and Tanis by using high-fidelity equipment and lengthening the presentation time for individual sounds. The overall recognition accuracy calculated from *S*s' confidence ratings was 85%, a figure noticeably higher than that reported by Miller and Tanis, but still somewhat below the level of picture recognition.

Philipchalk and Rowe (1971) asked whether memory for sounds vs. words would be differentially

[3] Now at Queen's University.

affected by the requirement to recall the items in their presented order, as had been demonstrated for pictures vs. words in the visual modality. Their results showed comparable performance for sounds and words in free recall, but recall of sounds was significantly worse in a serial recall task. The fact that order information can be better retained for verbal material offers one potential distinction between the processes that mediate retention of sounds and words and raises the possibility of separate verbal and nonverbal auditory memory systems.

The experiment reported here represents a more direct test of the independent-systems hypothesis. Triads of sounds and words were presented for retention in the Brown–Peterson paradigm (Brown, 1958; Peterson & Peterson, 1959) with either verbal or nonverbal auditory distractor activity. The verbal distractor task (repeating passages of poetry aloud) was intended to disrupt verbal memory processes, and the nonverbal distractor (humming passages of music) to disrupt nonverbal memory. If sounds and words are encoded, stored, or retrieved via different systems, selective interference in recall of the two types of triads by the two types of distraction is expected, such that sounds should be recalled better than words following poetry distraction and words should be recalled better following music distraction.

Method. Twenty-four easily identifiable sounds, which ranged 1.4–4.4 sec. in length ($\bar{X} = 3.0$), were selected from a larger pool of items obtained from commercial sound effects recordings (see Philipchalk & Rowe, 1971). Two separate sets of eight triads were constructed and recorded on tape. The individual sounds within a triad were separated by 2 sec. or less of silence, giving a mean triad length of 10.4 and 10.5 sec., respectively, for the two sets. Parallel sets of triads of the dominant labels of the sounds were recorded in a male voice with the items being read at a rate of one every 3 sec. Thus the word triads were all 9 sec. long.

Four different versions of the experimental tape were drawn up for both sounds and words. One of two kinds of distractor material—music (M) or poetry (P)—was recorded on the tape immediately following each triad. The order of occurrence of the distractor material was PMMPMPPM for one version of each triad set and MPPMPMMP for the other. The M distraction consisted of the initial 20-sec. segments of instrumental melodies taken from various types of popular recordings. The P distraction included either complete poems or complete stanzas from poems, read in a female voice and timed to last 20 sec. The word "recall," spoken in a female voice, occurred at the end of each segment of distractor material, followed after 10 sec. by the words "stop writing," and after 3 more sec. by the next triad.

Most of the *S*s were paid volunteers from undergraduate psychology classes. Twenty *S*s each were assigned to the sounds and words conditions, with distractor type as a within-*S*s variable. The *S*s were tested individually or in pairs. If 2 *S*s were tested together, they were separated by a high cardboard shield that prevented them from seeing each other. They were instructed to listen carefully to each triad, to shadow the distractor material, and then to write down the names of the sounds or words from the triad on a prepared answer sheet when given the signal to recall. Ordered recall was not required. Practice in shadowing both music and poetry was provided prior to presentation of the experimental tape. Most *S*s experienced very little difficulty in repeating the poems aloud and humming along with the music segments, so no more than two trials on either the M or P practice material were necessary. The tapes were played through high-quality headphones, and *S*s' shadowing was recorded on a second tape recorder. Equal numbers of *S*s received the two different sets of triads in both the sounds and words conditions, but a slight error occurred in assigning *S*s to each distractor sequence for one set of triads in the words condition only. This resulted in 4 and 6 *S*s being run for each sequence instead of 5 each. Otherwise, the assignment of *S*s to list conditions was completely balanced.

After completion of the memory task, *S*s heard the same set of triads a second time with no distraction and were allowed 10 sec. for immediate recall of each set. The *S*s in the sounds condition were asked to use the same names for the sounds as they had used for recall in the first part of the experiment.

Results and discussion. To control for the possible effects of auditory recognition errors, the recall scores were conditionalized on performance in the second phase of the experiment. Thus, an item had to be reproduced correctly on both tests in order to be counted as correct. If *S* failed to recall an item on both tests, performance on the first test was scored out of the number of items recalled in that condition the second time and adjusted to a denominator of 12 for direct comparison with the other scores. This occurred for eight *S*s who heard the sounds and for one *S* who heard the words. No *S* missed more than one item on both tests.

The results of the second test were also used in scoring the protocols of the sounds group where *S*s' answers did not clearly correspond to the dominant label for a particular item. In these cases the sound was scored as correct if the same name was used on both tests. For both conditions, words which were minimally discrepant from a presented item (e.g., minor misspellings and substitution of plural for singular nouns) were counted as correct, as were homophones of presented items (e.g., *symbols* for *cymbals*). Incomplete recalls and intrusions from previous trials were scored as incorrect.

The recall scores (Table 1) were analyzed by a 2×2 analysis of variance, which yielded a significant main effect of distractor type, $F(1, 38) = 62.7$, and a significant Item $\times$ Distractor interaction, $F(1, 38) = 29.6$, both $ps < .001$. The interaction qualifies the distractor-type main effect, since only word recall was significantly affected by M vs. P distractor tasks. Of the 20 *S*s in the words condition, 19 had lower recall following P distraction, while the remaining *S* had equal scores for both M

TABLE 1

Mean Number of Items Correctly Recalled and Mean Time Spent in Shadowing as a Function of Music and Poetry Distractor Tasks

Type of distraction	Sounds		Words	
	Recall	Shadowing	Recall	Shadowing
Music	9.0	15.1	11.3	16.0
Poetry	8.1	11.4	6.9	11.0

and P triads. With the sounds, 10 *S*s had lower recall following P material, 7 showed the opposite effect, and 3 had equal scores. Comparison of sound vs. word recall within each distractor condition showed that words were recalled better under M distraction, t (38) = 3.71, $p < .001$, while sounds were recalled better under P distraction, t (38) = 1.77, $p < .05$ (one-tailed tests).

Because of the difficulties inherent in scoring *S*s' shadowing of music on an accuracy measure, shadowing performance for both types of distractor material was examined by measuring the total amount of time *S* was actively engaged in shadowing during the 20-sec. retention interval. The means are included in Table 1. Since the responses produced in speaking and humming are qualitatively different, meaningful comparisons between distractor types are not possible. It should be noted, however, that the lower scores produced in shadowing the poetry probably do not reflect a lower degree of accuracy than in the music conditions, as informal observation of the *S*s suggested that performance on the poetry was quite high. The difference between the words and sounds conditions for music shadowing was reliable, t (38) = 2.27, $p < .05$ (two-tailed test). This might be interpreted to mean that attempts to rehearse the words during the retention interval did not interfere with humming as much as attempts at rehearsing the sounds. The reverse is suggested by the poetry shadowing data, but the difference here was not significant, t (38) = 1.05.

The differential effect of music and poetry distractor tasks on recall of sounds and words constitutes evidence for separate verbal and nonverbal auditory short-term memory processes. The results do not allow a firm decision regarding the possible localization of the selective interference in terms of the tripartite division of memory into encoding, storage, and retrieval phases. However, the fact that the recall differences between sounds and words are reflected in the shadowing scores, especially for music shadowing, suggests that the distractor tasks acted to disrupt attempts to rehearse the triads. This conclusion is supported by the informal comments of *S*s, especially those in the words condition, who reported that it was much easier to "think about" the words while humming the melodies than while repeating the poems. Thus, it seems that the interference is at least partly attributable to processes involved in the maintenance of the items in storage through rehearsal, but possible additional effects on encoding or retrieval cannot of course be ruled out.

The form of the obtained interaction between type of triad and type of distraction offers a clue to the way in which sounds are represented in memory. Assume that sounds may be represented either directly in an auditory imagery store or indirectly via their verbal labels in a verbal short-term store, or both. If only the names of the sounds are held in memory, then music vs. poetry distractor tasks should have affected recall of sounds and words in the same way. This clearly did not happen. If the sounds were stored only as nonverbal images, we might expect that the nonverbal distractor task would be more disruptive than the verbal task. This also is not reflected in the data. The most plausible interpretation, then, is that the sounds were represented via both modes, so that retrieval of the image could be used to offset the effects of verbal interference and retrieval of the word label could help counteract the effects of nonverbal interference.

The independence of verbal and nonverbal auditory memory stores has been previously demonstrated by Deutsch (1970), who found that interpolation of additional tones between two comparison tones in a *same–different* judgment task impaired performance, whereas interpolated numbers did not. Furthermore, Crowder (1971) has shown that the interfering effect of a redundant suffix in immediate recall of auditory letter sequences is restricted to verbal suffixes, the effect disappearing when a nonverbal suffix (a buzzer) is used. Both of these findings have been interpreted as reflecting the operation of sensory or precategorical memory processes. The present data show that the distinction between verbal and nonverbal auditory systems is still viable when processing proceeds to the extent of "depth" characterized by more meaningful sounds and real word stimuli presented under less stringent temporal conditions.

SHOCK-ASSOCIATED WORDS IN A NONATTENDED MESSAGE: A TEST FOR MOMENTARY AWARENESS

R. S. CORTEEN[1] AND D. DUNN

University of British Columbia

An experiment was carried out to test for momentary awareness of critical words in a nonattended message during shadowing. On only 1 out of 42 occasions when there was a significant galvanic skin response to critical nonattended words did an *S* signal awareness. This finding was taken as support for the hypothesis that there can be some semantic processing without awareness.

In a recent paper Corteen and Wood (1972) seemed to demonstrate that words that had been previously shock associated, and also words that had a class relationship with the shock-associated words, would give rise to a significant number of phasic skin conductance changes when they were embedded in a nonattended message. The concurrent attended message task involved shadowing a prose passage. The importance of the paper rests entirely on the claim that *S*s were not aware of the significant words in the nonattended channel. The idea of semantic processing without awareness suggests a wide range of interesting possibilities; but the study would be quite trivial if it could be demonstrated that *S*s were aware even momentarily of the significant words.

Corteen and Wood (1972, p. 311) employed a detailed and probing postexperimental interview procedure which certainly appears to indicate that, at the time of the interview, immediately following the experimental sequence, *S*s were not aware of having heard any of the critical words. This procedure, however, does not come to terms with a major criticism, which implies that *S*s might have been aware of the critical words at the time they were presented but that the interference produced by the shadowing task was so great as to produce complete forgetting, not only of the specific words but of the experience of having been aware of anything at all. This is an important and relevant criticism and the present experiment was designed in an effort to provide an answer to it.

The basic technique used in this experiment was a slightly modified form of the method used by Treisman and Riley (1969) where they instructed *S*s to stop shadowing at once and tap if they heard particular target letters in either shadowed or nonshadowed messages. The results obtained by Treisman and Riley indicate that the technique is workable and that detection in nonshadowed messages can be made quite successfully. In the present study the only concern was with responses to targets in the nonattended message, but beyond this and the substitution of a buzzer for ruler tapping, the method used was essentially the same.

Method. The method used was, up to a point, identical to that used by Corteen and Wood (1972). Three city names were presented aurally along with other words and the city names were paired with a mild but unpleasant electric shock. Phasic skin conductance changes were measured concurrently and were used to indicate the successful formation of shock association. The shock-associated city names, together with three city names that had not been included in the shock-association procedure and three nouns that had been in the original shock-association list, were now presented to one ear of the *S*, embedded in a list of randomly selected unrelated nouns. Prior to this, *S*s were given practice in shadowing a prose passage. They were now presented with a prose passage in the ear opposite to that being stimulated by the city names and other nouns and asked to shadow the passage. Skin conductance changes were recorded throughout.

All that has been described above is outlined in detail by Corteen and Wood (1972). The major change was that suggested by the Treisman and Riley (1969) paper. Prior to the dichotic listening sequence *S*s were shown a Morse key which activated a simple buzzer. They were asked to place the fingers of their free (right) hand on the key and they were told that if they heard any city names, in either ear, during the shadowing procedure, they were to stop shadowing immediately and press the buzzer. The importance of accurate shadowing was stressed but the need simultaneously to stop shadowing and press the buzzer upon hearing *any* city name was heavily emphasized.

A total of 19 experimental and 17 control *S*s were run. All *S*s were undergraduate students at the University of British Columbia. The control *S*s were exposed to exactly the same procedure as the experimental *S*s except that there was no prior shock association. The purpose of the control *S*s was to compare the incidence of buzzer pressing to city names when there had been no shock pairing. As it happened the control was unnecessary.

Results. The study confirmed the original findings of Corteen and Wood (1972) almost exactly. Indeed it would have been dismaying if it had not, as it was an almost exact replication. The findings concerning awareness appear to be quite unequivocal. The 19 experimental *S*s were each exposed

[1] Requests for reprints should be sent to R. S. Corteen, Department of Psychology, University of British Columbia, Vancouver, British Columbia, Canada.

to six "critical" words, three shock-associated city names and three other city names. This gave, in all, 114 opportunities to press the buzzer. The buzzer was pressed only once. Naturally this produced a phasic skin conductance response but it was impossible to determine whether this response was to the word or to the process of buzzer pressing. There were 41 significant phasic conductance responses to the remaining 113 critical words and on none of these occasions was the buzzer pressed. Of these 41 responses, 24 (42.1%) were to shock-associated city names and 14 (29.8%) were to non-shock-associated city names. There was a 7.3% responding rate for shock-list control nouns and a 5.7% responding rate for non-shock-list control nouns. The autonomic responding rate to city names of the control *S*s was higher than the rate to control nouns (12.3% vs. 6.9%) but the difference was not significant. The size of a significant phasic response is defined by Corteen and Wood as a change in resistance of at least 1 kΩ occurring within 3 sec. There were two buzzer presses by control *S*s.

Discussion. The hypothesis being tested by this experiment was that the results obtained in the Corteen and Wood (1972) study could be explained if *S*s were momentarily aware of stimulus words in the nonattended channel, but that this awareness was of such a transitory nature that no vestige of it remained at the end of the experiment. The hypothesis was suggested, but only barely supported, by the findings of Norman (1969) and Glucksberg and Cowen (1970) that memory for nonattended items, when they are probed for, persists for only a few seconds. Neither of these two cited studies demonstrated or sought to demonstrate that the items are in conscious awareness prior to being probed for, but they do suggest the idea of momentary awareness with subsequent complete loss.

The findings reported here seem to invalidate the above hypothesis. They do not, of course, deny the findings of Norman (1969) or Glucksberg and Cowen (1970) because, of course, the items they report memory for may only come into awareness when there is specific interruption and probe. But the results do certainly support the position taken by Corteen and Wood (1972) that there is no awareness of certain words in a nonattended channel even though those words are capable of giving rise to a significant phasic conductance response.

It is certainly still possible to argue about the precise meaning of the word "aware"; but insofar as it might be defined as the ability of *S*s to indicate the presence of a stimulus at the time of its occurrence, then this study strongly suggests that there can be autonomic responding to words that are not in the awareness of *S*s at the time of the responding.

RELATION BETWEEN SIMILARITY GROUPING AND PERIPHERAL DISCRIMINABILITY[1]

JACOB BECK[2]

University of Oregon

Four experiments studied the extrafoveal discriminability of a tilted T, an L, an X, and a sideways T from an upright T. In a patterned field in which an *S* did not know where to direct his attention, the discriminability of the figures corresponded to their effectiveness in producing similarity grouping in a pattern of upright Ts. In an empty visual field in which the brightness between a figure and a background was able to direct an *S* where to attend, the discriminability of the figures did not correspond to their effectiveness in producing similarity grouping. The results are interpreted as supporting the hypothesis that similarity grouping involves segregating a pattern into groups on the basis of extrafoveal difference signals that are responded to in parallel, or, if sequentially, very quickly and independently of focal attention.

Beck (1972) proposed that similarity grouping involves segregating a pattern into groups on the basis of extrafoveal stimulus differences that are readily discriminated when attention is distributed and not concentrated or focused. He reported that the similarity grouping produced by rotating some of the figures in a display corresponded to their extrafoveal discriminability in a patterned visual field in which an *S* did not know where to attend, but not in an empty visual field. This difference in the discriminability of figural differences in a patterned and in an empty visual field was interpreted as resulting from a narrowing or focusing of attention. In an empty visual field, the brightness difference between a figure and a background was able to direct an individual where to attend. The present experiments further compare the extrafoveal discriminability of a tilted T, an L, an X, and a sideways T from an upright T in a patterned and in an empty visual field. Beck (1966, 1967) reported that similarity grouping occurs strongly for a tilted T but not for an L, and X, or a sideways T in a pattern of upright Ts.

Experiment I. The patterned visual field consisted of four figures in the corners of an imaginary square 7.62 cm. on a side. Each target consisted of either four upright Ts in each of the four corners or three upright Ts in three corners and an L, a T rotated 45° clockwise (tilted T), or a T rotated 90° counterclockwise (sideways T) in the fourth corner. The lines composing the figures were always at right angles to each other. The figures were made out of black dry-transfer lines .04 cm. wide (approximately .04°), and .32 cm. long (approximately .3°) affixed to white paper. The targets were presented by means of a Gerbrands three-channel tachistoscope in which the preexposure and exposure fields were masked so that a target appeared in a circular field 18.89 cm. in diameter. The luminances of the white backgrounds of the preexposure and exposure fields were 17.13 cd/m². Following the presentation of a target, the preexposure field immediately reappeared. A black dot placed in the center of the preexposure field served as a fixation point. A dot was also placed in the center of the square array on each target and carefully aligned to coincide with the fixation point in the preexposure field. An *S* was instructed to fixate the dot in the center of the square array and told that this would enable him to perform optimally. The distances between the center dot on a target and the figures in the corners were 5.33 cm. (5° 7′ of arc).

The targets with an L, tilted T, and sideways T were presented in three separate sets. Each set consisted of four targets with an upright T in each of the four corners and four targets with an upright T in three corners, and a disparate figure in the fourth corner. An *S* was told before the presentation of each set which disparate figure would be presented in that set. He was instructed to report "same" for targets having all upright Ts and to identify the location of the disparate figure for targets having a disparate figure. An error was counted if an *S* reported a disparate figure when none was present, failed to report a disparate figure, or incorrectly reported the location of a disparate figure. Three of the 8 stimuli in a set were randomly added to a block of trials but were not analyzed (making 11 stimuli in all). The 11 stimuli in a set were presented twice to an *S* in a random order for a total of 22 presentations. The three sets were presented in a different order to each *S*. Thus, each *S* received 66 presentations in the experiment. Each *S* also received 66 presentations in a practice session before the experiment began. The practice period was used to determine an exposure duration that would give an overall percentage correct of between 70% and 75%. In Experiment I, the exposure durations ranged between 23 and 42 msec., with a mean of 30.3 msec.

TABLE 1

MEAN ERRORS AND STANDARD DEVIATIONS IN THE EXPERIMENTS

Experiment	*M*	*SD*
I: Patterned field ($N = 15$)		
Tilted T vs. T	3.1	1.6
L vs. T	4.9	1.5
Sideways T vs. T	6.4	1.6
II: Empty field ($N = 10$)		
Tilted T vs. T	4.3	1.9
L vs. T	3.5	2.2
Sideways T vs. T	5.0	1.5
III: Patterned field ($N = 15$)		
Tilted T vs. T	4.1	2.8
X vs. T	6.2	2.9
Sideways T vs. T	7.5	2.1
IV: Empty field ($N = 15$)		
Tilted T vs. T	2.9	1.6
X vs. T	3.0	1.7
Sideways T vs. T	5.6	1.4

Experiment II. In Experiment II, a single figure appeared on one corner of an imaginary 7.62-cm. square in an otherwise empty visual field. Three separate sets of stimuli were prepared. Each set consisted of four targets containing a single upright T in each of the four corners of the imaginary square and four targets containing either an L, a tilted T, or a sideways T in each of the four corners. An *S* was told before the presentation of each set which two figures (upright T and tilted T, for example) would be presented. An error was counted if an *S* incorrectly identified either a figure or the location of a figure. The procedure and experimental arrangement were the same as in Experiment I. In Experiment II, the exposure durations ranged between 11 and 35 msec., with a mean of 17.4 msec.

Experiments III and IV. In Experiment III, the targets were similar to those in Experiment I. Each target consisted of either four upright Ts or three upright Ts and an X, a tilted T, or a sideways T. In Experiment IV, the targets were similar to those in Experiment II. Each target consisted of a single upright T, tilted T, X, or sideways T on one corner of an imaginary square in an otherwise empty field. The stimulus sets, procedure, and experimental arrangement in Experiment III were the same as in Experiment I and those in Experiment IV the same as in Experiment II. The only differences were that the figures in Experiments III and IV were drawn in India ink and the vertical and horizontal lines of the exposure and preexposure fields were not masked. The exposure durations in Experiment III ranged between 10 and 20 msec., with a mean of 18 msec., and in Experiment IV ranged between 10 and 20 msec., with a mean of 15 msec.

Subjects. Four separate groups of *Ss* who had either normal vision or corrected-to-normal vision when wearing glasses served in the experiments. Fifteen *Ss* served in Experiments I, III, and IV and 10 *Ss* served in Experiment II.

Results. Table 1 presents the mean errors and standard deviations for the experiments. The error rate overall in Experiment I was [illegible]%. Statistical tests of the greater mean error for an L than for a tilted T, t (14) = 3.83, $p < .01$; for a sideways T than for a tilted T, t (14) = 6.49, $p <$ [illegible]; and for a sideways T than for an L, t (14) = 2.96, $p < .05$, were significant. The error rate overall in Experiment III was 37%. Statistical tests of the greater mean error for an X than for a tilted T, t (14) = 2.54, $p < .05$, and for a sideways T than for tilted T, t (14) = 4.21, $p < .01$, were significant. The greater mean error for a sideways T than for an X failed to be significant, t (14) = 1.60, $p > .1$. Thus, the results show that, in a patterned visual field, *Ss* made statistically significantly more errors in discriminating an X, L, and sideways T from an upright T than in discriminating a tilted T from an upright T.

The error rate overall in Experiment II was 27%. Statistical tests of the greater mean error for a sideways T than for a tilted T, t (9) = 1.07, $p > .2$; for a tilted T than for an L, t (9) = 2.22, $p > .05$; and for a sideways T than for an L, t (9) = 1.90, $p > .05$, were not significant.[3] The error rate overall in Experiment IV was 24%. A statistical test of the greater mean error for an X than for a tilted T, t (14) = .26, $p > .5$, was not significant. The greater mean error for a sideways T than for a tilted T, t (14) = 6.04, $p < .01$, and for a sideways T than for an X, t (14) = 5.71, $p < .01$, were significant. When a brightness difference between a figure and a background directed an *S* where to attend, the discriminability of an X and of an L from an upright T was similar to that of a tilted T. In an empty visual field, the discriminability of the figures, as hypothesized, failed to correspond to their effectiveness in producing similarity grouping.[4]

Discussion. The results are consistent with the hypothesis that the effectiveness of stimulus differences in producing similarity grouping correspond to their peripheral discriminability in a patterned visual field in which an *S* does not know where to attend. Beck (1966, 1967) found that Ls and sideways Ts in a pattern of upright Ts grouped more poorly than did tilted Ts. He also found that,

[3] The acceptance of the null hypoth[illegible]poses the problem of a Type II error. In Experi[illegible] an N of 10 increased this possibility. It is, therefo[illegible]nt to point out that the relative discriminability of a[illegible]nd of a tilted T in Experiment II was the opposite of t[illegible]n Experiment I. Though just missing significance, the mean error for an L was less than that for a tilted T in Experiment II. In contrast, in Experiment I, the mean error for an L was significantly greater than for a tilted T. Beck and Ambler (1972, 1973) also found that the peripheral discriminability of an L from an upright T was greater than or equal to that of a tilted T when attention was focused, but that the discriminability of an L became worse than that of a tilted T when attention was distributed over a patterned field. What is suggested is that focused attention increases the sensitivity of the visual system to the variable of line arrangement in the periphery. Information about line arrangement would facilitate discriminating an L from an upright T but would, if anything, because of their similarity in line arrangement interfere with discriminating a tilted T from an upright T.

[4] In Experiment IV, a tilted T was more discriminable from an upright T than a sideways T, but in Experiment II, it was not. A possible explanation is that the vertical and horizontal lines of the exposure field visible in Experiment IV served as cues for the tilt of a figure's lines. It is possible that masking the vertical and horizontal lines in Experiment II reduced the discriminability between a tilted T and an upright T.

though an X had the same slopes of lines as a tilted T, Xs grouped less readily than tilted Ts and similar to sideways Ts in a pattern of upright Ts.

An interpretation of the relation between similarity grouping and peripheral discriminability under uncertainty in a patterned field can be given by assuming that both are based upon stimulus differences computed from the figural properties that are responded to "quickly" and independently of focal attention (Beck & Ambler, 1972). What is proposed is that when attention is distributed over a patterned field, a tilted T is discriminated from an upright T on the basis of a parallel or, if sequential, almost simultaneous readout of differences in their line slopes from a visual information store (Beck & Ambler, 1973). The presence of confusable vertical and horizontal lines is assumed to interfere with a "quick" readout of differences in line arrangement. Thus, an L and a sideways T group poorly and are not discriminable with distributed attention in a pattern of upright Ts. Selective attention, however, can increase an *S*'s sensitivity to peripherally presented differences in line arrangement (Beck & Ambler, 1972, 1973). When a single figure is presented, the brightness difference between a figure and background directs an *S* where to attend and thereby improves the discriminability of an L, sideways T, and X.

The present results suggest that the Xs failed to group as well as the tilted Ts in a pattern of upright Ts because the central symmetry of an X causes it to readily lose discriminability outside of the fovea when it subtends a small visual angle. Under these conditions, the grouping of Xs in a pattern of upright Ts is weak. However, when the lines of an X are made larger, Xs grouped as well as tilted Ts (Beck, 1973).

CATEGORY SIMILARITY AND RETROACTIVE INHIBITION IN FREE RECALL [1]

ISABEL M. BIRNBAUM [2]
University of California, Irvine

Two successive lists of categorized words were presented for free-recall learning. Half of the categories appeared on both lists (repeated categories) and half appeared on only one of the lists (nonrepeated categories). A standard control group learned one list. On the final test of free recall of both lists, different patterns of first-list retention loss were seen for repeated and nonrepeated categories. There was a loss of words within categories in the former case, and a loss of whole categories in the latter.

Recent studies indicate that retroactive inhibition (RI) in free-recall learning is an increasing function of similarity between the category composition of List 1 and List 2. Shuell (1968) found that RI was greater when different words from the same category appeared on both lists than when completely different categories were used on the first and second lists. With a mixed-list design where half of the List 1 categories were repeated (different words from the List 1 category appeared on List 2) and half were nonrepeated (no words from the List 1 category appeared on List 2), there was greater retention loss for words in the repeated categories (Winograd, 1968).

The present experiment was designed to investigate recovery of List 1 repeated and nonrepeated categories over a 10-min. retention interval following

TABLE 1

MEAN NUMBER OF WORDS RECALLED AND MEAN NUMBER OF WORDS RECALLED PER CATEGORY FOR REPEATED (R) AND NONREPEATED (N) CATEGORIES

Data	Control[a]		E_1		E_2	
	R	N	R	N	R	N
Words	14.05	15.22	11.11	11.50	12.44	11.66
Words per category	3.89	3.85	2.94	3.39	3.23	3.49

Note. E_1 = experimental group with a predominance of study trials and E_2 = experimental group with a predominance of test trials in interpolated learning.
[a] R vs. N was a dummy variable in the control group.

two types of interpolated learning (IL); however, chance differences in original learning (OL) in the immediate recall groups precluded the planned comparisons. The remaining groups provided a modified replication and extension of the original phenomenon, and results in these groups are the basis for the present report.

Method. The *S*s were 54 students at the University of California, Irvine, whose participation in the experiment contributed to the fulfillment of a course requirement. The *S*s were run individually and were assigned to groups in randomized blocks in order of appearance at the laboratory.

Lists for OL and IL contained 48 words, 6 words from each of 8 categories. A repeated category appeared on the OL and IL lists and the specific words from the category were different on each list. A nonrepeated category appeared only on the OL list or the IL list. Three different 8-category lists were constructed from a pool of 12 categories with 12 words in each category, using the design described by Winograd (1968). Words were selected from the category norms of Battig and Montague (1969) and two subsets of 6 words from each category were balanced for mean frequency of occurrence in response to the category name. Each category was a repeated category one-third of the time, and any pair of lists contained 4 repeated and 4 nonrepeated categories. If the three lists are designated A, B, and C, then one-sixth of the *S*s in each group learned each of these OL–IL sequences: AB, AC, BA, BC, CA, and CB. Thus, each category and each subset of 6 items within the category was used equally often as a repeated and a nonrepeated category in OL and in IL.

Each list was tape recorded in four different random orders with the restriction that no words from the same category appear in adjacent positions. The words were recorded at a 1-sec. rate and three of the orders were used equally often as starting orders in OL and IL. All *S*s received four alternating study and test trials on List 1. The duration of each trial was 48 sec. and there was a 12-sec. intertrial interval. Three groups were differentiated on the basis of the interpolated task. The control (C) group worked on a paper-and-pencil numerical reasoning task throughout the retention interval. Two experimental (E_1 and E_2) groups received 12 trials of IL and then worked on the numerical reasoning task for 10 min. Group E_1 received a predominance of study trials during IL: each four-trial cycle consisted of three successive study trials followed by a single test trial. Group E_2 received a predominance of test trials during IL: each four-trial cycle consisted of a single study trial followed by three successive test trials. In all groups, the final recall test began 26.5 min. after the last test trial on List 1. The *S*s in Groups E_1 and E_2 were asked to recall the words from Lists 1 and 2 in any order; recall was oral and was terminated after 4 min. had elapsed. The *S*s in Group C were given 2 min. for oral recall of the words from List 1 in any order.

Results and discussion. The mean number of words recalled on the last test trial of OL was 24.8, 22.6, and 24.5 in Groups C, E_1, and E_2, respectively, F (2, 51) < 1.00. There was no significant difference in recall of words from to-be-repeated and to-be-nonrepeated categories, F (2, 51) $= 1.22$, $p > .25$.

Shuell (1968) used a between-*S*s design and found consistently poorer performance in IL when words from the same category appeared on Lists 1 and 2 than when new categories appeared on List 2. In the present experiment, performance on repeated and nonrepeated categories in the IL mixed list showed the same pattern. Three-way analyses of variance of recall in IL (Groups $\times$ Cycles $\times$ Type of Category) either on the first test trial of each cycle or the fourth trial of each cycle (a test trial for both groups) showed that fewer words (ps $< .05$) and a smaller number of words per category (ps $<$ .01) were recalled from repeated categories than from nonrepeated categories during IL. There was improvement over cycles in IL and Group E_1 showed consistently higher recall than Group E_2 (ps $< .01$).

First-list recall of words from repeated and nonrepeated categories in each group is shown in Table 1. The designation of words as repeated and nonrepeated in Group C was a dummy variable. Analyses of variance of absolute recall scores on the final test or loss scores (recall on Trial 4 of OL minus recall on the final test) yielded essentially the same results. There was a significant difference between groups in loss scores based on number of words recalled and number of words recalled per category, F (2, 51) $= 7.12$, $p < .01$, and F (2, 51) $= 5.09$, $p < .05$, respectively, confirming the phenomenon of RI in free-recall learning of categorized lists. There was no significant difference between E_1 and E_2 on either dependent variable (ps $> .10$) suggesting that first-list retention loss is not modified by the pattern of study and test trials in IL when the number of trials is held constant. There was greater RI for words recalled per category in repeated than nonrepeated categories, F (2, 51) $=$ 7.96, $p < .01$, for the Groups $\times$ Type of Category interaction, and there was no significant RI for nonrepeated categories alone, F (2, 51) $= 1.17$, $p > .25$. The results are consistent with those of

Tulving and Psotka (1971) who found no significant reduction in first-list within-category recall when successive free-recall lists contained different categories.

Winograd (1968) found that on the final test of recall, List 1 nonrepeated categories were less likely to be retrieved than repeated categories but more items within a recalled nonrepeated category were accessible. The interplay of these factors yielded an approximately equivalent total number of items recalled from repeated and nonrepeated categories, and the present results in the experimental groups confirm Winograd's findings. Category recall, defined as recall of at least one item from the category, was significantly higher for repeated than nonrepeated categories, F (1, 34) = 13.28, p < .01. It appears that the probability of recall of at least one word from a category was increased by the greater frequency and/or recency with which the category had been encountered. However, when different words from the same category were included in OL and IL there was a reduction in first-list within-category recall; given that a category was recalled, a significantly greater number of words from the category were recalled in nonrepeated than repeated categories, F (1, 34) = 8.68, p < .01. As in Winograd's study, there was no significant difference in the total number of words recalled from nonrepeated and repeated categories (F < 1.00). In contrast, Shuell (1968) found lower absolute recall as well as fewer words recalled per category when the same categories appeared on the first and second lists. The increase in category recall did not compensate for the reduction in within-category recall. On the basis of the present data and the data reported by Shuell and Winograd, it is clear that the occurrence of words from the same conceptual categories in two successive lists enhances recall of the categories on the final free-recall test and reduces the recall of first-list words within each category.

Given the large number of procedural differences between Shuell's (1968) and the present study, the similarity of results is striking. In addition to a smaller number and different pattern of trials in IL, Shuell used an unmixed-list design: Either all or none of the categories on List 1 were carried over to List 2. Thus, the overall contextual similarity between OL and IL (in terms of category composition) was higher when categories were repeated (same group) than when categories were not repeated (different group). In the present study, the overall contextual similarity of the interpolated list was somewhat similar to the original list for repeated or nonrepeated categories. Yet in both studies, significant within-category retention loss was found only for repeated categories. Nonrepeated categories appear to be highly resistant to interference, showing no reduction in within-category recall whether the categorical composition of the second list is completely changed (as in Shuell's study) or only partially changed (as in the present study). It will be of interest to determine whether a nonrepeated category remains impervious to interference when all but one category is carried over from OL to IL. In view of previous results on RI and contextual similarity, it seems reasonable to assume that within-category retention loss in nonrepeated categories will be a function of the similarity of the remainder of the interpolated list to the original list.

Special Announcement

Each year many of the manuscripts submitted to the *Journal* are reviewed by referees whose names do not appear on the Masthead of the *Journal* as regular Consulting Editors. Of the 805 manuscripts received in 1973, about 211 were reviewed by 73 such consultants. The names of 15 of these psychologists appear on the 1974 Masthead. The Editors of the *Journal* would like to express their appreciation for the services of all of these reviewers. They ably served the authors, editors, and readers of the *Journal* by their thorough and competent reviews. Their reviews were of the same high quality that we expect and get from our regular Consulting Editors, so that they helped to improve the authors' scientific communication and, in certain instances, aided the authors in improving their research methods. And so, the Editors wish to thank the reviewers listed below.
